E. Emmons reported amorphous brown or yellow granules, resembling the appearance of gum arabic, from Bare Hills, Md. The mineral was called *deweyite* after C. Dewey; and T. Thomson called it *gymnite*—*γυμνός*, naked—in allusion to the locality when the mineral was found. Specimens were described or analyzed by C. U. Shepard, T. Thomson, J. Oellacher, F. von Kobell, K. Haushofer, V. Widtermann, A. Bukovsky, F. A. Genth, W. Haidinger, F. von Richthofen, L. Liebner and J. Vorhauser, E. Hatle, E. Hatlo and H. Tauss, and E. F. Smith and D. B. Brunner. The composition corresponds with $\text{Mg}_3\text{Si}_2\text{O}_{10} \cdot n\text{H}_2\text{O}$; and it is usually represented as *magnesium tetrahydrotriorthosilicate*, $\text{H}_2\text{Mg}_3(\text{SiO}_4)_3$. W. W. Coblenz found the ultra-red transmission spectrum of deweyite gave strong bands at 3μ and 6μ , making it appear that the water is present as water of crystallization; in the ultra-red reflection spectrum there are maxima at 9.45μ and 10.5μ . F. Cornu found the moistened mineral reacted alkaline towards litmus. M. Websky said the structure is like that of chalcidony. F. Zambonini regards it as an adsorption product. J. Jakob applied the co-ordination formula:

to deweyite. Another mineral like deweyite in many respects was examined by D. Fogy, F. A. Genth, and F. Zambonini. The composition corresponds with $\text{Mg}_3\text{Si}_2\text{O}_{10} \cdot 3\text{H}_2\text{O}$. F. Zambonini called it pseudodeweyite, and he considered it to be a hydrogel. Their optical behaviours are similar. A. Breithaupt described a translucent yellowish or greenish-white mineral which was rather different from deweyite, and he called it *melopsite*—from *μήλον*, apple; *σφαρ*, meat. It was analyzed by F. Goppelsröder. F. Zambonini, and D. Fogy examined the loss of water under various conditions. A ferruginous gymnite—iron-gymnite—was examined by T. Thomson, and E. Hatle and H. Trauss.⁷

Serpentine may be nearly white or coloured various shades of green, brownish-red, or brownish-yellow. On exposure to air, the lighter shades may become grey. The **crystals** are pseudomorphs after chrysolite, pyroxene, amphibole, spinel, garnet, titanite, chromite, etc. G. Friedel argued that the pseudocubic crystals found at Brewster belong to serpentine itself, and are not pseudomorphs after an unknown mineral. The properties of the crystals correspond with those of the

monoclinic system. P. Groth regards antigorite as monoclinic, and chrysotile as rhombic; H. Michel also says fibrous serpentine is rhombic. These two varieties are regarded as isomeric forms of serpentine. The crystalline structure has been discussed by M. Websky, A. des Cloizeaux, E. Reusch, F. J. Wiik, E. Hussak, H. Rosenbusch, A. Michel-Lévy and A. Lacroix, G. Tschermak, H. B. Patton, R. Brauns, T. G. Bonney and C. A. Raisin, A. Hamberg, R. B. Hare, etc. According to W. H. Miller, the **optic axial angle** is $2E=22^\circ 20'$ for thermophyllite; and, according to A. des Cloizeaux, $2E=36^\circ 26'$ at 26° , it is reduced about 2° by raising the temp. to 196° . H. Michel gives for the axial angle of fibrous serpentine, $2E=16^\circ-50^\circ$; and for antigorite, $2E=16^\circ-98^\circ$. G. Tschermak said that the axial angle depends on the iron content of the mineral.

The **specific gravity** was determined by many of those who analyzed the mineral—*vide supra*. Specimens low in iron oxide and alumina have a sp. gr. ranging from 2.55–2.59; and the sp. gr. is raised by iron oxide, and lowered by alumina. The **hardness** of fresh serpentine is 3–4. Specimens with a hardness approaching 5 are supposed to be admixed with opaline or chalcedonic silica. L. H. Adams and E. D. Williamson found the compressibility of **serpentine** to be $\beta=1.80 \times 10^{-6}$ at 2000 megabars and 1.38×10^{-6} at 10,000 megabars; or $\beta=0.0_61804-0.0_{10}532(p-p_0)$. The **specific heat** of serpentine was found by A. S. Herschel and G. A. Lebour to be 0.27–0.28; by P. W. E. Oeberg, 0.2586; by J. Joly, 0.2529; by H. Hecht, 0.251 between 0° and 100° ; by G. Stadler, 0.2439. k denotes the **heat conductivity**; c , the sp. ht.; and D , the sp. gr., $a^2=k/cD$, and H. Hecht found $a^2=0.0113$, and G. Stadler, 0.0128. The **thermal dehydration** of serpentine has been studied by J. Lemberg, C. F. Rammelsberg, and others. A small proportion of water is expelled at 105° , but the bulk is lost only at a red heat. Thus, F. W. Clarke and E. A. Schneider found the percentage loss with four samples of serpentine:

Water lost at 105°	0.96	1.53	2.04	2.26
" " 250°	0.55	0.44	0.71	1.01
" " $383^\circ-412^\circ$	0.27	0.62	0.27	0.98
" " $498^\circ-527^\circ$	0.23	—	0.56	0.42
" " red heat	12.37	10.58	11.81	11.32
" " white heat	0.28	0.04	0.25	0.17

F. Zambonini found that with chrysotile confined over conc. sulphuric acid of sp. gr. 1.835:

Hours exposed	2	6	25	73	121
Per cent. water lost	1.71	1.98	2.18	2.37	2.18

The serpentine so dehydrated readily absorbs water again. He also measured the water lost at different temp. in a current of humid air by chrysotile with 15.4 per cent. of water, and bowenite with 13.20 per cent. of water:

	125°	250°	320°	345°	480°
Chrysotile lost	2.62	2.87	3.18	3.35	3.32 per cent.
	115°	160°	250°	300°	395°
Bowenite lost	0.28	0.47	0.59	0.69	0.76
				0.81	0.94 per cent.

A. Daubrée, and V. Iskyul believed that when melted, serpentine breaks down into enstatite and olivine: $H_4Mg_3Si_2O_9=2H_2O+Mg_2SiO_4+MgSiO_3$. According to H. Leitmeier, measurements of the **melting point** showed that serpentine from Snarum softened at about 1480° and was quite liquid with rapid heating at 1550° . The f.p. was 1400° , and olivine crystallized out, but no enstatite appeared. A. Michel-Lévy and A. Lacroix gave for the **indices of refraction** of antigorite $a=1.560$, $\beta=1.574$, and $\gamma=1.571$. A. des Cloizeaux gave $\beta=1.574$ for red light. H. Michel gave 0.013 for the **birefringence** of fibrous serpentine, and 0.011 for antigorite; he found the birefringence of villarsite to be strong, and that of radiatite to be medium. The

optical character of fibrous serpentine was positive, and those of antigorite and radiotite, negative. The optical properties of serpentine minerals have been studied by J. R. Schnell, K. Schuster, M. Websky, R. B. Håre, E. Reusch, F. Becke, H. Wiesel, R. Brauns, W. H. Miller, A. des Cloizeaux, G. Tschermak, M. Stark, etc. A. Michel-Lévy and A. Lacroix said that antigorite is feebly **pleochroic** in that α and β are a paler green than γ . H. Michel also said villarsite is strongly pleochroic. W. W. Goblenz found that serpentine has absorption bands in the **ultra-red transmission spectrum** at 1.4μ , 3μ , 5μ , 6.6μ , 7.4μ , 8.1μ , and 8.5μ . The large absorption band at 3μ corresponds with the assumption that hydroxyl groups are present. There are maxima at 9.7μ and 10.5μ in the reflection spectrum. W. Suida observed that serpentine is readily stained with aniline dyes—e.g. fuchsine, and methylene blue—and F. Cornu noted that the stained mineral is strongly pleochroic.

According to G. A. Kenngott, powdered and moistened, calcined or uncalcined, serpentine has an alkaline reaction. The mineral is readily attacked, and partially dissolved by **water** with carbon dioxide in soln. R. Müller found 1.24 per cent. passed into soln. H. Leitmeier found 3.68 per cent. was dissolved by the action of carbonated water on serpentine from Kraubath, Steiermark; and the soln. contained 3.07 per cent. of magnesium oxide, 0.38 of ferrous oxide, and 0.23 of silica. C. R. van Hise represents the action of water by: $H_4Mg_3Si_2O_{10} + H_2O = 3Mg(OH)_2 + 2SiO_2$; and the action of **carbon dioxide** by $H_4Mg_3Si_2O_{10} + CO_2 = MgCO_3 + 2Mg(OH)_2 + 2SiO_2$. F. W. Clarke and G. Steiger heated serpentine with **ammonium chloride** in a sealed tube for 5 or 6 hrs.; and leached the cold product with water. They found 0.18 per cent. of silica and 5.53 per cent. of magnesia passed into soln. A. Lindner also studied this reaction. F. W. Clarke and E. A. Schneider said that a soln. of **sodium hydroxide** does not attack serpentine, but if the mineral has been strongly calcined, from 2.00–6.23 per cent. of silica passed into soln. A. Lindner studied the action of **potassium hydroxide**. F. W. Clarke and E. A. Schneider found that when heated to 383° – 412° in a stream of dry **hydrogen chloride**, serpentine, unlike talc, is attacked, and when afterwards treated with water, from 9.98–16.73 per cent. of magnesia was extracted as chloride. The iron silicate is also attacked. A. Lindner, and R. Brauns also investigated the action of hydrogen on serpentine. Serpentine is attacked by **hydrochloric acid**, and more readily by **sulphuric acid**, with the separation of gelatinous silica; fibrous serpentine—e.g. chrysotile—yields fibrous silicic acid. A. Terrell found that all the magnesia and iron oxide dissolved by boiling with conc. hydrochloric acid. V. Iskyul studied the action of hydrochloric acid, and the solubility of silica in serpentine, antigorite, and chrysotile. A. Lindner examined the effect of **acetic acid**. H. Ota and M. Noda found that powdered serpentine does not show the **indophenol reaction**. The weathering of serpentine has been studied by A. Schrauf, and C. R. van Hise; and A. Lacroix investigated the action of the vapours from fumaroles on serpentine.

In his *Historia naturalis* (19. 4; 36. 31, c. 77 A.D.), Pliny refers to a rare and costly cloth, the cremation cloth of kings, which he called *linum vivum*. He thought that it was of vegetable origin, and gave an imaginary description of its growth in the deserts of India. He said that it was called by the Greeks *asbestinon*—from α , not; and $\sigma\beta\epsilon\rho\rho\mu$, to extinguish—in allusion to its incombustibility. He also mentions the *amianthus* or the *ἀμάνθος λίθος* of Dioscorides, *De materia medica* (5. 155)—from α , not; $\mu\alpha\iota\upsilon\epsilon\upsilon$, to stain—also indestructible by fire. Near the beginning of our era, Strabo, in his *Geographica* (10. i, 6), described the occurrence of the mineral at Carystus, Eubœa; Pausanias, in his *Græcia descriptis* (1. 26), written in the third century, also mentions the properties of the mineral occurring at Carpasius, Cyprus; and Plutarch, in his *De defectiōne oraculorum* (5. 2), in the first century of our era, said that the asbestos was used in ancient times for making the wicks of the lamps used by the vestal virgins. In the thirteenth century, Marcus Polo in his *Travels* (1. 39) mentioned an indestructible cloth made

by the Tartars which was said to be made from the skin of the salamander, supposed to live in fire, but which was found to be woven from a fibrous mineral called amianto. The knowledge of asbestos possessed by the ancients appears to have been forgotten. Apart from a few isolated cases, the industrial applications of asbestos did not attract serious attention until towards the middle of the nineteenth century.⁸

The term **asbestos** includes two distinct minerals—actinolite and chrysotile—both of which have a fibrous structure, silky lustre, and a more or less pronounced green colour. Tremolite, actinolite, crocidolite, serpentine, and the palygorskite minerals can form fibrous asbestos. Crocidolite is also known as blue asbestos. Actinolite, and tremolite are varieties of *hornblende asbestos*, or *amphibole asbestos*; and chrysotile is a variety of *serpentine asbestos*. Both are hydrated magnesium silicates, but actinolite is usually associated with more impurities, chiefly lime and iron oxide. Analyses of commercial samples gave:

	SiO ₂	Al ₂ O ₃	FeO	MgO	CaO	H ₂ O
Actinolite	61.82	1.12	6.55	23.98	1.63	5.45
Chrysotile	40.18	2.24	1.01	41.75	0.00	3.81

The sp. gr. of actinolite varies from 3.02–3.17, and that of chrysotile from 2.2–2.3. Chrysotile fibres are much more elastic than those of actinolite. When rubbed between the finger and thumb, actinolite splits into harsh brittle fibres, whereas chrysotile fibres are elastic and tough, so much so that it can be spun into articles of various kinds. Crocidolite is more elastic and possesses a greater tensile strength than chrysotile. Chrysotile-asbestos is decomposed by hydrochloric or sulphuric acid; tremolite is not attacked by acids; while crocidolite or blue-asbestos is fairly resistant to acids, chemical soln., and sea-water. C. Matignon and G. Marchal examined the corrosive action on asbestos of water in the presence of carbon dioxide under 10 atm. press. during 3 years. R. E. Wilson and T. Fuwa measured the water adsorbed by asbestos from air of different degrees of humidity.

Chrysotile-asbestos loses water at a red heat, not below, and thin fibres can be fused in the Bunsen flame; tremolite-asbestos fuses with difficulty; and crocidolite readily fuses to a black glass. When the water of hydration has been expelled, the fibres become brittle, and crumble to powder when rubbed. Asbestos fireproofing and building materials have been the subject of numerous patents. The heat-insulating qualities of asbestos have been tested by W. R. Degenhardt, H. Pratt, C. R. Darling, C. G. Lamb and W. G. Wilson, F. Bacon, W. Nusselt, etc. G. Sever found that asbestos is a better non-conductor than magnesite, but the latter has a greater electrical resistance and "break-down" voltage. The electric conduction and dielectric capacity of asbestos were discussed by W. S. Flight.

Spun asbestos is used for steam packing, fireproof curtains, etc.; as cloth, twine, and rope it is used as an insulator for steam and hot-water pipes and cold-storage plants; and as a lining for safes, stores, and furnaces. Along with other materials asbestos is made into bricks, tiles, millboard, plasters, and paints. Some of the preparations have special trade-names—e.g. *uralite*, *manderite*, *ceolinite*, *asbestolite*, etc. Uralite is a mixture of asbestos fibre, chalk, sodium carbonate, and water-glass moulded and heated in a stove. Asbestos in fibrous powder mixed with powdered clay or other refractory earth can be made into a paste with water and moulded into retorts, crucibles, or bricks; then dried; and fired. The Société Mèran make an asbestos "porcelain" from a mixture of about 70 per cent. of powdered asbestos and 30 per cent. of powdered steatite which is plastic enough to mould into bricks and larger quarries. When fired below 1400° the mass is firm and porous, and as the temp. approaches 1400°, the biscuit becomes more and more translucent and porous as the individual particles contract; between 1400° and 1650°, incipient vitrification occurs, the porosity diminishes; above 1650°, the mass fuses. Asbestos "porcelain" is used for diaphragms, and porous cells for electro-chemical work since the material is not attacked by ordinary acids and bases.

The mineral **meerschau** has long been known. J. L. Smith⁹ described it as occurring in earthy or alluvial deposits at the plains of Eskibisher,

Asia Minor; and as being formed by the decomposition of the magnesium carbonate embedded in the serpentine of the adjacent mountains. More or less magnesium carbonate is often found in meerschaum, so that R. J. Haüy could call it *une variété silicifère spongieuse de magnésie carbonatée*. A. Brongniart, indeed, under the term *magnésite* included (i) the carbonate, (ii) the hydrated silicate or meerschaum, and (iii) a siliceous carbonate from Piedmont, but F. S. Beudant reserved the term *magnésite* for meerschaum, and called magnesium carbonate, *gioberite*. Many French mineralogists adopted this nomenclature, but it is not justifiable on historical grounds. The name meerschaum was applied by A. G. Werner in 1788; it is the German word for sea-foam; which in French becomes *l'écume de mer*. The term may have been intended to emphasize the porosity and colour of the mineral, or the fact that when freshly dug it is soft, and forms a lather with water; or, as A. Estner expressed it, because it *eine schaumartige Leichtigkeit hat, und meistens von der Seeküste zu uns gebracht wird*; he also said the term may be a corruption of the local word Myrsen. E. F. Glocker proposed the term *sepiolite* from *σπία*, cuttle-fish, which has a light and porous bone-like structure, and being also a product of the sea *deinde spumam marinam significabat*. R. Kirwan called the mineral *keffekill*.

The mineral is used commercially for making tobacco pipes, and cigar- and cigarette-holders. In Spain, it is used as a building stone. The mineral in Morocco is used in place of soap in the Moorish baths of Algeria - hence the term *Pierre de savon de maroc*. Descriptions of the Asia Minor deposits have been made by C. C. von Leonhard, L. A. Emmerling, X. Landerer, A. Damour, etc.; and deposits in other localities have been reported by M. von Hantken, J. R. Blum, V. von Zepharovich, etc. Analyses of meerschaum were made by J. C. Wiegand, M. H. Klaproth, L. P. Lynchnell, T. Scheerer, A. Damour, A. Schrauf, F. von Kobell, X. Landerer, P. A. Dufrénoy, P. Berthier, A. H. Chester, A. Lacroix, A. von Fersmann, F. Zambonini, M. Kispatic, F. Katzer, J. W. Döbereiner, D. Fogy, W. T. Schaller, C. F. Rammelsberg, H. B. von Foullon, A. Liversidge, E. Weinschenk, F. Kovar, G. P. Merrill, P. H. Walker, etc.

The water of the analyses is significant. A. H. Chester found that about half of the 19-20 per cent. of water passed off below 110°, and the remainder between 200° and a red heat. Observations on this subject were made by E. Weinschenk, D. Fogy, and F. Zambonini. D. Fogy found that over conc. sulphuric acid, the mineral loses 6.53 per cent. of water, and 5.14 per cent. over calcium chloride. According to F. Zambonini, the loss of water at different temp. is:

	120°	165°	200°	280°	340°	400°	475°
Loss	18.60	19.21	19.33	19.92	20.92	21.74	21.96 per cent.

In T. Scheerer's analysis, the ratio $\text{SiO}_2 : \text{MgO} = 9 : 4$; and C. F. Rammelsberg gave 3 : 2. The latter is the value usually accepted. This makes meerschaum **magnesium tetrahydrotrisilicate**, $\text{H}_4\text{Mg}_2\text{Si}_3\text{O}_{10}$, or $\text{Mg}_2\text{Si}_3\text{O}_8 + 2\text{H}_2\text{O}$; F. Zambonini gave $\text{Mg}_2\text{Si}_3\text{O}_8 \cdot n\text{H}_2\text{O}$. H. Michel, and B. Sterett regarded the mineral as a colloid, and this agrees with F. Zambonini's observations on the dehydration and the substitution of the water by alcohol and other substances as in the case of the zeolites (*q.v.*). D. Fogy obtained metasilicic acid when the mineral is treated with acid, and hence argues that it is a metasilicate, $(\text{MgOH})\text{MgH}_2\text{Si}_3\text{O}_9$; and C. Doelter assumed that the water removed by conc. sulphuric acid is physically bound, and wrote $2(\text{MgSiO}_3) \cdot \text{H}_2\text{SiO}_3 \cdot n\text{H}_2\text{O}$, where n is one or more than one. L. Colomba gave $\text{H}_4\text{MgSi}_3\text{O}_{12}$. J. W. Döbereiner said that an artificial meerschaum can be made by precipitating a very dil. soln. of magnesium sulphate with one of potassium silicate, well washing the pasty precipitate, and drying it in air.

Meerschaum is found in irregular nodules which are opaque, with a dull lustre somewhat resembling ivory in appearance. The colour is white, pale grey, or cream, and sometimes pale green. The mineral is dull and earthy in appearance, but it can be polished by rubbing with the finger-nail which presses the particles close

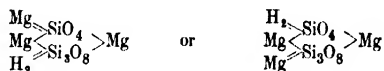

together. Meerschaum is so porous that it adheres to the tongue, and floats on water. It rarely occurs fibrous. A. Lacroix said that the so-called compact amorphous mineral is composed of minute scale-like crystals. A. von Fersmann applied the term *para-sepiolite* to meerschaum, which is largely crystalline. W. Vernadsky called it *α-sepiolite*; and the colloidal gel meerschaum is called *β-sepiolite—vide infra*. They gelatinize differently when treated with hydrochloric acid. F. Zambonini says that the gelatinization of the sepiolites depends on the conditions of the experiment and not on the constitution of the mineral. He also studied the dehydration of the mineral, and found about half the water is lost at 100° over conc. sulphuric acid; and most is expelled at 500°. When melted, enstatite and silica are produced. L. Colomba said that the crystals of meerschaum are pseudo-hexagonal. H. Michel gave for the optic axial angle $2V=40^{\circ}$ – 50° . The sp. gr. of meerschaum depends on the water content, and is about 2; the hardness is also about 2. H. Michel found the indices of refraction to be $\alpha=1.515$ – 1.519 , and $\gamma=1.525$ – 1.529 ; the birefringence is $\gamma-\alpha=0.009$. F. Tucar found that the fibres of meerschaum become pleochroic after taking up organic agents. F. Cornu said that when moistened with water it reacts alkaline. The mineral is gelatinized by hydrochloric acid. W. Suida found that meerschaum is readily stained by basic aniline dyes. According to H. Michel, the behaviour of the meerschaums towards aniline dyes, show that they are mixtures of a fibrous, crystalline silicate with constant optical properties, and of a gel. The crystalline constituent is basic and absorbs acid dyes, whilst the isotropic substance is acidic and adsorbs basic dyes. When a finely powdered sample of meerschaum is subjected to the action of a soln. containing methylene-blue and magenta, it is found that the mineral becomes blue and the soln. red. This is attributed to the much greater rate at which the basic dye is absorbed by the gel. It is used like fuller's earth for absorbing grease. The variable water content of the meerschaums is probably connected with the varying proportion of the two constituents, for the constancy of the optical properties of the crystalline constituent would seem to show that the proportion of water in this is quite constant.

A soft earthy mineral from Långban, Sweden, was named by N. J. Berlin¹⁰ *afrodite*, or *aphrodite*—from *ἀφρός*, foam. It was examined by A. Schrauf, T. S. Hunt, and H. Fischer. It resembles sepiolite or meerschaum; its composition, according to C. F. Rammelsberg, approximates $H_2Mg_2Si_4O_{14}$. The sp. gr. is 2.21. T. Scheerer obtained masses of stellate fibres from Arendal; and compact masses have been obtained from Eisenack, and Riesengebirge. The mineral was named *neolite*—from *νέος*, new. The colour is green or brown; the sp. gr. 2.625–2.837; and the hardness 1–2. Observations on the mineral have been made by C. M. Kersten, P. Hörter and E. Porth, A. Frenzel, and V. von Zepharovich. F. von Kobell found a flesh-red amorphous mineral filling the spaces among the crystals of wollastonite in the leucitic lava at Capo di Bove, Rome. He called it *spadaite*—after Modici Spada. The analysis corresponds with $5MgO.6SiO_2.4H_2O$, or, according to C. F. Rammelsberg, $H_2Mg_2Si_4O_{14}.3H_2O$. H. Fischer said the mineral is not amorphous but cryptocrystalline.

In his *Περὶ λίθων*, Theophrastus refers to the *μαγνήτης λίθος* as being a white mineral with a silvery lustre, and easily cut into any shape or figure. This description applies to steatite or talc, but the word "talc" does not occur in the writings of Theophrastus, Dioxorides, or Pliny. G. Agricola¹¹ gave *Talc*, *Silberweiss*, *Katzensilber*, and *Glimmer* as synonyms for *magnetis*. Glimmer is the present-day German term for mica; and probably talc was confused with some of the micas. G. Agricola referred to the fire-resisting qualities of talc, and referred to it as *lapis scissilis*. The name talc is generally considered to be of Arabic origin, and, according to C. Hintze, talc frequently appears in the recipes of the Arabian writers of the tenth to twelfth centuries. J. H. Pott quoted Avicenna: "the *aster samius* is talc." U. Aldrovandus stated that the term is of Moorish origin, and that *hoc nomen appud Mauritanos stellam significare dicitur*. The term *star* or *star of the earth* is an old name for the mineral, suggested by the silvery lustre. A. Breithaupt suggested that the term talc is derived from the Swedish *tälja*, to cut with a knife;

but this is very doubtful. J. H. Pott added that the word cannot be of German origin because there is nothing to show that Avicenna, who first used the term, ever came into contact with the Germans. In 1636, B. Casius used the word *talchus* for the mineral. A. B. de Boodt used *talcum*; J. G. Wallerius, *creta Brianzonica*, *creta Hispanica*, *creta Sartoria*, and *telgstein* or *lapis ollaris*; A. Cronstedt, *Talcum*, *tlgsten*, *Speckstein*, and *steatite*. The word *steatitis* occurs in Pliny's *Historia naturalis* as the name of an unctuous stone. A. B. de Boodt also employed the term *steatite*. J. B. L. Romé de l'Isle classed talc and steatite with the argillaceous minerals, and, like R. J. Haüy, regarded steatite as *une variété de espèce talc*.

The mineral was analyzed by M. H. Klaproth¹² in 1797, and by L. N. Vauquelin in 1800. Since then numerous analyses have been made, and many occurrences reported. Alkalies are usually present in very small proportions, if at all. Lime may be genetically connected with the derivation of talc from dolomites. In some cases the lime is present as admixed carbonate. Ferrous and manganese oxides are commonly present, possibly as silicates in solid soln. Nickel oxide is not uncommon—may be as a solid soln. of the oxide or silicate. Magnesium silicate is coloured green by nickel oxide. Chromic oxide is sometimes present, and the green colour of some specimens of talc is attributed by F. Cornu and K. A. Redlich to the tinctorial properties of that oxide. Alumina may be present in talc derived from chlorites and aluminous magnesium minerals. M. W. Travers found that talc from Greiner gave off, when heated, 0.04 per cent. of a mixture of carbon monoxide and hydrogen, and 0.07 per cent. of carbon dioxide. These gases are supposed to be produced by the action of ferrous oxide, water, and carbonate, and are not included in the mineral: $2\text{FeO} + \text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + \text{H}_2$; and $2\text{FeO} + \text{CO}_2 = \text{Fe}_2\text{O}_3 + \text{CO}$. From the collection of over a hundred available analyses, it is not quite clear what is the composition of the idealized mineral. E. Weinschenk gives MgO, 31.72 per cent.; SiO₂, 63.52 per cent.; and water, 4.76 per cent. This comes near to the generally accepted formula: $3\text{MgO} \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O}$. The analyses exhibit a variation in the Mg : Si ratio from about 1 : 1 to 4 : 3; and the water ranges from 3 to over 7 per cent. C. F. Rammelsberg gave for the ratio Si : Mg, 4 : 5; and for the ratio H : Si, nearly 1 : 2. The above formula makes talc to be **magnesium dihydrotetrasilicate**, $\text{H}_2\text{Mg}_3\text{Si}_4\text{O}_{12}$; but the formulæ, $\text{H}_2\text{Mg}_4\text{Si}_5\text{O}_{15}$, and $\text{H}_4\text{Mg}_4\text{Si}_5\text{O}_{16}$, have also been used to represent the composition of talc. W. F. Foshag found a sample from Russell, Mass., to lose 0.5 per cent. of water after standing over sulphuric acid for 23 days; 4.04 per cent. was lost at a dull red heat, and 3.4 per cent. of water was retained. The loss of the water at dull redness is not attended by any essential change in the optical properties, but when the firmly bound water is driven off the material loses its homogeneity. The water is assumed to be an integral part of the mol. because it is expelled only at comparatively high temp. In accord with F. W. Clarke and E. A. Schneider's observation that soda-lyc extracts about 17.36 per cent. of the silica from talc which has been calcined, the formula can be written, $3\text{MgSiO}_3 \cdot \text{H}_2\text{SiO}_3$, which makes the compound a tetrametasilicate, or, regarding Si_3O_8 as a quadrivalent radicle:

Talc appears to be formed in nature in many ways, most commonly by the hydrolysis of the pyroxenes or amphiboles: $4\text{MgSiO}_3 + \text{H}_2\text{O} + \text{CO}_2 = \text{H}_2\text{Mg}_3\text{Si}_4\text{O}_{12} + \text{MgCO}_3$; and $\text{Mg}_3\text{CaSi}_4\text{O}_{12} + \text{H}_2\text{O} + \text{CO}_2 = \text{H}_2\text{Mg}_3\text{Si}_4\text{O}_{12} + \text{CaCO}_3$. The reactions resemble those involved in the formation of serpentine. F. Cornu and K. A. Redlich trace the talc of Mautern, Styria, to the action of magnesium waters on the neighbouring schists. This subject has been investigated by C. H. Smyth, J. H. Pratt, A. A. Julien, A. Gurlt, C. H. Hitchcock, E. Weinschenk, J. Rumpf, J. Roth, F. Cornu and K. A. Redlich, etc. C. Doelter discussed the colloidal origin of talc.

R. Scharizer likens the formation of talc from enstatite to the formation of serpentinite from olivine, and of kaolinite from orthoclase. The idea is illustrated by the graphic formulæ :

when the conversion of enstatite to talc simply involves the removal of an atom of magnesium and the substitution of eq. hydrogen atoms. There is no change in the type of salt since both minerals are regarded as metasilicates, and both resist attack by acids.

Talc has not been unequivocally synthesized in the laboratory. J. Lemberg¹³ allowed a dil. soln. of sodium silicate to act on magnesite at 100° or 200°, and he obtained a mixture of magnesium carbonate and silicate by what C. Doelter and E. Dittler consider to be a reversible reaction: $3\text{MgCO}_3 + 4\text{Na}_2\text{SiO}_3 + \text{H}_2\text{O} = 3\text{MgSiO}_3 \cdot \text{SiO}_2 + 3\text{Na}_2\text{CO}_3 + 2\text{NaOH}$. C. Doelter and E. Dittler tried if talc is formed by the action of steam on a mixture of magnesium chloride and silicic acid. The reaction was symbolized: $3\text{MgCl}_2 + 6\text{H}_2\text{O} + 4\text{SiO}_2 + 3\text{H}_2\text{O} = 3\text{MgO} \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O} + 6\text{HCl} + \text{Aq.}$, but it was not clear whether talc was or was not formed. When $3\text{MgSiO}_3 \cdot \text{SiO}_2$ is hydrolyzed, enstatite is produced. Attempts to make talc by molten fluxes—magnesium chloride and ammonium fluoride—were not successful.

Talc occurs in foliated or lamellar masses which can be readily separated into thin scaly crystals. These flakes are easily bent, but, unlike mica, the flakes do not spring back to their original position when released. Hence, the mineral is flexible, but not elastic like mica. The thin cleavage flakes are white, yellowish, or more commonly of a pale green colour, with a silvery lustre. Talc does not occur in distinctly developed crystals. Thin cleavage flakes are transparent; their optical properties resemble those of mica and the chlorites, and, like them, probably belong to the monoclinic system. J. R. Schnell¹⁴ measured the crystal angles of talc. Talc or steatite occurs in crystals which are pseudomorphs after various minerals—quartz, dolomite, enstatite, topaz, etc. The original crystals have been largely replaced by steatite formed by the reaction of hot soln. of magnesium salts on the original mineral.

The mineral occurs in a compact massive form which feels greasy or fatty; it is then called *steatite*, *soapstone*, or *Spieckstein*. The coarse and granular steatite is grey, greenish-grey or brownish-grey in colour, and, when more or less impure, usually owing to admixed chlorite, it is called *potstone*, *lapis ollaris*, *Topfstein*, *Larenstein*, and *Gillstein*. The fine granular or crypto-crystalline steatite may be soft like chalk. The so-called *French chalk*, or *craye de Briançon*, is milk-white steatite with a pearly lustre. An indurated or slaty talc is called *talc schist*; *talcose slate* is a dark argillaceous rock containing more or less talc, which gives it a greasy feel. The so-called *rensselaerite* is a crypto-crystalline or wax-like mineral pseudomorphous after salite or pyroxene. It was described by E. Emmons, and L. C. Beck. It was named after S. von Rensselaer. E. Repossi found a talc-like mineral in the Valle della Gava, and he called it *gavite*. The analysis corresponds with $\text{H}_4(\text{Mg,Fe})_4\text{Si}_4\text{O}_{12}$. It resembles talc excepting for its ready solubility in hydrochloric acid, and in its water content. W. F. Foshag says that it is not a mineral species different from talc. A. R. Leids described a variety of talc pseudomorphous after pectolite, which he called *stevensite*; M. L. Glenn, and A. F. Rogers regard it as a colloidal magnesium silicate. L. W. Hubbard called a fibrous variety resembling asbestos, *beaconite*; and R. L. Packard, a variety with the appearance of vivianite, from Silver City, New Mexico, *native ultramarine*. The *pyralloite* of A. E. Nordenfjöld—from *pyr*, fire; *allo*, other—appears to be a pseudomorph after pyroxene. According to A. E. Arppe, it is not homogeneous, but is a pyroxene partially transformed into steatite. A variety of pyralloite was found in Sibbo, Finland, by J. J. N. Huot and named *vorgasite* after Count Vargas. The so-called *strakonitzite* of V. von Zepharovich is a kind of steatite. The *talcoid* of C. F. Naumann is a white foliated talc which T. Scheerer called *neutraler Kieselsauer Hydrotalc*. According to J. D. Dana, it is a mixture of talc and quartz.

M. H. Klaproth found the steatite from Göpfersgrün contained rather less silica and rather more water than usual, and he called it *hydrosteatite*. R. Hermann applied the term *hampshireite* to steatitic pseudomorphs after quartz. Analyses were made by C. Dewey. It is probably not a homogeneous mineral. A. E. Arppe found a greyish-green talc with 7.83 per cent. of ferrous oxide, and 1 per cent. of cupric and zinc oxides. He called it *Eisen-talk*, or *liparite*—from *λίπαρος*, fat.

The sp. gr. of talc has been determined by many of those who have analyzed the mineral. The values vary from 2.6–2.8. The hardness is very small; talc is one of the softest of minerals and represents No. 1 on Mohs' scale. It is scratched even by the finger-nail. F. Malt¹⁵ found the sp. gr. rose from 2.78 to 3.19 on calcination; and the hardness rose to about 6. P. J. Holmquist, and A. Rosiwal investigated the hardness; if the hardness on the (0001)-face of quartz is 1000, the abrasive hardness of talc parallel to (001) is 2.6, and perpendicular to (001), 9.3. The heating curve is normal up to 875°, and at about 960° an acceleration appears, and the ferrous oxide simultaneously oxidizes. Enstatite appears to be formed. J. Joly found the sp. ht. to be 0.2168. A. Dannholm studied the sp. ht. of soapstone. C. Doelter gave 1530° for the m.p.; W. S. Howat, 1380°. When melted, talc breaks up into enstatite or anthophyllite, quartz, and water: $H_2Mg_3Si_4O_{12} = 3MgSiO_3 + SiO_2 + H_2O$. Only hygroscopic water is lost at 110°; all the constitutional water is evolved only at a white heat. F. W. Clarke and E. A. Schneider found that at 105° talc lost 0.07 per cent. of water; at 250°–300°, 0.06 per cent.; at a red heat, 4.43 per cent.; and at a white heat, 0.35 per cent. E. Löwenstein found that over conc. sulphuric acid at 25° with a partial press. 21.58, 8.82, and 0.18 mm., the losses of water for equilibrium were respectively 0.10, 0.35, and 0.38 mol. A. des Cloizeaux found the optic axial angle $2E = 19^\circ 1'$ for the red ray, and $19^\circ 56'$ for the blue ray at 21.5°, and there is no perceptible change when the temp. is raised to 171°. W. F. Foshag obtained $2E = 20^\circ \pm 5^\circ$; and M. Bauer, $2E = 13^\circ$ for green talc. A. Michel-Lévy and A. Lacroix found $2Y = 7^\circ$. K. Zimanyi found the indices of refraction for Na-light to be $\alpha = 1.539$, $\beta = 1.589$, and $\gamma = 1.589$. W. F. Foshag obtained $\alpha = 1.540$ – 1.545 ± 0.005 ; and $\beta = \gamma = 1.575$ – 1.585 ± 0.003 . The birefringence is negative and strong $\alpha - \gamma = 0.050$; A. Michel-Lévy and A. Lacroix obtained $\alpha - \gamma = 0.038$ – 0.043 . W. W. Coblenz found no hydroxyl band at 3μ in the ultra-red transmission spectrum of talc. There are absorption bands at 5.6μ , 5.95μ , and 7.15μ . The reflection spectrum shows sharp maxima at 9.05μ and 9.75μ . The percussion figures were studied by A. Michel-Lévy and A. Lacroix, and H. Rosenbusch; the resulting six-rayed star is oriented as with the micas. P. W. Bridgman represented the compressibility of talc by $dv/v_0 = 0.0_{10}4p - 0.0_{12}63p^2$; and the thermal conductivity at a press. p , by $0.00733 + 0.0_{11}5p$ at 30°. He could not make finely powdered talc weld even at 30,000 kgms. per sq. cm. press., possibly owing to films of air. A. V. Henry found the resistivity, R , in ohms per c.c., of Maryland, Italian, and Indian talces, for a 45-volt, 1000-cycle alternating current, to be

	500°	600°	700°	800°	900°	1000°
Maryland . . .	282×10^8	719×10^8	219×10^8	861×10^8	389×10^8	238×10^8
Italian . . .	159×10^8	350×10^8	970×10^8	353×10^8	157×10^8	749×10^8
Indian . . .	670×10^8	178×10^8	544×10^8	179×10^8	760×10^8	340×10^8

Talc is considered to be a very stable mineral at low temp. G. A. Kenngott, and F. Cornu found that talc moistened with water reacts alkaline whether the mineral has been calcined or not. E. W. Hoffmann made some observations on this subject. F. W. Clarke and E. A. Schneider heated talc for 15 hrs. at 383°–412° in a stream of hydrogen chloride, and observed no change in weight. Talc is not decomposed by acids other than hydrofluoric acid. F. W. Clarke and E. A. Schneider found that with fuming hydrochloric acid on a water-bath, about 1.05 per cent. of magnesia passes into soln. They also found that when calcined talc is boiled with soda-lye, about a fourth of the silica presses into soln., but with uncalcined talc, there is no perceptible change. Hence, talc suffers a chemical

change on calcination: $\text{H}_2\text{Mg}_3\text{Si}_4\text{O}_{12} = 3\text{MgSiO}_3 + \text{SiO}_2 + \text{H}_2\text{O}$. C. Matignon and G. Marchal examined the corrosive action on talc of water in the presence of carbon dioxide under 10 atm. press. during ten years. E. C. Sullivan observed a basic exchange occurs when talc is treated with a soln. of cupric sulphate. H. Ota and M. Noda found that powdered talc does not show the indophenol reaction. The metamorphoses of talc in nature have been investigated by A. M. Finlayson, J. Roth, and E. Weinschenk.

Talc or steatite is used as a toilet-powder; for smoothing the floors of dancing rooms; and as a dry lubricant. Potstone can be turned in a lathe, and fashioned into fire-resisting vessels, and slabs. Steatite is used in making the tips of gas-burners, since it can be readily cut to the desired shape, and it becomes harder in use without fusing. Steatite was one of the fluxes used in making porcelain in England in former times; it is now used as a flux for clays, etc., in making sparking plugs; ¹⁰ it is also used in making furnace linings. The powdered mineral is used as a filler for paper, tailor's chalk, crayons, slate, pencils, shoe powder, wall plasters, etc.

A. Cronstedt ¹⁷ referred to *terra porcellanæ particulis impalpabilibus mollis*; M. H. Klaproth, to a *soapstone* or *Seifenstein* from Cornwall; R. Kirwan, to a *steatite* from Cornwall; R. J. Haüy, to *mountain soap*, or *pierre à savon*; L. F. Svanberg, to *saponite*—from *sapo*, soap—and also to *piotite*—from *πίον*, fat; R. Owen, to *thalite*; J. B. Hannay, to *birolingite* from Bowling, Scotland; and J. J. Dobbie, to *cathkinite* from Cathkin, Scotland; all these minerals, grouped as saponites, are probably different varieties of the same species, and represent variable mixtures of clay and hydrated magnesium silicates. The analyses are, as would be anticipated, very variable. According to M. F. Heddle, T. Thomson's *prasilite* is a variety of saponite, but is usually regarded as a chlorite (*q.v.*). E. W. Hilgard described a magnesian clay from Santa Lucia. Its analyses corresponded with an impure magnesium silicate which he called *Lucianite*.

§ 32. Zinc, Cadmium, and Mercury Silicates

In 1830, A. Lévy¹ described crystals of a mineral which he found at Altenberg, near Moresnet. The analysis corresponded with **zinc orthosilicate**, Zn_2SiO_4 ; and the mineral was named **willemite** after Willem I, King of the Netherlands; A. Breithaupt proposed to call it *hebetine*—from ἡβητικός, youth. The term willemite is generally adopted, though it has been variously mis-spelt—*williamsite*, *wilhelmite*, and *villemite*. L. Vanuxem and W. H. Keating had previously reported a ferruginous “siliceous oxide of zinc” from New Jersey which C. U. Shepard had designated *troostite* after G. Troost. This is of course not the troostite constituent of steel. At Mine Hill and Sterling Hill, New Jersey, the mineral occurs in such quantities as to constitute an important zinc ore. Analyses in agreement with the above composition have been reported by T. Thompson, K. Monheim, A. des Cloizeaux, J. Lorenzen, V. M. Goldschmidt, G. Tschermak, F. A. Genth, etc. Manganese often replaces part of the zinc, and ferrous oxide is usually present. Analyses of troostite in agreement with the view that it is an isomorphous mixture of zinc, manganese, and ferrous orthosilicates were made by R. Hermann, A. Delesse, W. G. Mixter, C. H. Stone, G. A. König, H. Wurtz, G. Tschermak, and H. B. Cornwall. The sample called by G. A. König *tephrowillemite* is a brownish-grey troostite.

The fusion temp. of mixtures of silica and zinc oxide is so great that it is difficult to make vessels to withstand the temp. G. Rupprecht² overcame the difficulty by making a paste of the mixture to be fused and forming it into a bar, which is then heated in an oxyhydrogen flame so that it is progressively melted, and so that each molten globule falls on to a surface covered with the substance under treatment. A. Daubrée synthesized willemite by the action of silicon chloride on red-hot zinc oxide; but H. St. C. Deville repeated the experiment and found that willemite is decomposed by silicon chloride. He obtained the mineral by passing hydrogen fluosilicate over heated zinc; by the action of silicon fluoride on zinc oxide; and by the action of zinc fluoride on silicic acid. J. J. Ebelmen obtained relatively large crystals by heating a mixture of zinc oxide and silica in molar proportions, with boric oxide in a platinum crucible for 5 days. A. Gorgeu obtained the crystals by fusing a mixture of one part of silicic acid with 30 parts of an intimate mixture of an eq. of sodium sulphate and 0.5–1 eq. of zinc sulphate. The soluble matter was removed by leaching with water. G. Stein, and J. M. Jäger and H. S. van Klooster made crystals of zinc orthosilicate by simply fusing the component oxides. With rapid cooling, a glass was formed. According to K. Endell, the temp. of formation is much below the temp. of fusion, and he noted that 45–60 per cent. of zinc orthosilicate is formed when a dry mixture of zinc oxide and silica is heated for 24 hrs. between 1075° and 2000°. M. Rüger obtained zinc orthosilicate by heating a mixture of the constituents in theoretical proportions for 2 hrs. at 1200°, and heating the product on a water-bath to remove soluble matters. P. Groth, A. Schulze and A. W. Stelzner, A. Scott, and W. M. Hutchings noted the formation of willemite in the masonry of zinc furnaces, or in slags from ores containing zinc. For colloidal zinc silicates, *vide supra*, water-glass.

Crystals of a zinc silicate have also been reported in glazes highly charged with zinc oxide.³ They were mentioned by C. Lauth and G. Dutailly in 1888, and ten years later they were adapted as a decorative glaze effect by A. Clément. J. W. Mellor's analysis of a large crystal, more or less contaminated with glaze, correspond better with willemite than with the metasilicate. K. Endell believes the crystals are those of zinc metasilicate. If the glaze contains a small proportion of cobalt oxide in soln., the crystals will abstract the colouring matter from the glaze and be stained a deep azure blue; with nickel oxide, free from cobalt, the crystals will be stained a fine turquoise blue; and with manganese oxide, brown.

The colour of the purer specimens is white, greyish-white, or greenish-yellow, but when contaminated with iron and other colouring oxides, it may be apple-green, flesh-red, yellowish-brown, and dark brown. It may occur in hexagonal prismatic crystals—long and slender or short and stout; it may also occur massive, in disseminated grains, and in fibrous masses. The crystals belong to the trigonal system, and, according to C. Palache,⁴ $a : c = 1 : 0.6679$; and, according to A. des Cloizeaux, troostite has the axial ratio $a : c = 1 : 0.66975$, and $\alpha = 107^\circ 46'$. Measurements have also been made by A. Arzruni, M. Bauer and R. Brauns, S. L. Penfield, A. Lévy, J. Lorenzen, C. Palache, etc. According to C. F. Rammelsberg, the crystals of willemite, troostite, phenacite, and diopase are isomorphous. A. Arzruni observed the **twinning** of the crystals; and H. Traube the **corrosion figures**. A. von Lasaulx found microscopic inclusions of franklinite in the crystals. A. Schleede and A. Gruhl obtained **X-radiograms** of phosphorescent zinc silicate.

The general properties of willemite and troostite are similar. J. Lorenzen gave 4.11 for the **specific gravity**; T. Thomson, 3.935; F. A. Genth, 4.10; W. G. Mixter, 4.11–4.16; and C. H. Stone,⁶ 4.132–4.188. A. Gorgeu's crystals had a sp. gr. 4.25; and G. Stein's 3.7—in the latter case, probably less zinc was present than was thought because of volatilization at the high temp. of the furnace. The **hardness** is between 5 and 6. F. M. Jäger and H. S. van Klooster gave 1509.5° for the **melting point**. G. Stein gave 1484° for the **freezing point**. E. Jannetaz found the ratio of the **heat conductivities** in the α and γ directions to be $\sqrt{\alpha/\gamma} = 0.854$. O. Mulert calculated the **specific heat** to be 0.14; the **heat of solution** of the

amorphous orthosilicate in $N\text{-HF}$, to be 99.54 ± 1.17 Cals. per mol; and of the crystalline, 90.5 ± 0.296 Cals. per mol. Hence, the **heat of crystallization** is 9.04 Cals. per mol, or 0.0405 Cal. per gram. The **heat of formation** of the glassy orthosilicate is -23.74 Cals. per mol; and the heat of formation of crystalline zinc orthosilicate from the crystalline metasilicate and zinc oxide is -17.20 Cals. per mol. The **indices of refraction** have been measured by O. B. Böggild, P. Gaubert, and C. Palache, and they respectively found for sodium light $\omega=1.6928$, 1.6931 , and 1.6939 ; and $\epsilon=1.7234$, 1.7118 , and 1.72304 ; and C. Palache gave for lithium light, $\omega=1.68897$ and $\epsilon=1.71812$. F. M. Jäger and H. S. van Klooster gave 1.719 and 1.697 for the indices of refraction of the artificial crystals. The **birefringence** is positive. V. M. Goldschmidt found for daylight $\gamma-\alpha=0.0237$; for red light, 0.0236 ; for green light, 0.024 ; and for blue light, 0.025 . The birefringence decreases as the contained manganese and ferrous oxides increase; thus:

Per cent. MnO + FeO	0.5	4.6	6.13
$\gamma-\alpha$	0.0306	0.0237	0.0187

G. Cesaro made some observations on this subject. A. Ehringhaus and H. Rose compared the dispersion and double refraction of the orthosilicates of copper, beryllium, and zinc with their mol. wts. According to J. D. Dana, willemite from New Jersey is **triboluminescent** since it glows with a blue light in a dark room when struck with a hammer. W. Crookes noted the phosphorescence of willemite when exposed to **cathode rays**—*vide* 4. 25, 5. G. F. Kunz and C. Baskerville noted the **fluorescence** and **phosphorescence** of troostite—particularly the green varieties—when exposed to ultra-violet light, X-rays, and radium radiations. Each α -particle striking against willemite produces a scintillation—*vide* radium. A. Schleede and A. Gruhl, and M. Curie studied the luminescence of zinc silicate containing traces of manganese; and obtained X-radiograms of the compound. T. Tanaka inferred the presence of manganese, iron, thallium, samarium, and ytterbium from the spectrum of the cathodoluminescence. The decay of the phosphorescence was studied by E. L. Nichols and E. Merritt; and the brightness of the luminescence by E. L. Nichols. C. Baskerville and L. B. Lockhardt and others noted that willemite phosphoresces under the action of **radium emanations**; and artificial as well as natural willemite phosphoresces if it contains small proportions of foreign oxides. E. Marsden noted the phosphorescence of willemite under the influence of **α -rays** and **β -rays**—*vide* 4. 26, 4. T. Liebig observed neither phosphorescence nor fluorescence with the brown crystals of Altenberg when exposed to **ultra-violet light**. He found the emission **spectrum** of troostite at ordinary temp. to be continuous from $620\text{--}510\mu$ with a maximum in the green. At the temp. of liquid air, the spectrum is resolved into two parts separated by a small gap in the yellow at 575μ . W. W. Coblentz found the ultra-red transmission spectrum of willemite has bands at 5.9μ and 6.75μ . The reflection spectrum has maxima at 10.1μ , 10.6μ , and 11μ , and a band at 11.6μ . He infers that the banding of the silica in willemite is different from what it is in quartz. M. Bauer and R. Brauns studied the **pyroelectric** properties of willemite. Willemite is soluble in cold dil. **hydrochloric acid**, and, according to G. Tschermak, orthosilicic acid separates out. J. D. Dana said that it is not gelatinized by **acetic acid**. H. C. Bolton found that willemite is not attacked by a cold sat. soln. of **citric acid**. A. H. Erdenbrecher studied the action of **hydrogen dioxide** on zinc silicate.

F. M. Jäger and H. S. van Klooster made **cadmium orthosilicate**, Cd_2SiO_4 , by fusing a mixture of finely powdered quartz and cadmium oxide or carbonate. The m.p. was about 1252° , and the indices of refraction over 1.739 . M. Rüger obtained cadmium orthosilicate by heating a mixture of the constituent oxides in theoretical proportions as in the case of zinc orthosilicate.

J. J. Ebelmen ⁵ made what he regarded as **zinc metasilicate**, ZnSiO_3 , in *groupes de cristaux assez volumineux mais peu nets de forme*, by heating a mixture of the required proportions of zinc oxide and silica, and boric oxide, in a platinum crucible

for 5 days. H. Traube also said that when amorphous zinc silicate, prepared by precipitating a soln. of zinc sulphate with sodium silicate, is heated with boric acid for 10 days at a high temp., it is converted into a white crystalline powder, which has the composition ZnSiO_3 . G. Stein made the metasilicate by heating a mixture of the component oxides in a porcelain tube. O. Mulert, and H. S. van Klooster employed a similar process. H. Schulze and A. W. Stelzner, and V. Steger reported crystals of the metasilicate in the walls of used zinc retorts. K. Endell—*vide supra*—said that the metasilicate is found in crystallized zinciferous glazes. The occurrence of the metasilicate in nature has not been reported. A. Gorgeu was unable to prepare the metasilicate by the processes just indicated. M. Rüger made zinc metasilicate by heating a mixture of zinc oxide and silica in the molar proportions 1 : 2 for an hour at 900° , and digesting the product with alkali-lye on a water-bath for several hours to remove soluble matters. Cobalt oxide is dissolved by zinc metasilicate when a mixture of the two is heated for 2 hrs. at 900° . R. Schwarz and G. A. Mathis made hydrated zinc metasilicate, $\text{ZnSiO}_3 \cdot \text{H}_2\text{O}$, by mixing dil. soln. of sodium metasilicate and zinc sulphate; and they converted this into hydrated zinc monamminometasilicate, $\text{ZnSiO}_3 \cdot \text{H}_2\text{O} \cdot \text{NH}_3$. A. H. Erdensbrecher obtained zinc peroxysilicates by precipitating a zinc salt with sodium metasilicate in the presence of hydrogen dioxide.

H. Traube said that the optical properties of the crystals show that they belong to the rhombic system, and that zinc metasilicate is accordingly a zinc-pyroxene isomorphous with enstatite. H. S. van Klooster said that the crystals are hexagonal. F. M. Jäger and H. S. van Klooster gave 3.52 at $25^\circ/4^\circ$ for the **specific gravity**. G. Stein gave 3.42 for the sp. gr. of the crystals, and 3.86 for the sp. gr. of the glass. It is very rare to find the sp. gr. of a glassy silicate greater than that of the same substance in the crystalline state. G. Stein gave 1429° for the **melting point**; H. S. van Klooster, 1419° ; and F. M. Jäger and H. S. van Klooster, 1437° ; and the last-named added that there is a regular decrease in the m.p. as the at. wts.—magnesium, zinc, cadmium—**increase**. O. Mulert estimated the **specific heat** to be 0.16 ; and he found the **heat of solution** of the crystals in $N\text{-HF}$ to be 51.48 ± 0.49 Cals. per mol.; the **heat of formation** of the crystalline metasilicate from amorphous silica and zinc oxide is 2.49 Cals. per mol. F. M. Jäger and H. S. van Klooster gave 1.623 and 1.616 for the two refractive indices. H. S. van Klooster observed with zinc metasilicate uniaxial positive interference figures; the **double refraction** was high. K. Endell found the metasilicate to exhibit fluorescence and phosphorescence when exposed to **X-rays** and to **radium rays**. H. Traube said that the metasilicate is insoluble in hydrochloric acid.

H. S. van Klooster prepared **cadmium metasilicate**, CdSiO_3 , by the direct union of the constituent oxides at a high temp. He said that while the crystals of zinc metasilicate are hexagonal, those of cadmium metasilicate are rhombic. The m.p. is 1155° . F. M. Jäger and H. S. van Klooster gave 1242° for the m.p., 4.928 at $25^\circ/4^\circ$ for the sp. gr., and the indices of refraction over 1.739 . Cadmium and zinc metasilicates form an unbroken series of mixed crystals with a minimum at 1052° , with 25 per cent. of zinc metasilicate, Fig. 104. G. Rousseau and G. Tite found that in preparing basic cadmium nitrate a layer of a solid product appears on the inner surface of the glass tubes. This can be freed from the cadmium salt by treatment with alcohol, and is removed from the glass

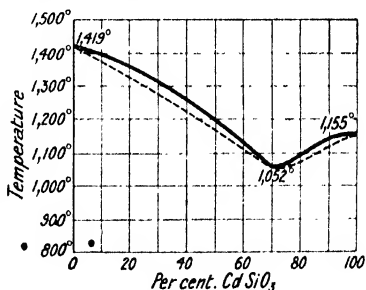

FIG. 104.—Freezing-point Curve of the Binary System: $\text{ZnSiO}_3\text{-CdSiO}_3$.

by prolonged treatment with warm water. It forms long scales which, when rubbed between the fingers, break up into microscopic needles, showing longitudinal extinction in parallel light. It has the composition, **trihemihydrated cadmium metasilicate**, $2\text{CdSiO}_3 \cdot 3\text{H}_2\text{O}$, and is soluble in hydrochloric acid with separation of pulverulent silica. At a dull red heat it loses very little water, but when heated to orange-redness it melts and then intumesces in consequence of the escape of water. If the heating is continued, cadmium oxide is volatilized, and after prolonged heating a residue of silica alone remains. It would seem that the presence of water is essential to the stability of the mol.

A. Schrauf⁶ reported that *ein Cadmium enthaltendes Silikat* occurred in minute triclinic crystals associated with the calamine of Altenberg. It was called *eggonite*—from *εγγονος*, a grandson—because it was supposed to be the third generation in a series of cadmium zinc silicates. According to J. D. Dana, the supposed cadmium silicate is really heavy spar or barite.

What may be *monohydrated zinc orthosilicate*, $\text{Zn}_2\text{SiO}_4 \cdot \text{H}_2\text{O}$, but is more probably **zinc dihydroxydisilicate**, $\text{Zn}_2(\text{ZnOH})_2\text{Si}_2\text{O}_7$, occurs in nature as the mineral **calamine**, but has not been made artificially. H. and W. F. Lowe⁷ found a boiler scale consisting chiefly of a hydrated zinc silicate which may have been an impure form of this compound. As indicated in connection with the history of our knowledge of zinc, the *cadmia* of Pliny and other ancient writers included the native silicate, the native carbonate, and the oxide—*cadmia fornacum*—which accumulated in the flues of zinc furnaces. Both J. G. Wallerius, and A. Cronstedt refer to *lapis calaminaris*, *cadmia officinalis*, *zincum naturale calciforme*, and *Galmey*. The term *Galmey* is now a miner's term applied to ores containing calamine, and zinc spar. The word "calamine" appears in the French translation of J. G. Wallerius' book, and it was also used by J. B. L. Romé de l'Isle. T. Bergman in his *De mineris zinci* (Upsala, 1779) showed that two minerals are in question; the one contained zinc oxide and silica, and the other zinc oxide and carbon dioxide. B. Pelletier found silica in a zinc mineral from Breisgau which had previously been called *zeolite of Breisgau* because it gelatinized with acids; and M. H. Klaproth found silica in a zinc ore from Scotland. J. Smithson, however, cleared up the subject in 1803, by showing clearly that the mineral from Rezbanya is a silicate, and the zinc spar from Derbyshire and Somerset is a carbonate. He called the silicate *electric calamine*. The distinction established by J. Smithson was recognized by R. J. Haüy, and A. Breithaupt. C. C. von Leonhard called the silicate *Galmey*, and the carbonate *Zinkspath*. J. F. L. Hausmann called the silicate *Zincglas*; D. L. G. Karsten, *Zinkglaserz*; and A. Breithaupt, *Kieselzinkspath*, and *Kieselzinkerz*. In 1807, A. Brongniart called the silicate calamine, and this term was adopted by F. S. Beudant, who called the carbonate *smithsonite* after J. Smithson. In 1852, H. J. Brooke and W. H. Miller reversed these names; and in 1853, G. A. Kenngott suggested *hemimorphite* for the silicate in order to avoid any confusion, and to emphasize a most interesting feature of the mineral, viz., its hemimorphism.

Clays carrying various proportions of zinc silicate are common in the zinc regions of south-western Missouri and Arkansas and in Virginia. They may be red, tough, but non-plastic; or yellow, gray, or brown with a greasy feel, and plastic when wet. In drying, they shrink and crumble into fragments. They have been called *tallow clays*.⁸ They were described by W. H. Seamon, J. C. Branner, T. M. Chastard and H. N. Stokes, W. F. Hillebrand, F. Schönichen, and B. H. Keyward. H. Rose reported a leek-green or emerald-green mineral from Altenberg near Morenet, and hence named it *morenetite*. G. A. Kenngott showed that it is a mixture of calamine and clay. C. U. Shepard obtained an ocherous aggregate associated with the zinc ores at Sterling Hill, N.J., and named it *vanuxemite*—after L. Vanuxem. J. D. Dana regards it a mixture of a zinc silicate and clay. E. E. Libman studied the products obtained by sintering mixtures of silica, alumina, and zinc oxide.

Numerous analyses⁹ have been made, and many occurrences reported.

C. F. Rammelsberg,¹⁰ J. F. Wiik, W. Vernadsky, and G. Tschermak favoured the hypothesis that calamine is *monohydrated zinc orthosilicate*, $\text{Zn}_2\text{SiO}_4 \cdot \text{H}_2\text{O}$. The water, however, is given off only at a red heat, and hence P. Groth, and F. W. Clarke and G. Steiger thought that the water must be an integral part of the mol., and assumed that calamine is *zinc dihydroxymetasilicate*, $(\text{ZnOH})_2\text{SiO}_3$. F. Zambonini showed that the contained water is present in two forms, since about half the water is lost continuously up to about 500° , and this loss is not attended by any marked change in the optical homogeneity of the crystal. He assumes that it is present as "dissolved water." The second half requires a very high temp. for its expulsion, and it is to be regarded as "constitutional water." He therefore assumes that the composition is best represented by the formula, $2(2\text{ZnO} \cdot \text{SiO}_2) \cdot \text{H}_2\text{O} + \text{H}_2\text{O}$; or $\text{Zn}_2(\text{ZnOH})_2\text{Si}_2\text{O}_7 \cdot \text{H}_2\text{O}$, thus making the compound *zinc dihydroxydisilicate*. This view shows how *clinocedrite*, $(\text{CaOH})(\text{ZnOH})\text{SiO}_3$, has no crystallographic resemblance to calamine, which would not be so clear if calamine has the formula, $(\text{ZnOH})_2\text{SiO}_3$. F. Zambonini emphasized the crystallographic relationship observed by K. Vrbá between calamine and bertrandite, $\text{Be}_2(\text{BeOH})_2\text{Si}_2\text{O}_7$.

The **colour** of calamine is usually white, but it may have a delicate blue or green tinge; the colour may also pass through various shades of yellow to brown. The mineral may occur massive in nodules and fibrous. The *variety* from Nijni-Jagurt, Ural, has been described by O. Radochowsky, G. A. Kenngott, A. des Cloizeaux, and G. J. Brush; it is considered to be a pale blue or green concretionary calamine. The mineral may also occur in **crystals**. These were described by J. B. L. Romé de l'Isle as prismatic with dihedral summits, whereas the carbonate was said to be scalenohedral like dog-tooth spar; but he did not appreciate the importance of this difference as a distinguishing test. R. J. Haüy described only the crystals of the silicate, and he regarded native *carbonatée zinc* as an impure calcareous *zinc oxyde*. The crystals were examined by F. Mohs, A. Lévy, H. Dauber, F. Hesselberg, A. des Cloizeaux, H. Schulze, M. Bauer and R. Brauns, G. Cesaro, G. A. F. Molengraaff, K. Monheim, J. R. Blum, G. Rose, H. Traube, P. Groth, etc. According to A. Schrauf, the crystals belong to the rhombic system, and have the axial ratios $a : b : c = 0.78340 : 1 : 0.47782$. The crystals exhibit **twinning** and have hemihedral forms. The **hemimorphism** was studied by M. Seebach and F. P. Paul. The **corrosion figures** were studied by H. Baumhauer. The **cleavage** according to (001) is imperfect, and perfect according to (110). V. von Lang found the **optic axial angle** for the red, yellow, and green rays to be respectively $2V = 47^\circ 30'$, $46^\circ 9'$, and $44^\circ 42'$; while A. des Cloizeaux found for the yellow ray $45^\circ 57'$. V. von Lang measured $2E = 81^\circ 3'$, $78^\circ 7'$, and 76° respectively for the red, yellow, and green rays, while A. des Cloizeaux gave $82^\circ 30'$, 80° , and 75° . By raising the temp. from 8° to 121° , the latter found the optic axial angle changed from $85^\circ 21'$ to $76^\circ 32'$. The **specific gravity** was determined by many of those who analyzed the mineral; A. Lévy gave 3.379; K. Monheim, 3.43-3.49; G. Rose, 3.435-3.871; F. P. Dunnington, 3.40; J. R. MacDirby, 3.338; etc. The **hardness** is 4-5. G. Spezia was able to melt the mineral to a white enamel, by feeding the flame with hot air. A. des Cloizeaux gave for the **indices of refraction** for yellow light, $\alpha = 1.615$, $\beta = 1.618$, and $\gamma = 1.635$; U. Panichi, $\alpha = 1.61376$, $\beta = 1.61673$, and $\gamma = 1.6355$; and V. von Lang, $\alpha = 1.61358$, $\beta = 1.61696$, and $\gamma = 1.63597$; the last-named also gave for red light, $\alpha = 1.61069$, $\beta = 1.61416$, and $\gamma = 1.63244$; and for green light, $\alpha = 1.61706$, $\beta = 1.6202$, and $\gamma = 1.63916$. U. Panichi found that the values of α and γ at the temp. of liquid air are but slightly reduced, while β is decreased by 0.0032. The decrease of β is attended by an increase in the optic axial angles. The **birefringence** is strong. V. von Lang gave for red light, $\gamma - \alpha = 0.02175$; and for green light, $\gamma - \alpha = 0.02210$; and U. Panichi gave for yellow light, $\gamma - \alpha = 0.02174$. The optical character is positive. T. Liebisch observed the **fluorescence** of the mineral under the influence of **ultra-violet light**. The **emission spectrum** at -180° behaves like that of troostite. The mineral is also **triboluminescent**. P. Riess and H. Rose, F. Köhler, and A. Lévy found the mineral is strongly

pyroelectric. M. Bauer and R. Brauns noted that with a fall of temp., the electrification is stronger the longer the heating. J. and P. Curie noted the **piezoelectric** effects of compression—the ends with (001), (011), and (101) are negatively electrified, and the end with (121) is positively electrified. Calamine is soluble in **acids**, and, according to G. Tschermak, gelatinous orthosilicic acid separates out. J. D. Dana said that the mineral gelatinizes with **acetic acid**; and is soluble in a conc. soln. of **sodium hydroxide**. H. C. Bolton said that a cold sat. soln. of **citric acid** attacks the mineral; and H. Brandhorst found that it is insoluble in an ammoniacal soln. of **ammonium carbonate**.

H. Borntrüger¹¹ mixed an aq. soln. of a zinc salt (1 : 10) with an equal vol. of a soln. of sodium silicate of sp. gr. 1.357 dil. with half its vol. of water. The mass was washed with hot water. It melted when heated, forming a transparent glass with a composition corresponding with *zinc trisilicate*, $\text{ZnO} \cdot 3\text{SiO}_2$. The description includes no trustworthy evidence of chemical combination.

L. Bourgeois¹² made **cadmium orthosilicate**, Cd_2SiO_4 , by heating mixtures of cadmium oxide and amorphous silica for several hours. It resembled cobalt orthosilicate (*q.v.*). A. Duboin first calcined a mixture of cadmium oxide, silica, and potassium fluoride; and remelted the product with an excess of potassium chloride for 72 hrs. He thus obtained crystals of the orthosilicate, and **cadmium oxyorthosilicate**, $\text{Cd}_2\text{SiO}_4 \cdot \text{CdO}$. A. I. Walcker found a soln. of sodium silicate gives a white precipitate with mercurous nitrate soln.—possibly *mercurous silicate*. Soln. of mercuric chloride give no precipitate of *mercuric silicate*, and when the soln. is evaporated, crystals of mercuric oxychloride are formed.

H. S. van Klooster¹³ found that no *lithium zinc silicate* is formed in the binary system with lithium and zinc metasilicates. The eutectic temp. is nearly 990° , and the eutectic mixture has nearly 52 per cent. of lithium metasilicate. The dotted portion of the curve, Fig. 105, was not determined thermally, but was estimated from optical observations on the solid products. R. Schindler said that a *potassium zinc silicate* separates in white flakes when zinc in contact with iron is dissolved in potash-lye containing silica in soln. He said that the flakes contain water; dissolve in an excess of potash-lye, and in acids with the

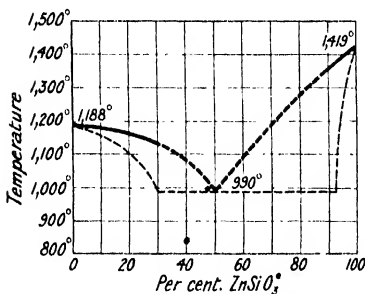

FIG. 105.—Freezing-point Curve of the Binary System: ZnSiO_3 - LiSiO_3 .

separation of gelatinous silica. There is here no evidence of the formation of a chemical individual. A. Duboin found that if precipitated zinc oxide is added to a soln. of silica in molten potassium fluoride, contained in a platinum crucible, and the cold mass remelted with the addition of potassium chloride, and maintained in that state for 72 hrs., two potassium zinc silicates are formed. These may be separated by a heavy liquid made by dissolving mercuric iodide in an aq. soln. of lithium or sodium iodide. The heavier silicate has a composition $\text{K}_2\text{O} \cdot 0.6\text{ZnO} \cdot 4\text{SiO}_2$, and it forms small prismatic crystals of sp. gr. 3.68 at 0° ; the lighter silicate has a composition $8\text{K}_2\text{O} \cdot 9\text{ZnO} \cdot 17\text{SiO}_2$, and it forms large prismatic crystals of sp. gr. 2.96 at 0° . Both are readily decomposed by hydrochloric acid. The constitution is not analogous to that of the potassium magnesium silicates. The data as to homogeneity are scarcely sufficient to justify naming the two products.

J. E. Wolff reported a white mineral from Franklin, N.J., which had a composition corresponding with the idealized formula $\text{Ca}_2\text{ZnSi}_2\text{O}_7$, or **zinc dicalcium orthosilicate**, and it was called *hardystonite*. The crystals are tetragonal; the index

of refraction for Na-light $\omega=1.6691$, and $\epsilon=1.6568$; or $\epsilon-\omega=0.0123$; for Li-light, $\omega=1.6758$, $\epsilon=1.6647$, and $\epsilon-\omega=0.0111$. The birefringence is negative. The sp. gr. is 3.396 and the hardness 3-4. The mineral gelatinizes with hydrochloric acid. K. Hofmann-Degen found a tetragonal silicate which he called *justite* in the slag at the Clausthal silver works. The composition approximates $(\text{Mg,Fe,Zn,Mn,Ca})_3\text{Si}_2\text{O}_3$, where $\text{Ca} : (\text{Mg,Fe,Zn,Mn})=1:1$. The refractive indices for Na-light are $\epsilon=1.6581$, and $\omega=1.6712$. Justite is isomorphous with hardystonite. A slag from Bochum contained tetragonal crystals of a member of the hardystonite family with the composition $\text{R}'_3\text{Si}_2\text{O}_{37}$, where R represents $\text{Ca} : (\text{Mg,Fe,Mn})=1:1$. A Duboin found crystals of **potassium cadmium triterosilicate**, $\text{K}_2\text{CdSi}_4\text{O}_{10}$, among those of the cadmium silicates indicated above.

S. L. Penfield and H. W. Tooto obtained a colourless, white, or amethyst-blue mineral from Franklin, whose composition agreed with formula $\text{H}_2\text{ZnCaSiO}_4$, or **zinc calcium dihydrometasilicate**, $(\text{CaOH})(\text{ZnOH})\text{SiO}_3$, and he called it *clinohedrite*. The monoclinic crystals had the axial ratios $a:b:c=0.68245:1:0.3226$, and $\beta=76^\circ 4'$. The birefringence is small. The optical character is negative. The sp. gr. is 3.33; and the hardness 5.5. The mineral gelatinizes with hydrochloric acid. Several cases in which zinc can replace more or less magnesium and calcium in the silicates have been indicated in connection with the magnesium silicates. G. A. König analyzed one with five basic elements—magnesium, zinc, manganese, calcium, and iron (ferrous)—present in appreciable quantities.

§ 33. The Borosilicates

M. Faraday,¹ and W. V. Harcourt prepared a number of borosilicate glasses; and W. Guertler showed that silica is insoluble or only slightly soluble in fused boric oxide. A. V. Bleining and P. Teetor prepared fused mixtures of boric

oxide and silica, presumably homogeneous, with a composition ranging between B_2O_3 and $B_2O_3 \cdot 3SiO_2$. The properties of various borosilicate glasses were investigated by W. F. S. Turner and co-workers—*vide glasses*. The constitution of the boratosilicate minerals was investigated by G. Cesaro and described in his memoir: *Sur le rôle du bor dans les silicates*. He considers that the boron is best regarded as part of the acid radicle, in which silicon is replaced by B_2O'' .

H. S. van Klooster² measured the f.p. curves of mixtures of lithium metasilicate and metaborate, and found that no *lithium borosilicate* is formed, but mixed crystals

FIGS. 106 and 107.—Freezing-point Curves of the Binary Systems: Li_2SiO_3 - $LiBO_2$, and Na_2SiO_3 - $NaBO_2$.

were produced with up to 24 per cent. of lithium silicate and with up to 9 per cent. of lithium metaborate—Fig. 106. In the case of mixtures of sodium metasilicate and sodium metaborate, no *sodium borosilicate* is formed, but the product is immiscible in the solid state when between 4 and 95 per cent. of sodium metaborate is present. E. S. Larsen and W. B. Hicks³ obtained a mineral from Searles Lake, San Bernardino, California, whose composition approximated to $Na_2O \cdot B_2O_3 \cdot 4SiO_2 \cdot 2H_2O$, when what appear to be accidental

impurities are eliminated. The composition of *searlesite*—as the mineral was called—is thus analogous with that of analcite—*vide infra*— $NaB(SiO_3)_2 \cdot H_2O$, or *sodium borodimetasilicate*. The crystals are probably monoclinic. The optic axial angle $2E$ is very large, and the indices of refraction $\alpha=1.520$, and $\gamma=1.528$. The mineral is fairly soluble in water, and is decomposed by hydrochloric acid. After treatment with dil. acid, the index of refraction fell to 1.47, and the optic axial angle also decreased.

H. Erni⁴ detected boric acid in a mineral from Danbury, Connecticut. C. U. Shepard found no boric acid, and named it *danburite*. J. L. Smith and G. J. Brush found about 27 per cent. of boric oxide. Analyses were made by G. J. Brush and E. S. Dana, J. E. Whitfield, E. Wittich and J. Kratzert, A. Schrauf, and E. Ludwig. It has also been found at Russell, N.Y., and C. Hintze, G. vom Rath, and G. Seligmann observed the mineral at Piz Valatscha, Switzerland; A. Lacroix in Maharitra, Madagascar; and N. Fukuchi in Obira, Japan. According to G. A. König, some slender prismatic crystals of danburite, associated with chlorite and tourmaline, were called *bementite*, after C. S. Bement. A. Lacroix estimated the composition of the idealized mineral to be 22.8 per cent. CaO ; 28.4 per cent. B_2O_3 ; and 48.8 per cent. SiO_2 , in agreement with the formula $CaB_2Si_2O_8$. W. Kupferbörger obtained a similar result. The constitution has been discussed by C. F. Rammelsberg. P. Groth compares the danburite with barsovit, $CaAl_2Si_2O_8$; and W. C. Brögger with hellandite, barsovit, abdalusite, and topaz. According to G. Cesaro, danburite is a neutral tricalcium metaboratosilicate with part of the silica replaced by the dyad radicle B_2O'' . F. W. Clarke regards it as *calcium diborylmetasilicate*, and barsovit as an orthosilicate:

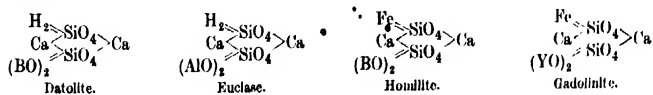

The mineral occurs massive and crystalline; and its colour is pale yellow or white. The crystals have been studied by H. Buttgenbach, G. J. Brush and E. S. Dana, C. Hintze, A. Lacroix, V. M. Goldschmidt and J. Philipp, H. L. Ungemach, etc. The crystals belong to the rhombic system, and, according to M. Schuster, they have the axial ratios $a : b : c = 0.54446 : 1 : 0.48006$. The cleavage

is distinct. G. J. Brush and E. S. Dana found the optic axial angle $2V$ to be $87^\circ 37'$ with Li-light; $88^\circ 23'$, with Na-light; and $90^\circ 56'$, with light filtered through a soln. of a copper salt. A. Lacroix gave $2V = 86^\circ 54'$. M. Kawamura gave $2V = 89^\circ 50'$. G. J. Brush and E. S. Dana gave for Li-light $2H = 100^\circ 33'$ and $100^\circ 35'$; for Na-light, $101^\circ 30'$ and $105^\circ 36'$; and for light transmitted by a copper salt, $107^\circ 36'$ and $102^\circ 13'$. A. des Cloizeaux, and E. Wittich and J. Kratzert made similar measurements. The sp. gr. found by G. J. Brush and E. S. Dana was 2.95–2.97; by C. Bodewig, 2.986; by E. Ludwig, 2.985; by W. T. Schaller, 2.98; by W. Kupferb rger, 2.95; and by A. Lacroix, 3.10. The hardness is about 7. The mineral readily fuses to a colourless glass. The indices of refraction, given by C. Hintze, are for the Li-, Na-, and Ti-rays respectively, $\alpha = 1.6258$, 1.6317 , and 1.6356 ; $\beta = 1.6293$, 1.6340 , and 1.6375 ; and $\gamma = 1.6331$, 1.6363 , and 1.6393 . M. Kawamura obtained $\alpha = 1.6303$, $\beta = 1.6333$, and $\gamma = 1.6363$; W. Kupferb rger, for Na-light, $\alpha = 1.630$, and $\gamma = 1.636$; and E. S. Larsen, $\alpha = 1.632$, $\beta = 1.634$, and $\gamma = 1.636$. The optical character is negative. The mineral exhibits thermoluminescence, glowing with a reddish light. The mineral is attacked slightly by hydrochloric acid; but if it is previously ignited, gelatinous silica is formed by the action of this acid.

J. Esmark⁵ obtained a boriferous mineral from Arendal, Norway, and he called it *datolite*—from $\delta\alpha\tau\acute{o}\lambda\alpha\iota$, to divide—in allusion to the granular structure of the massive variety. The mineral was analyzed by M. H. Klaproth, and L. N. Vauquelin. A. G. Werner, and A. Brougniart called it *datholite*, but C. C. von Leonhard emphasized that this spelling is wrong. R. J. Haiiy called it *chaur borat e siliceuse*; and J. F. L. Hausmann, *esmarkite*.

J. F. L. Hausmann, and R. J. Haiiy stated that the crystals of datolite belong to the rhombic system, and A. L vy found crystals of a mineral which belonged to the monoclinic system, and he named it *kumboldite*. F. Mohs and others showed that kumboldite and datolite are of the same mineral species. J. F. L. Hausmann called a fibrous form of datolite, *botryolite* or *botryolite*—from *      *, a grape. M. H. Klaproth, C. F. Rammelsberg, and A. Lacroix showed that botryolite is of the same mineral species as datolite. The *haytorite* from Hay Tor, Devonshire, described by C. Tripe, C. le Neve Foster, A. Volkman, W. Harding, F. Hessenberg, C. S. Weiss, E. Geinitz, E. F. Glocker, J. R. Blum, J. F. L. Hausmann, P. A. Duf r ny, H. J. Brooke and W. H. Miller, J. Phillips, A. L vy, and D. Brewster appears to be datolite altered to chalcodony. O. L decke has published a monograph on datolite.

Various occurrences and analyses of datolite have been reported.⁶ V. Goldschmidt gave for the loss on ignition of a specimen from Bologna, 1.0 per cent.; Arendal, 3.0 per cent.; and Bergenhill, 5.0 per cent. C. F. Rammelsberg said that the boron behaves as an electropositive element. The composition of the idealized mineral corresponds with $H_2Ca_2B_2Si_2O_{10}$; and P. Groth wrote the formula $Ca(B.OH)SiO_4$, calcium hydroxyboro-orthosilicate; and V. Goldschmidt represented it by $Ca_2(H_2B)Si_2O_{10}$. A. Himmelbauer found the silicic acid liberated by hydrochloric acid corresponded with G. Tschernak's $H_2Si_2O_5$, or *datolitic acid*. He assumed that the calcium is joined in part to the boron and in part to the silicon, $(H.B.Ca)_2(Si_2O_5)_2$. G. Cesaro supposed that datolite is calcium acid metasilicate with some silicon replaced by B_2O_3 . E. Baschieri made some observations on this subject. F. W. Clarke represents datolite as **calcium dihydrodiboryldiorthosilicate**, and shows its relation to humite, euclase, and gadolinite by the formul e:

A. de Gramont⁷ synthesized datolite in the form of long acicular crystals by heating in a closed steel tube a mixture of 5 grms. of precipitated calcium metasilicate and 25 grms. of borax for 36 hrs. at 400° . Less satisfactory results were

obtained with mixtures of soda water-glass and calcium borate at 300°, or of calcium oxide, boric oxide, and a soln. of alkali at 400° for 18 hrs.

Datolite occurs massive, botryoidal, and in crystals. The **colour** is white or it may be tinted grey, green, yellow, red, or blue; or the mineral may be a dirty olive-green, or yellow. The crystals have been studied by O. Luedecke, W. Schulze, E. V. Shannon, J. Lehmann, R. Riechelmann, V. M. Goldschmidt, L. Brugnatelli, H. P. Whitlock, M. F. Heddle, B. K. Emerson, C. U. Shepard, A. des Cloizeaux, A. C. Hawkins, O. C. Farrington, T. Nocca, R. Görgy and V. M. Goldschmidt, H. L. Ungemach, S. G. Gordon, F. H. Schröder, C. W. Cooke and E. H. Kraus, E. S. Dana, R. Köchlin, etc. The crystals belong to the monoclinic system, and, according to C. F. Rammelsberg, and H. Dauber, they have the axial ratios $a : b : c = 0.63287 : 1 : 0.63446$, and $\beta = 89^\circ 51' 20''$. The cleavage is distinct. H. Baumhauer studied the **corrosion figures**. The **optic axial angles** have been determined by C. Bodewig, F. Sansoni, O. Luedecke, etc. L. Brugnatelli gave :

	Li-line.	C-line.	D-line.	Tl-line.	E-line.	F-line.
2H	74° 44'	74° 34'	74° 6'	73° 27'	73° 25'	72° 31'
2V	74° 39'	—	74° 21'	—	—	—

A. des Cloizeaux found a rise of temp. from 17°–171.5° had no perceptible effect on the optic axial angles. C. Bodewig found $2H = 89^\circ 31' 7''$ at 20°; $89^\circ 28' 13''$ at 126°; $89^\circ 27' 36''$ at 130°; and $89^\circ 26' 28''$ at 222°. F. Ulrich gave $2V = 74^\circ 11'$ to $74^\circ 16'$. When cooled to 21°, $2H = 89^\circ 29' 41''$, indicating a slight change. The **specific gravity** was found by G. A. Kenngott to be 2.968; J. Fromme gave 2.950–2.952; T. Nocca, 2.995 at 18°; F. Ulrich, 2.993; L. Brugnatelli, 2.907; G. C. Hoffmann, 2.985; and A. Himmelbauer, 3.003. G. A. Kenngott found the **hardness** to be between 5 and 6. The mineral fuses to a clear glass before the blowpipe flame. According to C. F. Rammelsberg, the water is expelled from datolite only at a high temp. The **indices of refraction** were determined by A. des Cloizeaux, L. Brugnatelli, O. Luedecke, T. Nocca, etc. W. F. P. MacIntock found $\alpha = 1.626$, $\beta = 1.653$, and $\gamma = 1.670$. A. des Cloizeaux gave for the red and yellow light, $\alpha = 1.6248$ and 1.6260 respectively; $\beta = 1.6510$ and 1.6535 ; and $\gamma = 1.6670$ and 1.6700 . L. Brugnatelli gave for Li- and Na-light, $\alpha = 1.6217$ and 1.6246 respectively; $\beta = 1.6492$ and 1.6527 ; and $\gamma = 1.6659$ and 1.6694 . F. Ulrich gave $\alpha = 1.654$, $\beta = 1.654$, and $\gamma = 1.670$. U. Panichi investigated the action of low temp. on the refractive index of datolite. W. W. Coblentz found that in the ultra-red transmission spectrum of datolite the hydroxyl band appears at 2.8μ . There are other bands at 2μ , 3μ , 5.3μ , and 6.3μ . The reflection spectrum has small sharp maxima at 8.8μ , 9.2μ , 9.5μ , 10μ , and 10.8μ . W. G. Hankel studied the **pyroelectric** behaviour of datolite. According to G. A. Kenngott, when the powdered mineral, calcined or uncalcined, is moistened with **water**, it reacts alkaline. With **hydrochloric acid**, gelatinous silica separates. A. Himmelbauer found that the mineral is decomposed by cold **acetic acid**, and by **ammonium chloride** at 100°. F. W. Clarke and G. Steiger also investigated the action of ammonium chloride. The geological changes have been discussed by J. Roth.

S. R. Paijkull⁸ described a black or brown mineral found on the Stockö, Brevig, Norway; and he named it **homilite**—from *ὁμιλέω*, to occur together—in allusion to its accompanying melinophane and erdmannite. Analyses were made by S. R. Paijkull, and A. des Cloizeaux and A. Damour. They correspond very well with the formula $\text{Ca}_2\text{FeB}_2\text{Si}_2\text{O}_{11}$; and are thus related with those of datolite. G. Cesaro supposes homilite to be like datolite but containing some iron. The graphic formula given by F. W. Clarke—*vide supra*—is closely akin to that of datolite. This makes the mineral **calcium ferrodiboryldiorthosilicate**. A. E. Nordenskjöld emphasized the close similarity between the crystals of datolite and of homilite. The crystals are monoclinic, and, according to A. des Cloizeaux, the axial ratios are $a : b : c = 0.6249 : 1 : 1.2824$, and $\beta = 89^\circ 21'$. The cleavage is indistinct. A. des Cloizeaux found the optic axial angle $2H = 97^\circ 5'$ to $98^\circ 22'$ with

red light. The sp. gr. given by S. R. Pajkull is 3.28; and that given by A. des Cloizeaux and A. Damour is 3.34. The hardness is 4.5-5.5. A. des Cloizeaux and A. Damour said that some of the crystals are throughout doubly refracting; others have a green doubly refracting kernel surrounded by a yellowish crust of a singly refracting substance; and still others are entirely singly refracting. The composition of the singly refracting material is like that of erdmannite. E. S. Larsen made observations on the optical characters of homilite.

The complex mineral *erdmannite* has been treated among the rare earth minerals. It was first described by N. J. Berlin. It is dark brown without a sign of crystallization. Analyses were reported by A. des Cloizeaux and A. Damour, C. A. Michaelson, and N. Engström. W. C. Brögger gave it the formula $3\text{RO}''\text{R}'''\text{O}_2\cdot 2\text{SiO}_2$, where RO represents mainly calcium, ferrous, and beryllium oxides; $\text{R}'''\text{O}_2$ represents ferric and boric oxides; and the rare earth sesquioxides. He called it *cer-homilite*.

Rounded nodules of a calcium borosilicate mineral were found by H. How⁹ at Brookville, Nova Scotia. The mineral was called *howlite* by J. D. Dana. Analyses were made by H. How, S. L. Penfield and E. S. Sperry, A. S. Eakle, and W. B. Giles. The composition corresponds with $\text{H}_2\text{Ca}_2\text{B}_2\text{SiO}_{14}$. C. F. Rammelsberg gave for the formula $(\text{Ca}_2\text{B}_2\text{Si}_2\text{O}_{23}\cdot 5\text{H}_2\text{O})$, and he regarded the mineral as a complex of calcium borate, calcium silicate, and boric acid. P. Groth assigned to it the formula $\text{H}_2(\text{Ca}(\text{BO}_3)_2)_2\text{H}_2(\text{CaSiO}_4)$, and thus regarded it as a complex of metaborate and orthosilicate. G. Cesaro regards howlite as an orthosilicate with some silicon replaced by B_2O_3 . W. and D. Asch represented it by $4\text{CaO}\cdot 2\text{SiO}_2\cdot 5\text{B}_2\text{O}_3\cdot 5\text{H}_2\text{O}$. C. F. Rammelsberg found the water was expelled at 350°, and hence regarded it as water of crystallization. The acicular or prismatic crystals belong to the rhombic system. Howlite may also occur in white earthy masses. The sp. gr. is 2.55, and the hardness 3-4. H. How also described a white crystalline calcium borosilicate from Winkworth, Nova Scotia. He called it *winkworthite*. It is regarded as a mixture of gypsum and howlite. W. G. Giles obtained from San Bernardino, California, an amorphous mass of what he called *bakerite*—after R. C. Baker. The analyses corresponded with $8\text{CaO}\cdot 6\text{SiO}_2\cdot 6\text{B}_2\text{O}_3\cdot 6\text{H}_2\text{O}$. The sp. gr. was 2.73; and the hardness 4½. It is readily soluble in dil. hydrochloric acid. A. S. Eakle claims that *camacillite*—*vide* 5. 32, 12—is a *magnesium borosilicate*, $2(\text{MgO}, \text{FeO})\cdot \text{B}_2\text{O}_3\cdot \text{SiO}_2\cdot \text{H}_2\text{O}$.

A. Lacroix¹⁰ found a white basic lithium borosilicate near the Manandona river, Madagascar; and he named it *manandonite*. The analysis corresponds with $\text{Li}_4\text{Al}_4\text{B}_4\text{Si}_4\text{O}_{44}$. It occurs in lamellar aggregates or mammillary crusts of hexagonal plates.

M. Faraday¹¹ melted a mixture of 112 parts of lead oxide, 16 of silica, and 24 of boric oxide, and obtained a *lead borosilicate*; K. Beck and co-workers found that 5 per cent. of boric acid made lead silicate glasses more fusible—the monosilicate melted at 480°, the disilicate at 540°, and the trisilicate at 600°. The boric oxide increases the attack by one per cent. nitric acid, or 4 per cent. acetic acid. P. Bartel obtained an analogous result. *Azinite* may be a borosilicate—*vide* the iron silicates.

§ 34. Aluminium Silicates

N. G. Sefström¹ obtained a sintered mass by heating a mixture of 3 mols of silica and 2 mols of alumina in the strongest heat of a blast furnace. P. Berthier, W. A. Lampadius, and A. Gaudin made observations on fused mixtures of silica and alumina; but no definite combinations were produced, although several were reported. Thus, N. G. Sefström reported $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$; P. Berthier, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$;

4:3, 2:3, 1:3, and 2:9; and C. F. Plattner, $2\text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2$. W. Vernadsky obtained $\text{Al}_4\text{Si}_3\text{O}_{10}$ and $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ by strongly heating aluminosilicates—*vide infra*, andalusite and sillimanite; H. St. C. Deville and H. Caron, $4\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$ by heating alumina in silicon tetrafluoride; S. Meunier, $5\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$, by heating aluminium in silicon tetrachloride; H. St. C. Deville, by heating alumina in the same gas; E. Frémy and C. Feil, $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$, by heating silica in the vap. of aluminium fluoride; and F. Singer, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, by calcining ammonium zeolite. With the exception of sillimanite, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, the chemical individuality of none of these products has been established. There is evidence of the existence of another compound, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, on the f.p. curve. H. A. Seger² made some observations on the fusibility of mixtures of alumina and silica. He found evidence of a eutectic with about 17 mols of silica per mol of alumina. H. A. Seger's results were replotted by B. Neumann; and verified by L. Bradshaw and W. Emery. For colloidal aluminium silicates, *vide supra*, water-glass.

S. Kozu³ and co-workers reported a mineral from Kochi-mura, Rikuchu, Japan, which they called **kochite**. It formed a granular aggregate of cubic crystals, with the composition $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 5\text{H}_2\text{O}$, or $\text{Al}_4(\text{SiO}_4)_3 \cdot 5\text{H}_2\text{O}$, or normal **aluminium orthosilicate**. Its sp. gr. at 15° was 2.929; and its index of refraction for the

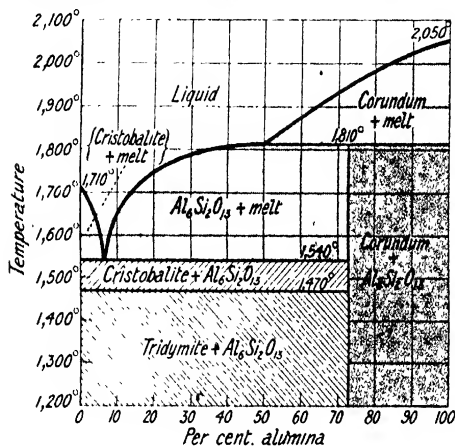

FIG. 108.—Freezing-point Curves of the Binary System :
 $\text{Al}_2\text{O}_3\text{--SiO}_2$.

D-line, 1.590. The water is rapidly evolved when the mineral is heated in air at 725°–800°; and in water-vap. at atm. press. it is given off at 775°–790°. G. A. Rankin and co-workers, and N. L. Bowen and J. W. Greig, have studied the general behaviour of the binary system, $\text{Al}_2\text{O}_3\text{--SiO}_2$, illustrated by Fig. 108. Only one compound appears in the system at these temp., and its composition is represented by $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$. There is no evidence of the formation of sillimanite, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, under these conditions. The observations by G. Shearer, and J. W. Mellor and A. Scott show that the X-radiograms of kaolinite, and of a mol of kaolinite mixed with a mol of alumina fired at 1700°, are quite different from the X-radiogram of a mixture of a mol of kaolinite with two mols of alumina. The inference is that there are two distinct compounds, sillimanite, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, and what N. L. Bowen and J. W. Greig propose to call **mullite**, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, in allusion to the fact that the “best described examples” of sillimanite are those of H. H. Thomas from the Island of Mull. It is probable that the two compounds can form solid soln. R. Ballo and E. Dittler also found only the one aluminium silicate to be stable in contact with molten lithium silicate. R. C. Wallace observed the formation of sillimanite when silica and alumina are melted together—*vide infra*. P. J. Holmquist discussed this subject.

Three distinct crystalline minerals can be represented by the empirical formula $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, and this aluminium silicate is therefore trimorphous. The three forms are called sillimanite, andalusite, and cyanite or disthene. As shown by W. Vernadsky, and E. H. M. Beekmann, sillimanite is the only form stable at a

high temp., and presumably has the simpler constitution. Cyanite has the highest sp. gr., and sillimanite the lowest. The metasilicates are usually more stable than the orthosilicates. P. Groth therefore argued that andalusite is probably an orthosilicate: $\text{Al}\equiv\text{SiO}_4\cdot\text{Al}:\text{O}$; or $\text{SiO}_4\equiv\text{Al}_2:\text{O}$ —provided the molecules are not polymerized. Cyanite and sillimanite can thus be regarded as metasilicates—i.e. **aluminium dioxy-metasilicate**:

If the mols. have a higher mol. wt. than is represented by the formula $\text{Al}_2\text{O}_3\cdot\text{SiO}_2$, the possibilities of isomeric forms are multiplied. F. W. Clarke and J. S. Diller gave for sillimanite:

K. Zulkowsky found that disthene gives off $1\frac{1}{2}$ mols of carbon dioxide when a mol is fused with 3 mols of alkali carbonate. He thinks that this is not in accord with P. Groth's disthene formula, $(\text{AlO})_2\text{SiO}_3$. He represents the three forms by

K. Zulkowsky has separate formulae for andalusite and cyanite, but when expressed in this way, they both give the same result. Since topaz and andalusite readily form muscovite mica, F. W. Clarke suggests that the empirical formulae of the two former minerals should be tripled so as to keep the formulae of all three minerals of the same type:

This subject was discussed by L. Grünhut without relevant evidence. Sillimanite, $\text{Al}_2\text{O}_3\cdot\text{SiO}_2$, can be represented as **silicon oxydialuminate**, $\text{O Si Al}(\text{O}_2)_2$, which is related to mullite, $3\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$, as indicated by the formula $(\text{AlO}_2)_3\text{Si}-\text{O}-\text{Si}(\text{AlO}_2)_3$ for **silicon oxyhexaluminate**. In the absence of more definite facts, there is no profit in pursuing the subject further. R. B. Sosman suggested a possible parallelism between cyanite and quartz, cristobalite and sillimanite, and between tridymite and andalusite.

Sillimanite occurs in separate crystals—usually long and slender—or in aggregates of fibres arranged in a diverse or radiating manner. There are several varieties differing simply in texture, and more or less contaminated with quartz, corundum, etc. The mineral may be colourless, white, or tinged brown, grey, or green. A dense compact form is one of the many different minerals which have been called *jade*; and, according to A. Damour,⁴ F. W. Clarke, and F. Quiroga, it was sometimes used by prehistoric man in Western Europe for making implements and utensils.

In 1792, B. von Lindacker described a fibrous mineral from Bohemia which he called *Faserkiesel*, and which, according to A. G. Werner, and C. C. von Leonhard, might be a mixture of tremolite and quartz. J. L. Bournon called a variety which he found in some Asiatic corundum, *fibrolite*. J. A. H. Lucas proposed the name *bournonite*. Fibrolite was analyzed by R. Chenevix, and B. Silliman. According to C. N. von Fuchs, fibrolite is a mixture of disthene and quartz. L. J. Spencer reported a blue fibrolite from Burma and Ceylon; it had the indices of refraction with Na-light: $\alpha=1.6584$, $\beta=1.6596$, and $\gamma=1.6789$; and birefringence $\gamma-\alpha=0.0205$. The optic axial angles were $2E=52^\circ 2'$, and $2V=28^\circ 2'$. R. Brandes called a variety which he found in Tyrol, *bucholzite*—after C. F. Bucholz. These three terms were regarded by E. F. Glocker, C. Hartmann, and J. F. L. Hausmann as synonyms for the same mineral species. A mineral from Saybrook, Connecticut, was described by G. T. Bowen; it was called *sillimanite*, after B. Silliman, who showed that it is chemically and crystallographically like fibrolite. A. Erdmann called a mineral from Bamle, Norway, *bamlite*. L. Saemann, and P. A. von Sachsen-Coburg showed that it is a

mixture of sillimanite and quartz. N. Nordenskjöld named a mineral from Peterhof, Finland, *xenolite*—from *févor*, *stranger*. A. Lacroix showed that it resembles fibrolite. *Xenolite* accompanied the mineral *wörthite*—named after M. von Wörth, by H. Hess. *Wörthite* is a partially hydrated and altered sillimanite. The *monrolite* from Monroe, N.Y., described by B. Silliman is a mixture of sillimanite and quartz. The *Glanzspath*, or *glance spar*, of H. von Dechen, and G. vom Rath, was shown by W. Vernadsky to be impure sillimanite. C. Hintze takes the same view. The mineral *westanite* from Westana, Sweden, was described by C. W. Blomstrand. It is regarded as a hydrated fibrolite; P. Groth suggested that it is an altered andalusite. T. Thomson mentioned *hydrobucholzite*, probably from Sardinia. A. des Cloizeaux said that mineral is a doubtful species and has little in common with bucholzite.

Analyses of the different varieties have been reported; and various occurrences recorded. The mineral is mined at Assam, India. A compound resembling sillimanite was made by H. St. C. Deville and H. Caron⁵ by the action of silica on aluminium fluoride, or of alumina on silicon fluoride at a high temp. Similar results were obtained by E. Frémy and C. Feil, and by A. Reich. Andalusite and cyanite were shown by W. Vernadsky to be each transformed into sillimanite between 1320° and 1380°, with the disengagement of heat. He obtained sillimanite by fusing together silica and alumina. R. C. Wallace, and G. Stein obtained sillimanite crystals in a similar manner. When fused sillimanite is rapidly cooled, said E. S. Shepherd and G. A. Rankin, it always crystallizes as sillimanite. Soln. of sillimanite in fused calcium vanadate, borax, albite, etc., always give crystals of sillimanite. W. Vernadsky said that better crystals are produced if 2 to 4 per cent. of magnesia is present in the magma. J. Morozewicz studied the conditions under which sillimanite can form magmatically; in a fused magma of the composition $RO \cdot mAl_2O_3 \cdot nSiO_2$, if magnesia and iron oxide are absent, and $m=1$, sillimanite is always developed if n be greater than 6. Artificial sillimanite was discussed by C. E. Sims and co-workers, O. Rebuffat, A. Malinowszky, etc.

The formation of crystals of sillimanite in porcelain was observed by C. G. Ehrenberg, A. Bünzli, A. Zöllner, E. Plenske, G. N. White, M. Glasenapp, E. Rosenthal, A. Oschatz and A. Wächter, H. Behrens, E. Hussak, W. Vernadsky, J. W. Mellor, P. Stutschinsky, P. A. Schemjatschensky, A. S. Watts, A. A. Klein, A. Scott, H. Ries and Y. Oinoye, L. Bertrand, etc.; and in firebricks by J. W. Mellor, A. H. Cox, H. M. Kraner, and others. It also appears when china clay has been heated to a high temp. short of fusion. The temp. of formation must be lowered in the presence of felspar, because A. Heath and J. W. Mellor observed them in pottery bodies fired below 1200°. W. Eitel observed their formation in aluminothermic processes. From the observations of N. L. Bowen and J. W. Greig, it is probable that mullite has not always been distinguished from sillimanite in these reports of sillimanite; and F. H. Riddle, and T. S. Curtis said that the crystals they obtained had the composition of mullite, not sillimanite. In some cases, the artificial crystals have been analyzed, and the results are in agreement with the mullite ratio, but it is not always clear that the isolation of the crystals by hydrofluoric acid does not leave an aluminous residue behind, since there are no indications that this has been removed by washing preferably with a soln. of ammonium acetate. The use of sillimanite as a refractory material was discussed by A. Malinowszky, A. F. Greaves-Walker, and S. English; and of andalusite for sparking plugs, by A. B. Peck. Sillimanite makes a very good refractory brick when mixed with 10-20 per cent. of a good type of plastic clay as a bond.

According to E. Taubert, the **crystals** of sillimanite belong to the rhombic system, and they have the axial ratios' $a:b:c=0.9696:1:0.7046$; A. des Cloizeaux gave $0.6873:1:—$. G. A. Rankin and F. E. Wright said that sillimanite crystallizes from the melt in fine-grained, fibrous, or lath-shaped individuals, which, like the natural mineral, are often in close parallel columns. It is difficult to cool molten sillimanite quickly enough to prevent crystallization, but the glass can be obtained by dropping the fused mass from the tip of a perforated conical crucible directly from the electric furnace into cold water. The glass

readily crystallizes into sillimanite when heated to 1200°, or when heated to 350°–400° in bombs containing a 10 per cent. soln. of sodium chloride. The **cleavage** with the natural crystals is well defined; and in the artificial crystals the cleavage is distinct in the direction of elongation of the fibres. The **optic axial angle** of the artificial crystals is not large. A. des Cloizeaux found the optic axial angle at 18° is $2E=49^{\circ}9'$ for the red ray; $42^{\circ}30'$ for the yellow ray; and $38^{\circ}41'$ for the blue ray. For white light, $2E=35^{\circ}\text{--}40^{\circ}$. The effect of temp. is as follows:

	12°	15°	47°	95°5'	121°	146°5'	175°
2E	44°4'	44°4'	44°23'	45°0'	45°18'	45°54'	46°8'

A. Lacroix found $2V=26^{\circ}$ for yellow light; G. Melezer, $31^{\circ}11'5''$; and A. Michel-Lévy and P. Termier about 20° ; W. Eitel, 43° ; and E. S. Larsen, 20° . The **X-radiograms** were examined by G. Shearer, and F. Reune. The **specific gravity** of the mineral is 3.235–3.248. E. H. M. Beekmann gave 3.152 for the sp. gr. before calcination, and 3.157 after calcination. E. S. Shepherd and G. A. Rankin gave 3.031 for the sp. gr. of the artificial crystals, and 2.54 for the glass. I. I. Saslavsky studied the mol. vol. of sillimanite. The **hardness** is between 6 and 7. G. Spezia tried the action of the oxygenated blowpipe flame on sillimanite. The **melting point** of artificial sillimanite is 1811° , according to E. S. Shepherd and G. A. Rankin; and $1816^{\circ}\pm10^{\circ}$, according to G. A. Rankin and F. E. Wright. As indicated in Fig. 108, N. L. Bowen and J. W. Greig found that mullite melts incongruently at 1810° , forming corundum and liquid. Natural sillimanite though unstable at higher temp. does not suffer any change when heated for several days at 1545° , but above this temp. it breaks up into crystals of mullite and liquid. The passage of cyanite and of andalusite into sillimanite appear to be monotropic changes, for E. S. Shepherd and G. A. Rankin were quite unable to produce either cyanite or andalusite from sillimanite. They add that it seems reasonably certain that andalusite and cyanite are formed by crystallization from soln. at low temp. G. A. Rankin and F. E. Wright state that terminal sections of the fibres of artificial sillimanite are square in outline, and that the centre of nearly every section has a minute inclusion in the shape of a cross with arms parallel to the sides. Minute inclusions of a lower refracting isotropic substance are almost always present in artificial sillimanite. It is postulated that at its m.p. sillimanite is dissociated into alumina and this glass. The temp. of dissociation is so high—above 1800° —that the hypothesis has not been tested. O. S. Buckner gave 0.00432 for the coeff. of **thermal conductivity** in C.G.S. units.

A. des Cloizeaux gave for the **index of refraction** of the mineral for the red ray, $\beta=1.660$; A. Lacroix gave for the yellow ray $\alpha=1.659$, $\beta=1.661$, and $\gamma=1.680$; E. S. Larsen, $\alpha=1.659$, $\beta=1.660$, and $\gamma=1.680$; and G. Melezer, $\alpha=1.6562$, $\beta=1.65765$, and $\gamma=1.6766$. G. A. Rankin and F. E. Wright found for the artificial crystals with Na-light, $\alpha=1.638$, $\beta=1.642$, and $\gamma=1.653$, each ±0.003 ; and W. Eitel, $\alpha=1.648$, $\beta=1.652$, and $\gamma=1.664$. These values are lower than those of the mineral. E. S. Shepherd and G. A. Rankin gave for the index of refraction of sillimanite-glass, 1.625. N. L. Bowen and J. W. Greig gave the following comparison of the properties of mullite and sillimanite:

	Mullite.	Sillimanite.
Crystal system	rhombic	rhombic
Prism angle (110)–(110)	$89^{\circ}13'$	$88^{\circ}15'$
Cleavage	(010)	(010)
Refractive indices	$\alpha=1.654$, $\gamma=1.642$	$\alpha=1.677$, $\gamma=1.657$
Axial angle, $2V$	$45^{\circ}\text{--}50^{\circ}$	25°

The **birefringence** of the artificial sillimanite crystals is about $\gamma-\alpha=0.014$. The **optical character** is positive. Observations on the optical constants were also made by F. Grünling, and by E. Taubert. A. des Cloizeaux found the mineral to be **pleochroic**, being colourless when viewed in one direction, and pale rose-red in another; H. Rosenbusch found a sample from Saybrook to be dark brown in

the direction *c*, and pale brown in the directions *b* and *a*. A. Lacroix also made some observations on this subject. F. Haber said that porcelain containing a large proportion of sillimanite does not conduct electricity below 900°; but beyond that the **electrical conductivity** increases with the temp. A. V. Henry found the electrical resistivity, *R* ohms per c.c., of sillimanite refractories with a 45 volt, 1000-cycle alternating current to be

	400°	600°	800°	1000°	1200°	1400°	1500°
<i>R</i>	358×10^5	148×10^4	179×10^3	363×10^3	115×10^3	4290	3150

Sillimanite, as prepared by G. A. Rankin and co-workers, is not affected by hot or cold **water**; and is but slowly attacked by **acids** or **alkalies**. It is practically unaffected by hot or cold hydrochloric, sulphuric, or nitric acid, or by cold hydrofluoric acid. It is slowly decomposed by mixed hydrochloric and hydrofluoric acids, and by fused **sodium carbonate**. P. Sustschinsky studied the action of sodium carbonate on sillimanite. H. Hanemann found that molten **cast iron** reduces silicon from the aluminosilicates.

The mineral **andalusite** was first obtained from Andalusia, Spain, and this name was first applied by J. C. Delamétherie.⁶ Previously, J. L. Bournon referred to it as *spath adamantin d'un rouge violet*, and L. B. G. de Morveau as *felspath du Forez*.

R. J. Haüy called andalusite *felspath apyre*; J. Brunner, *micaphyllite*—from *φλος*, loved—not *micaphyllite*. M. Flurl called a variety from Stenzen, Bavaria, *stanzait*. The so-called *chiastolite*—from *χιαστός*, arranged diagonally, from *chi*, the old Greek name for the letter *χ*—has been under observation from early times. J. J. Bernhardt, F. S. Boudant, R. Bunsen, and G. Landgrebe showed that it is a variety of andalusite which was so named by D. L. G. Karsten because it exhibits in cross-section a coloured cross, or mosaic pattern. It was referred to by C. Gesner in 1565. M. Mercati called it *lapis crucifer*; C. P. G. de Robien, *pierre de macle*; J. Hill, *cross-stone*, or *Spanish shirl*; U. Aldrovandi, and J. B. L. Romé de l'Isle, *pierre de croix*; J. C. Delamétherie, *crucite*; R. J. Haüy, *macle*; and A. G. Werner, *Hohlepath*. The term *macle*, said C. P. G. de Robien, is from the Latin *macula*, a spot, and refers to the *muscle* or *macula* in heraldry, where it means a design with a lozenge-shape or a rhomb with an open centre. It has been suggested that the *macula* in the armorial bearings of the family of the Vicomte de Rohan was taken from the chiastolite of their neighbourhood. H. F. Link's *maranite* is andalusite, which occurs on the Serra de Marus. J. J. Sederholm called a variety of chiastolite from Ladoga Lake, Finland, *mallesite*; H. Bäckström, a variety of andalusite with about 7 per cent. of manganese oxide, *manganandalusite*. G. Klemm's green variety *rhindine* from Darmstadt is andalusite containing iron and manganese.

Many analyses of andalusite have been made, and various occurrences reported.⁷ Andalusite is commonly found in the zones of contact of clay slate near dykes of granite or diorite. It is also found in many metamorphic schists. A. Knopf reported a large body of rock, almost entirely andalusite, at Inyo Range, California. The earliest analyses by C. F. Bucholz, L. B. G. de Morveau, etc., appear to have been made on specimens contaminated with quartz because their formulae—e.g. $\text{Al}_8\text{Si}_9\text{O}_{30}$ and $\text{Al}_6\text{Si}_7\text{O}_{23}$ —deviate from the Al_2SiO_5 of later analysts with clean homogeneous samples. The constitution has been discussed in connection with sillimanite. One plausible hypothesis makes it *aluminium monoxorthosilicate*, or **aluminium aluminoxorthosilicate**, $\text{Al}_3(\text{AlO})_3(\text{SiO}_4)_3$, or $\text{Al}(\text{AlO})\text{SiO}_4$. The alleged syntheses of andalusite by H. St. C. Deville,⁸ E. Frémy and C. Feil, and S. Meunier have not been established—*vide* sillimanite. E. Baur prepared a product with optical properties similar to andalusite excepting a different refractive index. He heated to 300°–500° in an autoclave a mixture of silicic acid, alumina, and potassium silicate; or a mixture of silica, aluminium hydroxide, and potassium aluminate. Other silicates were formed at the same time—possibly pyrophyllite and muscovite.

The **colour** of natural andalusite may be white, grey, red, violet, brown, or green. It occurs massive and crystalline. The **crystals** have been studied by W. Haidinger,⁹ A. Schrauf, V. M. Goldschmidt, P. E. Haefele, J. Krejci, E. S. Dana,

etc. According to A. des Cloizeaux, the axial ratios of the rhombic crystals are $a:b:c=0.98613:1:0.70238$. The (110) **cleavage** is perfect, while the (100) and (010) are less well defined. The **optic axial angle**, $2V$, was found by A. des Cloizeaux to be $84^{\circ} 30'$; P. von Jeremejeff gave $2V=87^{\circ}$ and $2H$ from $96^{\circ} 30'$ to 113° . E. Bertrand gave $2H=96^{\circ} 32'$. A. des Cloizeaux found that the optic axial angle is reduced about $2\frac{1}{2}^{\circ}$ by a rise of temp. from 21° – 191° . E. E. Schmid gave 3.07 – 3.11 for the **specific gravity**; C. M. Kersten, 3.152 – 3.154 ; J. Roth, 3.401 ; A. von Hubert, 3.103 ; G. Grattarola, 2.86 ; M. F. Heddle, 3.121 ; P. von Jeremejeff, 2.944 – 3.14 ; G. F. Kunz, 3.2 – 3.4 ; W. Haidinger, 3.170 ; and A. Damour, 3.160 . E. H. M. Beekmann gave 3.158 for the sp.gr. of the mineral before calcination, and 3.150 after calcination. The **hardness** is generally rather less than 7. G. Lindner found the **specific heat** to be 0.1684 at 50° ; 0.1731 at 100° ; 0.1774 at 150° ; 0.1819 at 200° ; and 0.1861 at 250° . R. Cusack gave 1209° for the **melting point**. This value is far too low. A. L. Fletcher gave 1259° ; and C. Doelter gave 1330° – 1395° . The m.p. of the pure compound must be like that of sillimanite if, as W. Vernadsky said that andalusite changes into sillimanite at 1300° with the evolution of heat. E. S. Shepherd and G. A. Rankin found the change takes place so slowly at that temp. as to mask completely the character of the corresponding heat change. They found that no sillimanite is produced by heating the mineral for 28 days at 900° , or 168 hrs. at 1150° ; but there is much alteration after 4 days at 1500° . Sillimanite was observed after heating andalusite with sodium chloride at 800° for 168 hrs. or with calcium vanadate for 48 hrs. at 100° or 216 hrs. at 900° . At higher temp., the andalusite is decomposed by reacting with the *agent minéralisateur*. The change of andalusite to sillimanite is monotropic, for the reverse change did not occur under any of the numerous conditions tried. This agrees with W. Vernadsky's observation that andalusite does not occur in igneous rocks. A. B. Peck, and N. L. Bowen and J. W. Greig represent the change, not into sillimanite, but into mullite, $Al_6Si_2O_{13}$, at about 1350° . A. des Cloizeaux found the **indices of refraction** for the red ray to be $\alpha=1.632$, $\beta=1.638$, and $\gamma=1.643$; and E. Taubert obtained respectively for the *C*-, *D*-, and *F*-lines, $\alpha=1.6300$, 1.6361 , and 1.6410 ; $\beta=1.6326$, 1.6390 , and 1.6440 ; and $\gamma=1.6386$, 1.6453 , and 1.6511 . The **birefringence** $\gamma-\alpha$ is 0.011 ; $\gamma-\beta=0.005$; and $\beta-\alpha=0.006$. The optical character is negative. M. Lewitskaja found that although each of the principal refractive indices of andalusite has a maximum absorption of light near $485\mu\mu$, yet only β has an absorption maximum in this region. According to A. Bertin, E. Mallard, and W. Haidinger, sections of andalusite normal to an optic axis are idiophanous, or show polarization brushes distinctly. The crystals are strongly **pleochroic**. W. Haidinger found crystals showing, *a*, olive-green; *b*, green; and *c*, dark blood-red. A. des Cloizeaux, E. Bertrand, P. von Jeremejeff, and W. Haidinger made observations on this subject. The red and green dichroism of andalusite from Minas Geras, Brazil, is remarkable; and sections cut from the mineral may be so faceted that the light obliquely reflected from the sides may be differently coloured from light more directly reflected from the centre. According to O. Mügge, **radium radiations** do not affect andalusite; but, according to C. Doelter, **X-rays** affect this mineral more than they do quartz. Stout crystals of chialtolite or macle often have the axis and angles a different colour from the remaining mass. This is due to a regular arrangement of the impurities in the interior. The crystals may therefore show a coloured cross, or a tessellated structure when viewed transversely. J. J. Bernhardt found the central column sometimes widens from the middle towards each end. C. T. Jackson made similar observations. Observations on this subject have been made by the early mineralogists—*vide supra*—and by J. F. L. Hausmann, H. Rosenbusch, W. Cross, F. Zirkel, J. Durocher, A. des Cloizeaux, H. Fischer, G. A. Kennigott, A. von Lasaulx, F. E. Müller, C. E. M. Rohrbach, A. Gramann, E. Weinschenk, R. Rüdemann, etc. The peculiar structure is supposed to indicate a skeletal growth of the crystals in which the carbonaceous residue has followed the lines of growth during the conversion of slate into crystals of andalusite.

Andalusite is insoluble in acids; but it is decomposed by fused alkali hydroxide or carbonates. It is slowly attacked by fused borax. P. Jannasch¹⁰ said that: unlike most silicates andalusite is only partially decomposed by fused boric oxide. G. A. Binder studied the behaviour of andalusite towards water at 160°. F. Cornu found the moistened mineral reacted alkaline towards litmus. W. Suida found the mineral feebly adsorbed aniline dyes. C. Doelter heated andalusite with potassium carbonate and fluoride for several weeks at 250°, and observed the formation of scales of mica. He also compared the effect of a number of chemical agents on andalusite and cyanite. With fused potassium hydroxide no measurable difference was observed; a similar result was obtained when dry hydrogen chloride was passed over the heated minerals, which were afterwards leached with water to find what proportion was made soluble. When heated in a stream of chlorine, cyanite lost but a slight amount more than andalusite. Ten per cent. hydrofluoric acid dissolved 84 per cent. from cyanite, and 44.4 per cent. from andalusite. The amount of alumina dissolved in both cases was nearly the same, namely, 40.2 per cent. from cyanite, and 43.1 per cent. from andalusite. When digested at 180° in an autoclave with a soln. of sodium hydroxide, andalusite lost an unweighably small amount, while cyanite lost 1.23 per cent. The conclusion is that, although in particular cases there might be a difference, in general, the two minerals behave very much alike towards these reagents. J. Lemberg heated andalusite or cyanite with alkali silicates or carbonates under press., and found that zeolitic substances were formed. K. Zulkowsky studied the action of fused sodium carbonate on andalusite.

The change of andalusite into muscovite was observed by A. Gramann; and into chlorite and kaolinite by P. E. Haeferle. The reaction for muscovite is symbolized by C. R. van Hise: $6\text{Al}_2\text{Si}_2\text{O}_6 + \text{K}_2\text{CO}_3 + 11\text{H}_2\text{O} = 6\text{Al}(\text{OH})_3 + 2\text{H}_2\text{KAl}_3\text{Si}_3\text{O}_{12} + \text{CO}_2$; and for kaolinite, $2\text{Al}_2\text{SiO}_5 + 5\text{H}_2\text{O} = 2\text{Al}(\text{OH})_3 + \text{H}_4\text{Al}_2\text{Si}_2\text{O}_9$. Analyses of transformation products have been reported by C. G. C. Bischof, P. von Jeremejeff, J. Roth, J. R. Blum, G. Grattarola, E. Hussak, J. Romberg, etc. M. Weibull showed that the so-called *vestanite* or *vestanite* is an altered andalusite. F. Slavik found pseudomorphs of chistolite after mica near Příbram.

A blue mineral from Botolphine, Scotland, was called by B. G. Sage¹¹ *talc bleu*, and later *beril feuilleté*. When the mineral is blue and transparent, and in large enough pieces, it can be used as a gem, and it then resembles sapphire. N. T. de Saussure, by a misreading of a label "sapphire," called it *sappare*. A. G. Werner designated it **cyanite** or rather *kyanite*—from *κυανός*, blue. R. J. Haüy called it *disthène*—from *δύς*, twice; and *αβείος*, strong—in allusion to the unequal hardness and electrical properties in two different directions. C. A. S. Hofmann called a white variety of cyanite *rhaetizite*—from Rhaetia, the ancient name of Pfitschthal where the mineral occurs.

Cyanite occurs principally in gneiss, mica slate, and crystalline schists. It does not occur as a pyrogenetic mineral in igneous rocks. Various occurrences and analyses¹² have been reported. The results agree with the formula $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$. The constitution has been discussed in connection with sillimanite. A. Daubrée thought that he had synthesized cyanite by the action of silicon tetrachloride on alumina at a red heat, but H. St. C. Deville showed that he was mistaken—*vide* sillimanite and andalusite. The colour is white, blue, grey, green, or black; the crystals may be blue along the centre of the blades, and the margins may be white. It may occur in transparent crystals which are usually long-bladed crystals; the crystals may also be coarsely bladed columnar, or subfibrous. The first measurements were made by R. J. Haüy. The angles were also measured by W. Phillips. Observations on the crystals have been also made by T. Liebisch, A. des Cloizeaux, J. Plücker and A. Beer, G. Cesaro, G. Rose, A. Böhm, etc. The crystals belong to the triclinic system, and M. Bauer's values for the axial ratios $a:b:c$ are $0.89912:1:0.69677$; $\alpha=90^\circ 23'$, $\beta=100^\circ 18'$, and $\gamma=106^\circ 1'$; G. vom Rath gave $0.89942:1:0.70898$, and $\alpha=90^\circ 5\frac{1}{2}'$, $\beta=101^\circ 2\frac{1}{4}'$, and $\gamma=105^\circ 44\frac{1}{4}'$. F. Rinne has

studied the **X-radiogram** of cyanite. The (100) **cleavage** is perfect, the (010) is less so, and the (011) imperfect. M. Bauer, and O. Mügge studied the **gliding planes** of the crystals. H. Traube, and T. L. Walker studied the **corrosion figures**; and E. S. Federoff, the orientation of the crystals. The **twinning** of the crystals is common; and the crystals may be so combined as to make right- or left-handed twins analogous to those of orthoclase; the twins may also occur in staurolite-like forms crossed at an angle of 60° . F. von Kobell studied the axial figures in twin crystals; he said that the right- and left-handed twins may be easily distinguished by means of the polariscope. In polarized light, they give a cross in an oblique position, but the principal optical section does not revolve with the revolution of the crystal. The colours with right- and left-handed twins change in different order with the revolution. The **optic axial angles** were found by A. des Cloizeaux to be $2H=101^\circ 6'$ and $2V=82^\circ 16'$ for red light. O. Korn gave for different samples $2H=99^\circ 18'-101^\circ 2' 30''$ for Li-light, and $98^\circ 55'-100^\circ 45'$ for Na-light. A. des Cloizeaux found that there is no perceptible change in the optic axial angle between 12° and 17.8° . A. Michel-Lévy and A. Lacroix made some observations on this subject.

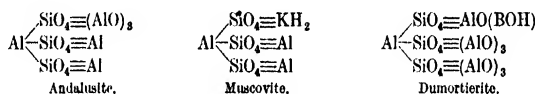

The **specific gravity** was found by F. Oswald¹³ to be 3.057; by G. C. Hoffmann, 3.6005; and by E. H. M. Beekman, 35.6-3.59 before calcination, and 3.236-3.240 after calcination. The **hardness** on the (100)-face parallel to the *c*-axis, 4-5; on the (100) face and parallel to the (100) (001)-edge, 6-7; and on the (010)-face, 7. R. Cusack gave 1090° for the **melting point** of cyanite; A. L. Fletcher, 1140° ; and A. Brun, 1190° - 1210° ; C. Doelter observed no fusion at 1340° , and gave 1370° - 1430° for the m.p. A. Brun stated that at 1310° there is a mol. change. W. Vernadsky found the mineral changed to sillimanite above 1300° , with the evolution of heat. E. S. Shepherd and G. A. Rankin found the change to be very slow, but more rapid than in the case of andalusite. Cyanite was decomposed after heating half an hour at 1500° , but no sillimanite could be detected. Similar remarks apply after 48 hrs. heating in calcium vanadate at 1000° . There was very little change in cyanite after being 7 days at 1150° , 2 days at 1000° , or 28 days at 900° . Similar remarks apply after heating cyanite 72 hrs. in the presence of sodium chloride at 800° . Under no condition tried could sillimanite be converted to cyanite. A. B. Peck, and N. L. Bowen and J. W. Greig say that cyanite changes to mullite, not sillimanite, at about 1350° . R. Lorenz and W. Herz studied the relation between the m.p. and the critical temp. A. des Cloizeaux obtained for the **index of refraction** with the red ray, $\beta=1.720$. E. Taubert gave for the *C*-, *D*-, and *F*-lines, $\alpha=1.7101, 1.7131$, and 1.7201 respectively; $\beta=1.7189, 1.7201$, and 1.7219 ; and $\gamma=1.7256, 1.7282$, and 1.7372 . E. Wülfing gave for the Na-light, $\alpha=1.7171-1.7124$; $\beta=1.7222$; and $\gamma=1.728-1.729$. For the **birefringence** $\gamma-\alpha=0.0119$; $\gamma-\beta=0.0068$; and $\beta-\alpha=0.0051$. Observations were also made by A. Michel-Lévy and A. Lacroix, and by O. Korn. The former gave $\alpha=1.712$; $\beta=1.720$; and $\gamma=1.723$; and $\gamma-\alpha=0.011$. E. Mallard and H. le Chatelier found at θ° between 0° and 300° , for the change in the double refraction $(225.7+4.68\lambda^{-2})(1+0.0000475\theta)\times 10^{-6}$; and between 300° and 600° , $(221+5.56\lambda^{-2})(1+0.0000744\theta)\times 10^{-6}$. The optical character is negative. Cyanite is feebly pleochroic; this is noticeable in strongly coloured crystals between colourless and blue. C. Doelter found that cyanite is almost transparent to **X-rays**; nor did he obtain any colour change by exposing the mineral to **cathode rays** or to **radium rays**. O. Mügge obtained no result with radium rays. J. Plücker investigated the **magnetic properties** of cyanite.

Cyanite is not decomposed by acids; hydrofluoric acid attacks it very slowly. The action of chlorine, hydrogen chloride, hydrofluoric acid, alkali hydroxides, boric oxide, etc., are indicated in connection with andalusite. K. Zulkowsky studied the action of fused sodium carbonate on cyanite; J. Lemberg noted that a soln. of sodium silicate at 200° - 210° forms a substance like analcite. F. Cornu said that the moistened powdered mineral gives a feeble alkaline reaction with litmus.

Cyanite does not decompose so readily as andalusite, and the transformation products, in nature, are potash-mica, tale, steatite, and pyrophyllite.

Z. Weyberg¹⁴ in his experiments on the action of fused barium chloride on china clay obtained besides the hexagonal crystals of $4\text{BaO} \cdot 4\text{Al}_2\text{O}_3 \cdot 7\text{SiO}_2$, isotropic irregular grains with the composition $2\text{Al}_2\text{O}_3 \cdot 15\text{SiO}_2$, or $\text{Al}_4\text{Si}_{15}\text{O}_{34}$.

The fibrous mineral **dumortierite** was discovered by F. Gonnard¹⁵ in 1881, and named after E. Dumortier. It was found embedded in the felspar in the gneiss blocks near Beaunant, France; and other localities have been reported by G. vom Rath, H. Traube, A. Michel-Lévy and A. Lacroix, R. B. Riggs, J. S. Diller and J. E. Whitfield, J. Romberg, E. Wittich, H. A. Weber, W. E. Ford, and A. Damour. In most of these cases analyses were also given, and the results of the earlier analyses agree with the formula $\text{Al}_9\text{Si}_3\text{O}_{18}$. W. E. Ford gave $\text{Al}_{20}\text{Si}_7\text{O}_{44}$, and he assumed that it is a basic orthosilicate, $(\text{AlO})_{16}\text{Al}_4(\text{SiO}_4)_7$, corresponding with heptaorthosilicic acid, $\text{H}_{28}\text{Si}_7\text{O}_{28}$. The later analyses show that up to about 6 per cent. of boric oxide may be present. W. T. Schaller then represented the composition of the boriferous mineral by $\text{HAl}(\text{AlO})_7(\text{BO})(\text{SiO}_4)_3$, i.e. **aluminium heptaluminy-boro-hydroxytriorthosilicate**, and that of the boron-free mineral—if such really exists—by $\text{HAl}(\text{AlO})_8(\text{SiO}_4)_3$, i.e. **aluminium octoaluminy-hydroxytriorthosilicate**. W. F. Clarke represents andalusite, muscovite, and dumortierite by the related formulæ:

In place of the bivalent BOH-group, W. T. Schaller introduced the two univalent radicles, BO and H. The mineral usually occurs in fibrous or columnar aggregates; rarely in distinct crystals. The colour is ultramarine-blue or greenish-blue—rarely colourless, white, or green. According to J. S. Diller and J. E. Whitfield, the axial ratios of the rhombic crystals $a:b:c=0.5317:1:-$; the prismatic angle approximates 56° . The (100) cleavage is distinct. A. Damour gave 3.36 for the sp. gr.; G. Lück, 3.22; and J. S. Diller and J. E. Whitfield, 3.265. The hardness is 7. The index of refraction is moderately high; A. Michel-Lévy and A. Lacroix gave $\beta=1.65$; and G. Linck, $\alpha=1.678$, $\beta=1.686$, and $\gamma=1.689$. The former gave for the birefringence $\gamma-\alpha=0.010$, and the latter, 0.011. The optical character is negative. The pleochroism is strong; α is deep ultramarine-blue; β , reddish-violet; and γ , colourless. It shows idiophanous figures analogous to those of andalusite. Observations on the optical properties were made by E. S. Larsen, E. Wittich and J. Kratzert, and E. Rimann.

The so-called *serendibite* is a dark bluish-green mineral occurring in triclinic crystals in the moonstone pits near Kandy, Ceylon. According to A. K. Coomaraswamy,¹⁶ its composition corresponds with $10(\text{Fe,Ca,Mg})\text{O} \cdot 5\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot \text{B}_2\text{O}_3$; its sp. gr. is 3.42; and hardness 7. The pleochroism ranges from pale yellowish-green to deep indigo-blue.

§ 35. Hydrated Aluminium Silicates—Clays

The hills are shadows, and they flow
From form to form and nothing stands;
They melt like mists, the solid lands
Like clouds they shape themselves and go.—T. HUTCHINSON (1889).

Rocks show striking differences in behaviour when exposed to the weather for long periods of time. Some remain hard and firm, others crumble and powder in a comparatively short time. Many ancient Egyptian and Grecian monuments show relatively slight symptoms of decay, whereas in many other countries buildings made from apparently similar rocks soon deteriorate, and are saved from disintegration only by continued renovation. Calcareous building stones decay comparatively quickly when exposed to the moist, acid vapours which prevail in the atmospheres of towns.¹

Felspar and felspathic rocks are rather susceptible to weathering agents. The mineral is rarely found pellucid and clear; it appears to be first attacked along the cleavage cracks. The felspar becomes turbid or opaque, due to the formation of innumerable particles of what appears, in some cases, to be white clay. When the change is advanced the felspar becomes friable. A granitic rock with its constituents originally bonded by the felspathic matrix, may thus disintegrate and leave behind the clay mixed with the more resistant varieties of mica, quartz, and other minerals which originally formed the granitic rock. It is, however, probable that the product of the weathering of these rocks is not always kaolinite or clayite.

In the extraction of china clay, the products² formed by the weathering of the less ferruginous granitic rocks are leached from the sides of the mine by streams of water. The velocity of the stream of water carrying the clay, mica, quartz, etc., in suspension is allowed to slow down gradually whereby all the coarser particles of sand and mica settle. The fine-grained clay, together with a very small amount of fine-grained mica and quartz, is allowed to settle in suitable pits; part of the water is syphoned off; part is removed by evaporation; and the clay is finally dried in suitable kilns. The water may also be removed by filter press; by electrical deposition on the anode of a suitable electrical cell; by centrifuge; etc. The product is known as **china clay** and is sometimes called **kaolin**—generally outside the industry. The disintegrated granite from which china clay is washed is called **china clay rock**; a crystalline form of china clay is called **kaolinite**, and non-crystalline particles are called **clayite**—the chief impurities are very fine-grained particles of mica, and quartz. Analysis of the purer varieties approximate to $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. Many of the impurities in the commoner clays can be removed by washing. Some of the "iron" in some clays cannot be removed in this way, and Y. Ichikawa claimed to have removed it by the action of chlorine on the clay at 100°–110°. Chlorine attacks metallic iron or ferric oxide plus charcoal at this temp., but not iron oxide without the carbon. The process though costly is sometimes effective, sometimes not. The same remark applies to other modes of purification—*vide infra*. A more or less decomposed form of granite is called *Cornish stone*, which contains more or less undecomposed felspar, and it is graded for the market according to the stage of weathering—*purple stone* is hardest,

least weathered, and the most fusible; *dry white and buff stones* are most weathered, softest, and least fusible; while *mild purple* represents an intermediate stage of weathering. The Cornish stone is ground to powder and used as a flux in the manufacture of pottery.

D. G. de Dolomieu³ said the rock in which the change is in progress is affected by *la maladie du granat*. The action is extremely slow, but nature is in no hurry. While the decomposition of silicates by weathering furnishes colloidal silica—opal, the weathering of the aluminosilicates furnishes colloidal clay—clayite. There are many intermediate products of the decomposition. The transformation of felspar to china clay in nature was recognized by J. B. L. Romé de l'Isle as early as 1783, by A. G. Werner in 1791, and by R. J. Haüy in 1801. The last-named called the china clay *feldspath décomposé*. The plagioclase felspars highest in lime are attacked most readily, orthoclase is more resistant. Both E. Mitscherlich,⁴ and C. G. C. Bischof have remarked that when soda- and potash-felspars are together present, the former is frequently found decomposed and friable when the latter is but slightly affected.

The mechanical disintegration⁵ of rocks by the alternate freezing and thawing of water in fissures and cracks; and the crazing of the surface by the diurnal variations of temp.—as illustrated by the fact that some buildings show most signs of weathering on the sunny and not the shady side—facilitate the weathering of rocks by bringing fresh surfaces into contact with the agents which produce chemical changes; mainly water carrying various agents in soln.—carbon dioxide, oxygen, organic acids, hydrogen sulphide, and sulphuric acid. The products of the chemical decomposition of rocks are very varied; but with felspathic and related rocks, the hydrated aluminium silicates, known as clays, are produced. Among the clays, the so-called kaolin or china clay is perhaps the most important. Consequently, the conversion of felspar and related rocks into clay, by weathering, is sometimes called the *kaolinization* of these rocks.

Kaolin or china clay is not to be regarded as a primary mineral, as M. H. Klaproth⁶ assumed, but is always a secondary product formed by the chemical decomposition of other rocks. J. Hawkins⁷ even suggested that china clay rock is the original or parent rock; granite the derivative. He maintained that the lapidifying influence has acted from below upwards. The arguments are quite inadequate. J. Fournet's⁸ ideas are difficult to understand; he suggested that those minerals which at the time of their formation have a tendency to crystallize in two different forms, are least stable, and rocks containing such minerals readily decompose. The felspar was supposed to be partly kaolinized during the cooling of the granitic magma, and more complete decomposition was supposed to be induced by local electric currents set up by contact with rocks of different kinds. Following up a suggestion by A. F. Gehlen,⁹ A. Brongniart and J. Malaguti, in 1841, attributed the kaolinization of felspathic rocks to a kind of electrolysis because they were able to decompose felspar by passing an electric current through water holding ground felspar in suspension. A. S. Cushman and J. Hubbard's process for the extraction of the alkali from potash-felspar is based on the same reaction.

There are three recognized hypotheses on the kaolinization of felspar all of which have given rise to much discussion. For example, H. Rösler¹⁰ maintains that the china clay of Halle, and indeed all clays, are produced by the operation of thermal waters with their gaseous emanations; E. Wüst considers that the Halle clay has been produced by the action of humus acids; and V. Selle ascribes the kaolinization of the Halle clay to the chemical activity of water containing carbonic acid.

1. *Volcanic gases and vapours, or pneumatolytic actions*—from *πνευματικός*, air or gas; *λύνειν*, to loosen. G. Forchhammer¹¹ showed the possibility of the formation of clay by the action of water-vapour at a high pressure upon felspar. This view was generally adopted by L. von Buch, F. H. Butler and J. H. Collins, who emphasized the effects of fluorides and borates in the vapours of fumaroles. The assumption that the clay in Cornwall has been in many cases formed by pneumatolytic action, from below upwards, is supported by the facts: (i) the

deep-seated disintegrated granite or china-clay rock—extending sometimes over 600 ft.—is often most affected in the lower parts of the bed, and tongues of clay pass upwards into granite much less affected; (ii) boriferous and fluoriferous minerals—tourmaline, topaz, and fluoro-apatite are common in the clay localities; and (iii) the quartz grains are etched¹² or altered into rounded grains owing to the attack by the acidic vapours. J. H. Collins found that vapours of hydrofluoric acid acting on felspar produced a white amorphous powder which has some analogies with clay; and he further noticed that potash-felspar was more susceptible to attack than soda-felspar, or soda-lime-felspar. Some investigators¹³ have perhaps over-emphasized the action of fumarole discharges from below upwards, and assumed that all china clay has been so produced. A summary of the available evidence shows that the kaolinization of feldspathic rocks may also proceed by surface weathering acting from above downwards. According to this interpretation, the rotting or weathering of the rock will gradually diminish downwards until finally fresh rock is reached. The surface weathering of some of the rocks in South Brazil and in the Transvaal is considered deeper than usual,¹⁴ and here it extends downwards about 200 ft. Again, according to H. Ries,¹⁵ the Brandywine Summit clay deposits were worked for a number of years, and abandoned when the surface clay gave out; the mine was afterwards worked for the felspar lower down. Presumably, the surface layers of felspar had been kaolinized. According to H. Ries, all the beds of china clay hitherto exploited in the United States have been formed by surface weathering from above downwards.

2. *The action of surface waters charged with carbon dioxide.* Numerous observers¹⁶ have demonstrated the decomposition of felspar, mica, and related minerals by the action of water, and particularly water charged with carbon dioxide. W. P. Hadden, for instance, said that water holding carbon dioxide in soln. is nearly nine times as active as distilled water when in contact with felspar (*q.v.*). Water can work its way into the body of granite rocks through pores and cleavage cracks; for, according to C. R. van Hise,¹⁷ granite rocks have a porosity of 0.2–0.5 per cent. According to C. G. C. Bischof, one of the springs in the vicinity of Lake Leach (Germany) discharged nearly 176,000 lbs. of water carrying 0.13 per cent. of sodium carbonate in 24 hrs.; assuming that the sodium in felspar is converted into soluble sodium carbonate, this would represent the decomposition of nearly 18,000 lbs. of soda-felspar per annum. A few centuries would thus suffice to decompose enormous masses of granitic rock. It does seem curious to find a dil. soln. of carbon dioxide has sufficient chemical strength to decompose a combination like felspar which is fairly resistant to the most powerful mineral acids; but H. Rose¹⁸ pointed out, in 1842, the enormous quantities of carbonic acid which are brought into contact with the rock make up for its deficiency in chemical strength. According to L. von Struve and H. Müller,¹⁹ carbon dioxide under compression is more active than it is at ordinary press. A. Stahl²⁰ considers that the clay deposits of Passau, Mederschlesien, and Odenwald have been formed from gneiss rocks by the action of the carbon dioxide. The china clay at Auvergne (France) is supposed to have been formed in this way; W. S. Bayley found the china clay in the Piedmont Plateau, North Carolina, gradually merges downwards into felspar. The effect of carbonated waters can be easily over-estimated, in contrast with the action of organic acids which are probably more powerful than carbonic acid. I. Ginsberg,²¹ however, claims that the formation of china clay by the action of organic acids in natural waters has not been demonstrated. H. Strenme²² considers that the efficiency of all the different weathering agents is really due to the chemical activity of aq. soln. of carbonic acid—cold or hot; and K. Endell has shown that the acidity of moor-waters is largely due to the carbonic acid they contain.

E. Mitscherlich²³ suggested that the pyrites occurring in carboniferous strata is oxidized by the percolating water holding oxygen in soln. Sulphuric acid is formed. This decomposes the underlying feldspathic rocks into kaolin, and other

products. Since most china clay beds do not occur in the vicinity of carboniferous strata, the hypothesis is inadequate. According to R. Bunsen, aq. soln. of hydrogen sulphide, derived from neighbouring sulphide ores, can kaolinize feldspathic rocks more vigorously than soln. of carbon dioxide. There is a little evidence to show that dil. soln. of sulphuric acid derived from the oxidation of neighbouring sulphide ores, can kaolinize feldspathic rocks.

3. *The action of water draining from peat bogs, etc., containing organic acids in solution.*—According to E. Wüst,²⁴ and V. P. Smirnkoff, organic acids—humic and crenic acids—derived from vegetable matter have a far greater corrosive action on minerals than has carbonic acid. Water is the agent which brings the acid in contact with the rocks. The drainage from bogs and peat beds, water percolating through soils, river and other surface waters, carry in soln. ammoniacal salts and organic acids—humic, oxyhumic, crenic, apocrenic, and other acids. E. Wüst claims that humic acid is the important agent in the kaolinization of feldspathic rocks; and A. Stahl²⁵ has shown that the majority of the deposits of china clay in Germany—Saxony, Thuringia, Silesia, etc.—occur near beds of lignite—*Braunkohle*—and in many cases underneath these beds. The drainage-water—*Moorwasser*—from the bogs, peat, and lignite has presumably been the active agent in the kaolinization of the underlying rocks. The china clays which have been formed in this way are usually more pure and more free from ferruginous impurities than clays formed in other ways, because, as F. Senft has pointed out, organic acids have a solvent action on these impurities.

According to K. D. Glinka, it is very probable that the products obtained by the weathering under different conditions are not the same.²⁶ There are also many hydrated aluminium silicates—such as pyrophyllite, $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O}$; halloysite, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 4\text{H}_2\text{O}$; etc.—whose mode of formation has not been made clear. In tropical and subtropical regions—India, Malabar, Surinam, Seychelle Islands, Hawaiian Islands, Madagascar, British Guiana, etc.—the chemical action seems to proceed further than in temperate zones. The silicates are more thoroughly decomposed, and lateritic earth, and gibbsite are produced. Laterite appears to be a variable mixture of ferric and aluminium hydroxides with free silica.²⁷ E. E. Schmid, and H. Herold consider kaolinite to be the end-product of the change, and the former designates the intermediate products as α , β , γ , and δ -kaolins: thus he said that α -kaolin is $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; β -kaolin, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 1\frac{1}{2}\text{H}_2\text{O}$; γ -kaolin, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot \text{H}_2\text{O}$; and δ -kaolin, $\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. H. Rösler, however, considers that E. E. Schmid was working with mixtures, and not with chemical individuals. J. M. van Bemmelen determined the ratio Al_2O_3 : SiO_2 dissolved when clays are treated with acids, and from the results inferred that clays produced by ordinary weathering are probably hydrogels with the ratio 1 : 3–5; those formed by kaolinitic weathering, have the ratio 1 : 1–2; and in lateritic weathering free gibbsite is formed as indicated by R. Lenz. M. Bauer obtained similar results. As shown below, it is doubtful if the solubility test is of much value.

The transformation of feldspar into kaolin or china clay is usually symbolized: $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 + 2\text{H}_2\text{O} + \text{CO}_2 = \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O} + 4\text{SiO}_2 + \text{K}_2\text{CO}_3$; after representing the action by an equation eq. to $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 + n\text{H}_2\text{O} = \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O} + \text{K}_2\text{SiO}_3 + 3\text{SiO}_2 \cdot n\text{H}_2\text{O}$, G. Forchhammer said: "It is highly probable that the second product of the decomposition, water-glass, will be found somewhere in nature," and he succeeded in establishing the existence of this salt in the water of the geysers in Iceland. The bases and soluble silicic acid derived from the decomposition of feldspathic rocks are partially retained by the soil and partially washed into the sea. The formation of gibbsite or laterite has been symbolized in an analogous manner. The formation of *sericitic mica*, $\text{K}_2\text{O} \cdot 3\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, a common intermediate product of the conversion of feldspar into kaolin, is symbolized: $3(\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2) + 2\text{H}_2\text{O} + 2\text{CO}_2 = \text{K}_2\text{O} \cdot 3\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 2\text{H}_2\text{O} + 12\text{SiO}_2 + 2\text{K}_2\text{CO}_3$. W. W. Hutchings,²⁸ for instance, inferred that the *sericitic mica* in some fireclays was produced from the decomposition of the feldspar. The experiments of

A. E. Tucker on the action of carbonated water on felspar resulted in the formation of white scaly crystals. Magnesium and iron salts may also take part in the degradation of felspar forming biotite, epidote, etc.

The clay may be leached by natural streams of water from the place where it was formed, transported from the hills, and deposited at lower levels where the velocity of the stream slackens down. All kinds of *débris* from the rocks and soils, etc., over which the clays are carried may be transported along with the clay. Hence, many clays are the washings and sweepings of the hills which Nature has accumulated as her rubbish-heaps in convenient places. Transported clays are usually, but not always, less pure than the residual clays. The term *clay* is applied industrially to a fine-grained mixture of various minerals which has these qualities: (i) It is plastic enough to be moulded when it is wet; (ii) It retains its shape when dried in spite of a certain amount of contraction; and (iii) when the moulded mass is heated to a high enough temp. it sinters together, forming a hard coherent mass without losing its original contour. These properties have given clays an important place—probably third or fourth—in the world's industries. Clays are used in the manufacture of building bricks, tiles, firebricks, crucibles, gas retorts, sanitary goods, pottery, etc. China clay is also extensively employed for filling paper, cotton, etc. It is used in making white paints, alum, ultramarine, wall-plasters, etc.; and it appears as an ingredient in some pharmaceutical preparations. The agriculturalist's definition of clay is quite different from that employed in ceramics, because he arbitrarily selects from a mixture of grains of various sizes a particular fraction and calls it clay. Some of the definitions would apply equally well to pulverulent coal, cocoa, and clay.

The discovery of china clay in Europe is usually considered to date from the beginning of the eighteenth century when J. F. Böttger²⁹ made porcelain in imitation of that brought to Europe from China by Eastern traders. It is said that J. F. Böttger had acquired a good knowledge of the properties of clays in making crucibles for his alchemical experiments; and that he wanted only a white burning clay to produce the desired result. With the coloured clays then available, he made red stoneware or a vitreous body known as *Böttger's red porcelain*. He is said to have accidentally discovered the white clay which he desired at Aue near Schneeberg. This white clay is now known as porcelain clay, china clay, or *kaolin*. The term "kaolin" is said to be a corruption of the Chinese *kao*, high; and *ling*, hill, in allusion to the Kaoling Mt., North China, whence much of the clay used by the Chinese for the manufacture of porcelain was obtained. As a matter of fact, the white clays were known in Europe long before J. F. Böttger's time, and E. W. von Tschirnhausen, before J. F. Böttger, made experiments with the white clays, and came very near to the discovery of porcelain. H. Peters, indeed, claimed that E. W. von Tschirnhausen actually made porcelain before J. F. Böttger, but E. Zimmermann showed that H. Peters was probably mistaken, and that the first porcelain was made by J. F. Böttger in 1709, a year after the death of E. W. von Tschirnhausen.

In early days, a white clay from the islands of Lemnos and Samos was known in Europe as *Diana's earth*, and *terra sigillata*, and used as a medicine. The beneficent virtues of this *edible clay* were extolled by Homer, and Herodotus. The *Lemnian earth* was mentioned by Theophrastus, and Dioscorides; and Pliny confused the *terra sigillata*, which he called *sphragis*, with the *Lemnian red earth* used as a pigment. The edible clay occurred in the Lemnian hills, and the mine, so to speak, was in charge of the priests of Diana. They alone had the right of access to the mine. A supply of clay was extracted once a year as a solemn religious ceremony. The temple priests mixed the clay with the blood of goats, moulded it into pastils, and impressed the slabs with the sacred symbol of Diana. In the Middle Ages, the edible clay was obtained from other localities, and the tabloids were stamped with various symbols and legends. The earth was used as a panacea against all kinds of diseases. Copies of the different stamps which were employed in the

marketing of *terra sigillata* will be found in D. C. G. Ludwig's *Terræ musei regii Dresdensis* (Lipsie, 1749). Through some confusion, the red *Samian pottery* of the Romans has been called *terra sigillata*—e.g. F. Oswald and T. D. Davis, *An Introduction to the Study of Terra Sigillata* (New York, 1920); and many others. M. B. Valentini, J. J. Wagner, A. Bertold, J. T. Schenck, J. Montanus, J. G. Geilfusius, L. F. Jacobi, D. Richter, and G. A. Volkmann wrote memoirs on the *terra sigillata*. C. Gesner, J. R. Speilmann, A. Baumé, and several others wrote monographs about clays before the eighteenth century. Clay was also in use by the Chinese, about 536 A.D., as a therapeutic agent; and edible clays have been discussed by E. G. Love, C. Schmidt, C. W. C. Fuchs, C. Hebbelung, M. M. P. Muir, etc.

B. Palissy experimented with *terra sigillata* for pottery purposes before J. F. Böttger's work, but there is no evidence that he made porcelain. Had he been looking for porcelain, however, he would probably have found it because it is scarcely conceivable that some of his trial mixtures were not adapted for the work; but they were probably rejected as over-fired. In the official deed providing for the manufacture of porcelain at Meissen, reproduced by E. Zimmermann, it is specified that the ware is to be made *von sogenannter Terra Sigillata*. The discovery of a white clay at Allençon, France, in 1758, enabled J. E. Guettard, and B. Lauraguais to make porcelain; and the subsequent discovery of a deposit of this clay at St. Yriex, Limoges, by M. H. Vilaris, in 1766–68, led to the manufacture of porcelain at Sévres and elsewhere. Likewise also the discovery of china clay in Cornwall, by W. Cookworthy, enabled him in 1768 to apply for a patent for the manufacture of porcelain, and this resulted in factories being started at Plymouth and Bristol. The manufacture of hard porcelain, for some reason or other, has never flourished in England.

The term *bole*—from βῆλος, a clod of earth—is applied to a number of clay-like earths used medicinally. The more common varieties occur in yellowish-brown masses, with a greasy feel, and crumble to powder when placed in water. The composition of boles from different localities is very variable; the silica, for example, may range from 20.65 per cent. C. F. Rammelsberg gave a number of analyses. The red earth of Lemnos was probably a bole. It is alluded to by Theophrastus, Dioscorides, and Pliny. D. L. G. Karsten called a variety *sphragit*, and E. F. Glocker, *sphragulite*. The *oropion* of E. F. Glocker is a dark brown or black bole, and the *Bergschiefe* of A. G. Werner from Olkutsch, Poland. The colour is due to the presence of some bituminous matters. *Oropion* was analyzed by C. F. Bucholz. A. Breithaupt's *ochran* is a yellow bole from Oranitzka of sp. gr. 2.4–2.5. It was analyzed by C. M. Kersten. E. Löwenstein measured the vap. press. of a number of boles. The red clay referred to by Theophrastus as σινωφίς, by Pliny as *sinopsis*, by M. H. Klaproth as *sinopische Erde*, and by J. F. L. Hausmann as *sinopite*, is a bole. A honey-yellow clay from Amberg, Bavaria, etc., was called by E. F. Glocker *melinite*—from μέλι, honey; and a variety from Vierzon, France, was called *vierzonite*. It appears to be the *Gelberde* referred to by C. A. S. Hofmann. Melinite was analyzed by O. B. Kühn; and analyses of boles were reported by C. C. von Leonhard, H. W. F. Wackenroder, E. Zellner, etc. P. Dwojtschenko obtained a mineral resembling kaolinite from Aluschtsa, Krim, and it was called *aluschlite*.

The old German term *Steinmark*—from *Mark*, marrow—was applied by G. Agricola³⁰ to a firm compact clay occurring in fissures in rocks, was likened to marrow in bones. The same kind of clay was called *lithomarge*—from λίθος, stone; and *marga*, marl—and A. Breithaupt called it *lithocolla*—from λίθος, stone; and κόλλα, glue or cement. J. G. Wallerius called it *leucoargilla*, as well as *marga porcellana*; and A. Croustedt, *terra porcellana*. The general properties of these varieties of clay resemble those of compact, more or less indurated, kaolinite. J. F. L. Hausmann called the hard compact china clay *Steinmark*, and the friable clay *porcelain earth*. The older mineralogists seem to have regarded this variety of clay as a magnesian earth or an earth allied to talc. A. G. Werner, for instance, said it was a *Talkerde* composed of scaly particles. C. A. S. Hofmann, and D. L. G. Karsten also called it *earthy talc*; and R. J. Haüy, *talc granuleux*. A green *lithomarge* from Oravice, coloured with ferrous oxide, was called by A. Breithaupt³¹ *oravizite*. A little zinc oxide is sometimes present. The sp. gr. may rise to about 3.1. C. M. Kersten, H. Naschold, M. H. Klaproth, and A. Frenzel analyzed a white or reddish-white variety from Rochlitz, Saxony, called by J. C. Freiesleben *Falksteinmark*; it had a sp. gr. 2.488–2.505; A. Breithaupt called it *myelin*—from μυελός, marrow—and a *flesh-red* variety with a sp. gr. 2.543 was called *carnat*—from *carnis*, flesh. Analyses show that these

substances are varieties of clay associated with more or less iron oxides, in place of alumina. A lavender-blue, grey, or dark red earth was called by A. Breithaupt³⁴ *Eisensteinmark*. It appears to be the old *sächsische Wandererde* of D. Richter, and J. E. de Schütz; it was called *teratolite*—from *répas*, wonder—by E. F. Glocker. It was analyzed by J. C. Freiesleben, who found that about 12 per cent. of alumina was replaced by ferric oxide. A. Knop, and A. Frenzel described the clay, and H. Fischer, the crystalline structure.

W. A. Ross³⁵ described a yellowish-white mineral obtained from Simla, India, which appeared like meerschäum, and had an earthy or conchoidal fracture. He called it *meerschaluminite*; and A. Schrauf, *simlaite*. Its sp. gr. is 1.5–2.0. N. S. Maskelyne and W. Flight analyzed it and found the composition: $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 4\text{H}_2\text{O} + \text{H}_2\text{SiO}_3$. The white or grey clay from the diaspore rocks at Dilln, Hungary, was called *dillnite* by A. Hutzelmänn.³⁴ It has an earthy or conchoidal fracture; its sp. gr. is 2.574–2.835. Analyses by A. Hutzelmänn, and J. L. Smith agree with $4\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 9\text{H}_2\text{O}$. W. Haidinger thought it to be a mixture of diaspore and clay. M. H. Klaproth's *Bildstein* is regarded as a mixture of dillnite and aluminium hydroxide. G. Ulrich³⁶ described silver-white, or greenish *talcosite* as a mineral resembling talc occurring in the selwynite of Heathcote, Victoria. Its sp. gr. is 2.46–2.50, and the hardness over 1. Its composition approximates $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$. P. Termier³⁶ described vermiculitic aggregates of a related mineral which he obtained from St. Etienne, France, etc., and called *levernite*—*vide infra*. C. F. Rammelsberg³⁷ described a straw-yellow clay from Schlackenwald, Bohemia, which he called *carpolite*. The composition approximated $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, with some alumina replaced by ferric and manganese oxides. The sp. gr. was 2.935. T. Thomson described a brownish-red earth from Antrim, Ireland, which he called *plinthite*. Its composition approximated $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 6\text{H}_2\text{O}$, with up to half the alumina replaced by ferric oxide. M. F. Heddle analyzed a sample from Skye. A soft rose-red earth from the same locality was called by T. Thomson *rhodolite*.

A very large number of analyses of china clay have been published,³⁸ and analyses are made every day. From the very way in which clays have been formed in nature it might be anticipated that they are particularly liable to be contaminated with impurities. Even supposing the clay in china-clay rock to be fairly pure, its subsequent transport by currents of water may be attended by the introduction of *débris* carried by other streams. Thus, there are arenaceous clays, calcareous clays, micaceous clays, ferruginous clays, felspathic clays, etc. The analyses in Table XVII will give an idea of the composition of some clays used in the manufac-

TABLE XVII.—THE COMPOSITION OF SOME CLAYS.

	Stourbridge siliceous clay.	Ruabon clay.	Leeds clay.	Devon clay.	Kingswinford clay.	Kilwinning clay.
SiO_2	80.86	72.46	67.24	62.24	54.86	41.44
TiO_2	1.00	1.31	1.00	1.90	1.42	1.56
Al_2O_3	11.92	17.28	20.45	25.56	29.01	33.71
Fe_2O_3	0.81	0.77	2.19	0.94	1.70	1.87
MgO	0.11	0.36	0.27	0.16	0.40	0.19
CaO	0.10	0.26	0.18	0.24	0.24	0.44
K_2O	0.32	1.74	0.90	3.74	0.78	0.40
Na_2O	0.40	0.48	0.30	0.58	0.48	0.26
Loss on ignition	4.40	5.30	7.40	5.80	10.87	20.60
Refractoriness	1660°	1650°	1660°	1690°	1710°	1770°

ture of firebricks. The refractoriness refers to the squatting temp. A. Brongniart and J. Malaguti gave $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 4\text{H}_2\text{O}$ for the best representative value of the composition of the ideal clay base; L. F. Bley, $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$; J. N. von Fuchs, $4\text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 12\text{H}_2\text{O}$; R. Fresenius, $\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; and G. Forchhammer, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. The last result is the generally accepted formula. It is in close agreement with the analysis of the purer types of china clay, and with analyses of crystalline kaolinite. Assuming that this hydrate occurs in all true clays, and is the cause of their plasticity, A. Brongniart and J. Malaguti called it *le véritable argile*; and F. Senft called it *Thonsubstanz* or *clay substance*, a term much in use for the clayite or kaolinite in clays. The method of estimating the amount

of clay substance in clays by finding the amount soluble in hot conc. sulphuric acid was shown by J. W. Mellor to be fallacious. H. le Chatelier assumed that halloysite is the clay-base in some clays, montmorillonite in others; and J. W. Gregory, and D. P. McDonald assumed a halloysitic base in Glenboig clay.

Attempts have been made to find the constitution of china clay by observations on the effects of acids, alkalis, and heat. S. J. Thugutt³⁹ stated that one-third of the alumina is more rapidly dissolved by hot sulphuric acid than the other two-thirds. J. H. Collins said that half the alumina is dissolved relatively quickly by hot sulphuric acid, and the other half slowly. The retardation of the reaction is partly due to the formation of a protective layer of silica over the unattacked cores of the granules. There is nothing to show that the rate of decomposition and dissolution differ from those of other heterogeneous reactions. According to A. Brongniart and J. Malaguti, and C. F. Rammelsberg, aq. soln. of potassium hydroxide extract a quarter of the silica from kaolinite. The kaolinite was probably impure because P. Berthier showed that caustic alkalis scarcely attack the fired or unfired clay. The action is really determined by the conc. of the soln. and the temp. since J. Lemberg showed that by digesting china clay with aq. soln. of alkali silicates, hydroxides, or carbonates, natrolite, $K_2O \cdot Al_2O_3 \cdot 3SiO_2 \cdot 3H_2O$, is formed. The action is represented, $3(Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O) + 6KOH \rightarrow 2(K_2O \cdot Al_2O_3 \cdot 3SiO_2 \cdot 3H_2O) + 3H_2O + K_2O \cdot Al_2O_3$. This led R. Brauns to assume that the molecule of kaolinite should be symbolized $2(Al_2O_3 \cdot SiO_2 \cdot 3H_2O) \cdot Al_2O_3 \cdot 3SiO_2$. If the argument were valid, the action of chlorine on potassium hydroxide: $3Cl_2 + 6KOH \rightarrow 5KCl + KClO_3 + 3H_2O$, might be cited as evidence for a more complex formula for potassium hydroxide. However, the original experiment, if modified a little, gives quite a different result. There is no worthy evidence that the aluminium atoms of kaolinite have different characteristics; a similar remark applies to the silicon atoms. W. Vernadsky assumed that the water in kaolinite is held half by the alumina and half by the silica; only that held by the alumina is driven off at low redness leaving a partially dehydrated molecule which is readily decomposed by hydrochloric acid — *vide infra*. As a matter of fact, no reliable evidence justifying this conclusion is available. All the water can be driven from kaolinite below redness. The action is slow at low temp., more rapid at high temp. It will be shown later on that there is no evidence of two breaks in the dehydration curve, and both the molecules of contained water behave similarly.

Until suitable evidence is forthcoming, undue emphasis should not be placed on constitutional formulæ which assume dissymmetrical atoms like R. Brauns' formula, $H_2(AlOH)_2Si_2O_7$; or the metasilicate formula, $HO \cdot Al(HSiO_3) \cdot SiO_3 \cdot Al(OH)_2$. P. Groth's formula is $\{Al(HO)_2\}_2Si_2O_6$, or $\{SiO \cdot O \cdot Al(OH)_2\}_2O$; R. Scharizer's $O\{Si(OH)_2 \cdot O \cdot Al : O\}_2$ or $O(Al : SiO_4 = H_2)_2$; K. von Haushofer's, W. Pukall's, and F. Hundeshagen's $O(HO \cdot Si = O_2 = AlOH)_2$; and C. Simmonds's $(HO \cdot O)_2Si : Si(O \cdot O \cdot AlOH)_2$. H. C. McNeil, K. D. Glinka, Y. V. Samoiloff, W. and D. Asch, and W. Vernadsky have also recommended formulæ for kaolinite. F. W. Clarke emphasized the relation between kaolinite and muscovite, and between kaolinite and felspar by means of the graphic formulæ:

With these and other possibilities, the choice is largely a matter of temperament; but if there be any weight in (i) the continuity in the rates of dissolution of kaolinite by acids and alkalis; and (ii) the continuity in the rate of decomposition at different temp., the aluminium and hydroxyl groups are symmetrically placed in the molecule, and P. Groth's formula is preferable. This may be written as a **dialumino-disilicic acid**, the so-called *kaolinic acid*:

in harmony with F. Ullfers's idea that kaolinite is derived from an hypothetical *anhydrid der Tonerde-monokieselsäure*, $\text{Al}(\text{OH}).\text{O.SiO.O}$. . ., by analogy with chromomonoxalic acid. B. Kosmann regarded kaolinite as one member of a family of aluminium silicates which he represented $\text{Al}_2\text{O}_3.\text{SiO}_2$; $\text{Al}_2\text{O}_3.\text{Si}_2\text{O}_4$; and $\text{Al}_2\text{O}_3.\text{Si}_3\text{O}_6$, in which part of the silica may be hydrated. In the case of kaolinite he wrote $\text{Al}_2\text{O.Si}_2\text{O}_4(\text{OH})_4$.

R. Schwarz and A. Brenner⁴⁰ studied the action of sodium silicate on soln. of aluminium chloride. The precipitates were filtered off, dried in a steam-oven, and washed successively with water, alcohol, and ether. The influence of conc. was such that the mol. ratio of silica to aluminium hydroxide diminished with increasing dilution, but was always slightly in excess of the proportion, 1.5:1, thus showing that silica was invariably adsorbed by the primary product, $2\text{Al}_2\text{O}_3.3\text{SiO}_2$. The proportion of silica in the precipitate increased with increasing conc. of sodium silicate, although the latter never entered quantitatively into the reaction; when 6–10 mol. proportions of silicic acid were present, a compound corresponding in composition with natural kaolinite, $\text{Al}_2\text{O}_3.2\text{SiO}_2.2\text{H}_2\text{O}$, was invariably produced. Normal *aluminium metasilicate*, $\text{Al}_2(\text{SiO}_3)_3$, appears incapable of existence. The primary product of the action is the compound, $2\text{Al}_2\text{O}_3.3\text{SiO}_2.n\text{H}_2\text{O}$, which absorbs silicic acid when left in contact with the soln. and tends to pass into the compound, $\text{Al}_2\text{O}_3.2\text{SiO}_2.2\text{H}_2\text{O}$. If the precipitate is heated in contact with the soln., the substance $\text{Al}_2\text{O}_3.2\text{SiO}_2.2\text{H}_2\text{O}$ (after desiccation at 110°) is obtained. X-radiograms of the products show that the primary compound, $2\text{Al}_2\text{O}_3.3\text{SiO}_2.6\text{H}_2\text{O}$, is amorphous, and that from it there is formed in course of time a crystalline material, $\text{Al}_2\text{O}_3.2\text{SiO}_2.2\text{H}_2\text{O}$, which is similar or closely related to natural kaolin in structure. The natural product loses its two molar proportions of water continuously above 360° , and becomes anhydrous at 640° . The artificial material loses one molar proportion below 260° , and the second proportion between 360° and 640° . It appears that in the neutral ternary system, $\text{Al}_2\text{O}_3\text{--SiO}_2\text{--H}_2\text{O}$, a single compound, $\text{Al}_2\text{O}_3.2\text{SiO}_2.n\text{H}_2\text{O}$, is capable of formation, and it is uninfluenced by the presence of an excess of silica, or by the period of the reaction; this compound is formed with particular readiness when at least six mols of silica are present for each mol of aluminium oxide.

The hydrated aluminium silicates resembling kaolinite behave very like acids in many reactions, for, as P. A. Schemjatschensky⁴¹ showed, the hydrogen is partly or wholly replaceable by a metal. Again, when fused with alkali carbonates, kaolinite displaces carbonic anhydride, and probably forms aluminosilicates soluble in a large excess of water. Kaolinite gives off hydrogen sulphide when heated with many sulphides; it displaces sulphuric anhydride from sulphates; and A. Gorgeu showed that it reacts in a similar manner with chlorides, bromides, and iodides. Z. Weyberg found that by the prolonged fusion of a mixture of kaolinite, and potassium carbonate or chloride, the silicate $\text{K}_2\text{O.Al}_2\text{O}_3.2\text{SiO}_2$ is formed; and with potassium dichromate at a low temp., $\text{K}_2\text{O.Al}_2\text{O}_3.2\text{SiO}_2$ is produced, but at a high temp. $\text{K}_2\text{O.Al}_2\text{O}_3.\text{SiO}_2$ is formed. He also found that when fused with barium or strontium chloride a product $4\text{RO}.4\text{Al}_2\text{O}_3.7\text{SiO}_2$ is formed. The work of J. Lemberg, H. P. Armsby, E. C. Sullivan, etc., shows that the salts of aluminosilicic acids resemble the salts of the ordinary acids in that the bases can be interchanged in accord with the laws of mass action—*vide* zeolites.

If china clay, free from soluble salts, be boiled with distilled water and allowed to stand 24 hrs., extremely fine particles of solid remain in suspension, and pass through porous earthenware filters. It is not possible to separate this suspended matter by settling; but it can be sedimented by the addition of lime-water or sodium chloride. The addition of the salt causes the fine particles of clay to aggregate or flocculate into masses which settle rapidly. The finest particles are invisible

under a $\frac{1}{12}$ th objective. The suspended matter from china clay can also be isolated by evaporation, when a pale brown mass is produced; that from ball-clay is dark brown. Like gluc, the mass shrinks enormously when dried, and furnishes a horny mass which adheres tenaciously to the tongue. The gluc-like mass was termed by T. Schloesing⁴² *argile colloïdale*, or *colloidal clay*. When wetted, the colloidal clay swells enormously, furnishing a sticky plastic mass. Only about 0.50 per cent. was obtained from china clay. This amount probably represents a small fraction of the colloidal clay which is present. The colloidal non-crystalline particles of clay were termed *clayite* by J. W. Mellor. S. Kasai found no colloidal matter in the clay from Zettlitz. J. Splichal, and R. C. Wallace and J. C. Maynard determined the colloidal matter in a number of clays; A. Vasel found 3 per cent. in Meissen clay.

The china clay or kaolin formed by the decomposition of aluminium silicate rocks is usually a mixture of amorphous granules of clayite, and crystalline plates, termed by S. W. Johnson and J. M. Blake,⁴³ **kaolinite**. C. G. Ehrenberg, A. Knop, A. Safarik, W. Cross and W. F. Hillebrand, and R. C. Hills regarded the crystals as hexagonal or rhombic; and H. Reusch, as triclinic; but A. B. Dick, and H. A. Miers proved that they belong to the monoclinic system, and this was confirmed by E. Hussak. Kaolinite occurs in minute hexagonal plates, Fig. 109, with edges at 60° and 120°. H. A. Miers, and A. B. Dick gave for the axial ratios

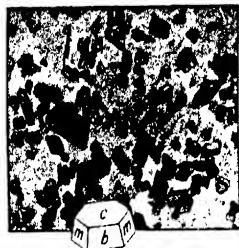

FIG. 109.—Crystals of Kaolinite from Amlwch (Anglesey) $\times 50$.

FIG. 110.—Vermiculites or Rouleaux in Clay.

$a : b : c = 0.5748 : 1 : 1.5997$; and $\beta = 83^\circ 11'$. In Fig. 109, $b(010)$, $c(001)$, $m(110)$; and $b : m = 60^\circ 16'$; $c : m = 84^\circ 16'$. The thinnest plates are at most 0.000002 mm. in thickness.

Well-formed crystals of kaolinite are not common; they are regarded as a mineralogical curiosity. Pockets or veins have been found at Silverton, Colorado; Porth-y-r-hwech, near Amlwch, Wales; Bolton Abbey, Yorkshire; Congleton Edge, Cheshire; Newcastle-on-Tyne; Glamorganshire; Diendorf, Bavaria; Ziesigwald, Chemnitz; Schlan, Bohemia; Altenberg, Saxony; Tuolumne, California; Mount Savage, Maryland; Bradon, Vermont; Richmond, Virginia; Perth Amboy, New Jersey; Reading, Chester; Tamaqua, and Pottsville, Pennsylvania; etc. The crystals may occur in aggregates of plates piled one above the other so that by screwing the cover-glass under slight press, it is possible to spread out the plates much as if a pack of cards were spread out fan-wise by pressing and screwing with the thumb at the other end. Curious vermicular—*vermis*, a worm—aggregates or rouleaux of plates, Fig. 109, have been found in many clays.⁴⁴ A. B. Dick⁴⁵ found that the chlorite-like form of kaolinite has the same refractive index and behaviour when heated as kaolinite; and the optical character is negative like that of nacrite. The **X-radiograms** have been examined by G. Shearer, and F. Rinne. The **cleavage** of kaolinite is perfect and parallel to the face $c(001)$. Some of the larger grains—0.0005 mm. in diameter—of china clay give with polarized light pale bluish-white gleams of light, but particles less than 0.0001 mm. do not show polarization effects.

The **index of refraction** of kaolinite is 1.563, very near to that of Canada balsam; A. B. Dick gave 1.56-1.57; W. T. Schaller and R. K. Bailey, and E. T. Wherry and G. V. Brown, and E. S. Larsen gave $\alpha=1.561$, $\beta=1.565$, and $\gamma=1.567$. The **double refraction** is low, approximately 0.008. Both the index of refraction and double refraction of kaolinite are very close to those of mica, so that the one mineral is frequently mistaken for the other, but, as A. Michel-Lévy and A. Lacroix pointed out, the refractive index and birefringence of kaolinite are less than those of mica or talc. A. Johnsen gave $2E=1.563$ for the optic axial angle. H. Zocher found that suspensions of clay in water are birefringent.

Varieties from different localities have received different names—nacrile, and pholerite. The term **nacrile**—from *nacre*, mother-of-pearl—was applied by A. Brongniart⁴⁶ to a mineral which resembled lepidolite in composition, but differed in its extreme unctuousness; later on A. Breithaupt employed the term for what appeared to be “an earthy talc” which occurred in snow-white or yellowish, six-sided plates aggregated in fan-shaped or reniform masses of sp. gr. 2.63. The pearly lustre sometimes approaches that of adamantinite. The plates are flexible and non-elastic, with a soft soapy feel. The pearly lustre appears to be due to strata of air included between the separate crystalline plates forming a crystalline mass. The lustre can be seen under the microscope by oblique reflected light. Analyses of the mineral correspond closely with those of kaolinite. According to F. Sandberger, the mineral can be decomposed by hydrochloric acid. The sp. gr., hardness, and refractive index also approach the values for kaolinite. According to A. B. Dick, the crystals of nacrile are optically negative, those of kaolinite positive. Summarizing these results:

Kaolinitic minerals	{ Crystalline	optically negative . . .	<i>Nacrile</i> .
		optically positive. . .	<i>Kaolinite</i> .
		Non-crystalline or colloidal . . .	<i>Clayite</i> .

A. Breithaupt also claimed that the mineral “with white pearl-like scales; soft and friable to the touch; with the property of sticking to the tongue when wetted; and of forming a plastic mass with water” which J. Guillemin⁴⁷ called **pholerite**—from *pholis*, a scale—was identical with nacrile. A. Ledoux studied the pholerite and nacrile from St. Vincent. Pholerite was formerly regarded as a distinct mineral species with analyses in agreement with $2Al_2O_3 \cdot 3SiO_2 \cdot 4H_2O$; and, accordingly, H. A. Wheeler assumed that the *flint clays* of Missouri are variable mixtures of kaolinite and pholerite. Analyses by S. W. Johnson and J. M. Blake, with samples likely to be free from impurities, correspond with those of kaolinite. On similar grounds, T. S. Hunt suggested that pholerite is an impure variety of kaolinite. O. Koch called an impure variety of kaolinite from Ancud, Island of Chiloé, *ancudite*. F. Wöhler described a similar product occurring at Schneckstein “in shining laminae which when magnified 200 times appeared as transparent rhomboidal plates. The mass had an earthy fracture, and became lustrous when rubbed. The sp. gr. was 2.6.” S. W. Johnson and J. M. Blake considered this substance to be kaolinite. The white claystone at Chemnitz was thought by A. Knop to be pholerite; it consists of aggregates of scaly crystals.

The “clay” of ordinary china clay is a mixture of particles of clayite and kaolinite; and, with respect to the **grain-size of the particles**, J. Stark⁴⁸ found that the particles of Zettlitz china clay had a mean diameter of 4.8μ , and those of a more plastic clay, 3.6μ . The former clay contained 32 per cent. of coarser particles 11μ – 49μ , and the latter 21 per cent. ranging from 9μ to 40μ . Both clays contained some very fine particles—suspensoids. There were approximately 6.6×10^9 particles per gram of the Zettlitz clay, and 15.8×10^9 particles per gram of the plastic clay. A. B. Dick found the **hardness** of kaolinite to be 2.0–2.5 on Moh’s scale; and the **specific gravity** 2.60–2.63. The reported values for the sp. gr. of china clay range from 2.2–2.6. The former number is too low—due probably to the presence of entangled air bubbles, and possibly to the presence of hydrogels.

The *sp. gr.* alters when the clay is calcined, the magnitude of the change depends on the temp. of calcination. A. Laurent found the *sp. gr.* increased from 2.47 (dried at 100°) to a maximum 2.70 after calcination at *rouge sombre*—perhaps 500°; and then dropped to 2.64 at *rouge vif*—perhaps 800°; and finally to 2.48 at the temp. *de essais de fer*. The clay must have been rather impure, and fluxing must have occurred, because J. W. Mellor and A. D. Holdcroft found that the *sp. gr.* of china clay and of alumina behave in quite the opposite way. For instance, the *sp. gr.* of alumina and china clay calcined at different temp. are:

	110°	600°	700°	800°	900°	1200°
China clay	2.615	2.473	2.489	2.497	2.560	2.734
Alumina	—	2.824	2.828	3.394	3.525	3.914

G. H. Brown and E. T. Montgomery working up to 700° obtained analogous results with a number of different clays. The apparent volume of clay, corresponding with the contraction which occurs when clays are heated, was measured by J. Burton, P. Braesco, R. Wallach, J. M. Knote, H. Hecht, R. Lucas, E. Berdel, etc. The results show that a slight contraction occurs up to about 300°; and an increase in the volume occurs between 450° and 500°, which attains a maximum between 550°–600°. Above this temp., contraction sets in. Thus, E. Berdel found with a 4 hrs. heating of china clay slabs at the indicated temp., the percentage linear contraction—**fire-shrinkage**, or *fire-contraction*—and porosity are:

	970°	1150°	1170°	1190°	1230°	1290°
Contraction	2.1	2.4	3.1	4.2	8.2	9.5
Porosity	41.6	41.9	42.1	31.6	26.3	20.8

The actual results vary with different clays; with different methods of making the slabs; with the rate of rise of temp.; and with the time of firing. The pyrometer of J. Wedgwood in 1782 was based on the definite contraction of clay bits when heated to definite temp. under constant conditions. There have been several modifications in the method of measurement, but the fundamental principle is extensively employed to-day.

Wo. Ostwald and F. Piekenbrock found that the viscosities of wet china clay, and ordinary clays differ in that the value for the latter increases rapidly to a maximum with age and mechanical working, but that of china clay increases slowly. The presence of 1.0 per cent. of quartz in clay, after mechanical treatment, gave a higher viscosity than did the untreated clay. The optimum quartz content varies with the grain-size. It is inferred that in china clay suspensions, the viscosity is determined by the grain-size, and the hydration and swelling of the particles.

The contraction which occurs when slabs made of wet clays are dried is called the **drying-shrinkage** or *drying-contraction*. B. A. Keen, and E. A. Fisher studied the drying of wet masses of clay which was conditioned by evaporation from the surface, and the movements of water in the capillary pores. J. Aron⁴⁰ showed that there are three stages in the drying: (i) as the water evaporates from the wet clay the volume-shrinkage is equal to the volume of water lost. This means that the space vacated by the water is taken up by the clay. After a time (ii) air spaces begin to appear and the volume-shrinkage is then less than the volume of water, since the space vacated by the water is not all reoccupied by the clay. Finally, (iii) the volume-contraction virtually ceases although water is still being lost by the clay. The shrinkage of the clay is due to the work of capillary attraction by films of water surrounding the clay particles. These results were in the main confirmed by W. J. Jackson and E. M. Rich, and C. Bischof. The ceramic journals teem with observations on these various properties of clay. The **tensile strength** of slabs made with wet clay varies with the amount of moisture present, and on drying, W. Jackson and E. M. Rich found that the tensile strength slowly increases to a maximum of about 3 kgrms. per sq. cm. when about 20 per cent. of water is present. The clay is then "white-hard," or "leather-hard." The subsequent evaporation of the water lowers the tensile strength to a minimum value of about 1.5 kgrms. per

sq. cm. with about 1-2 per cent. of water. The tensile strength then rapidly increases until the clay is quite dry and reaches 5 kgms. per sq. cm. E. Orton found that the tensile strength of clay admixed with a given proportion of sand increases as the grain-size of the non-plastic material decreases. A. V. Bleining gave for the tensile strength, the transverse modulus of rupture and the compressive strength in pounds per square inch:

	Tensile strength.	Transverse modulus.	Compressive strength.
English ball clay . . .	210	558	1148
English china clay . . .	41	98	228
American ball clay . . .	125	380	635
Florida china clay . . .	104	239	539
Georgia china clay . . .	147	325	455
North Carolina china clay . . .	69	166	349

W. Schumacher⁵⁰ gave for the **specific heat** of dried clay, 0.1784; H. Platter, 0.2231 if dried at 100°, and 0.3063 if air-dried; V. C. Lang, 0.233; and R. Ulrich, 0.2243 between 20° and 98°. J. M. Knoté gave for raw clay between 22° and 150°, 0.237, for clay previously heated to 650°, 0.204; and for clay previously heated to 1050°, 0.200. C. F. Howe and C. B. Harrington gave for bricks made from clay 0.196+0.00533θ between 0° and 1100°; S. T. Wilson and co-workers, 0.193+0.00006θ between 0° and 1300°; and L. Bradshaw and W. Emery, 0.193+0.000075θ between 0° and 1400°. Observations were also made by E. Heyn and co-workers, M. Kinoshita, A. Bigot, W. Steger, Y. Tadokoro, J. K. Moore, L. Navias, etc. L. Navias found that the heat absorbed per gram per degree on heating air-dried clays from 25°-1200° is 0.50-0.55 cal. per gram per degree, whereas the heat evolved on cooling the final product is 0.23-0.29 per gram per degree. The former includes the latent heat of evaporation of the water adsorbed by air-dried clays, the combined water, etc. The **thermal conductivity** of clay is small. A number of determinations have been made on bricks made from clays. The results therefore represent the conductivity of the fired clay plus pore-spaces. O. S. Buckner found 0.00169-0.00251 in standard units, and S. Wologdine 0.0035 at 1050° to 0.0042 at 1300° for the coeff. for different fired fireclays. J. W. Cobb and co-workers gave for the thermal conductivity K at θ°, $K=0.00155+0.00025θ$. The literature has been summarized by P. Gilard, and A. T. Green. Observations on commercial firebricks were made by H. A. Wheeler, G. H. Brown, A. S. Watts and R. M. King, A. T. Green, R. A. Horing, J. W. Cobb and co-workers. V. Tadokoro, E. Heyn and co-workers, P. Goerens and J. W. Gilles, B. Dudley, S. M. Marshall, S. Wologdine, J. D. Pennock, M. Simonis, F. Tschaplowitz, P. Rosin, and J. K. Clement and W. L. Egy. The porosity of the sample tested is an important factor. As predicted in 1914 by J. W. Mellor, A. T. Green found that while a high porosity is unfavourable to thermal conductivity below red heat, there is an inversion near 1100°, so that at higher temp. a high porosity enhances the thermal conductivity. The coeff. of **thermal expansion** of bricks made from clays have been measured, and the results have been summarized by J. W. Mellor. H. Kohl gave 0.00419 for the mean linear coeff. at 1150°; 0.00520 at 1250° of a china clay, and for a plastic clay, 0.00729 at 1000° to 0.01079 at 1250°. Recalculating the results of H. J. Hodsman and J. W. Cobb for the coefficient of thermal expansion of china clay at different temp.

	195°	450°	700°	900°
Coeff. expansion . . .	0.00571	0.00495	0.00477	0.00469

In one case there is an increase with rise of temp. and in the other a decrease. The results must be greatly influenced by the presence of quartz. G. Tammann and H. Diekmann found that when dry clay is warmed to 48°, superimposed mercury begins to pass through.

W. C. Heraeus gave between 1667° and 1680° for the **melting point** of china

clay. H. A. Seger showed that the curve for the softening temp. of mixtures of clay and quartz has the U-form with a minimum at about 1650° , and a ratio

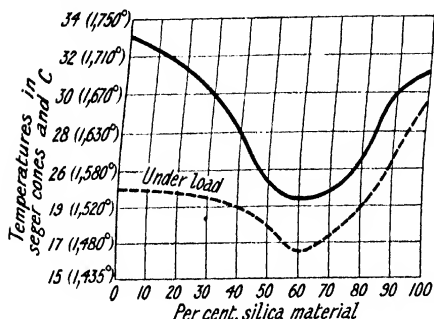

FIG. 111.—The Effect of Silica on the Softening Temperature of Fireclay.

$\text{Al}_2\text{O}_3 : \text{SiO}_2 = 1 : 16$; L. Bradshaw and W. Emery confirmed these results. The results with mixtures of commercial fireclay and silica are shown in Fig. 111. See also aluminium silicates, Fig. 108. The effect is greater with fine-grained than it is with coarse-grained silica. J. W. Mellor and B. J. Moore found that the effect of load is to depress the softening temp. in accord with the expression: $\text{Squatting temp.} = 35e^{-0.0082w}$, where w represents the load

in lbs. per sq. in. for loads up to 112 lbs. per sq. in., when the softening temp. are expressed in terms of Seger's cones. This corresponds with a depression of one cone per $5\frac{1}{2}$ lbs. per sq. in. press. With mixtures of silica, the difference between the softening temp. is less marked the higher the proportion of silica. This result was confirmed by L. Bradshaw and W. Emery. L. Bertrand studied the effect of the proportion of alumina in natural clays on the softening temp. H. Hirsch and M. Pulfrich examined the behaviour of a large number of clays when heated under load. E. L. Dupuy found the resistance to crushing on a rising temp. at first decreased, then rapidly increased to a maximum at about 1000° , being then sometimes double or triple the value at atm. temp., at still higher temp., the strength rapidly diminished until fusion was complete. A felspathic china clay exhibited two maxima, the second being near 1400° . Many other observations have been reported.⁵¹

The action of heat, etc., on various mixtures of clay and silica or quartz has been discussed by M. Simonis,⁵² E. Berdel, F. Kraze, R. Lucas, S. L. Galpin, etc. An indefinitely large number of observations have been reported in the ceramic

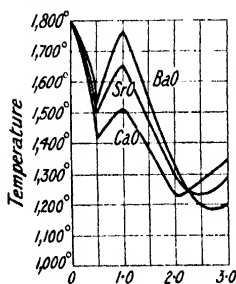

FIG. 112.—The Effect of Alkaline Earths.

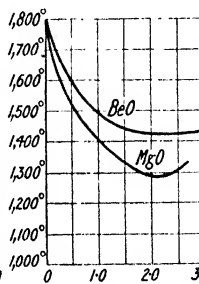

FIG. 113.—The Effect of Beryllia and Magnesia.

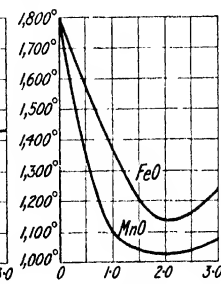

FIG. 114.—The Effect of Ferrous and Manganous Oxides.

journals. The effect of heat on mixtures of clay with felspar, and mica is discussed in connection with these minerals. The effect of lithium oxides on the fusibility, etc., of clay was investigated by R. Rieke; of potassium and sodium oxides, by R. Rieke, and G. Flach; of calcium oxide, by G. Flach, and R. Rieke, Fig. 112—*vide infra*, cements; of strontia, and of baryta, by G. Flach, and R. Rieke—Fig. 112; of beryllia, by R. Rieke—Fig. 113; of magnesia, by H. Mäckler, A. F. Hottinger,

L. E. Barringer, G. Flach, and R. Rieke—Fig. 113; of *iron oxide*, by R. Rieke, and J. W. Mellor—Fig. 114; of *manganese oxide*, by R. Rieke—Fig. 114; of *chromic oxide*, by K. Dornhecker, and S. Sandlund; of *uranium oxide*, by O. Kallauner and J. Hruda; and of *zirconia*, by R. Rieke. The effect of *titanic oxide* on the fusibility of clay was shown by H. A. Seger and E. Cramer to be greater than is the case with silica. The subject was investigated by H. Ries, C. Bryce, and R. Rieke. The latter showed the fusibility with the following percentage amounts of titanic oxide was:

TiO ₂	0	10	20	30	50	70	80	90	100
Temp.	1770°	1670°	1580°	1530°	1525°	1530°	1565°	1580°	1810°

G. Tammann studied the effect of alkaline earths on clay. E. Richter examined the influence of different fluxes on the fusibility of clay, and concluded with what has been called Richter's law: *Chemically equivalent quantities of magnesia, lime, ferrous oxide, soda, and potash exert the same influence in lowering the fusibility of a clay.* The subject was discussed by C. Bischof, and it was found that at high temp. silica itself acts as a flux with clay, and should not be present in excess; the presence of an excess of silica also intensifies the effect of other fluxes. E. Cramer also found that the fluxes do not act according to F. Richter's law in the presence of free silica. T. Ludwig inferred that E. Richter's rule is a special case of the law of dil. soln.: *Equimolar quantities of different substances dissolved in equal amounts of the same solvents, lower the m.p. to the same extent.* R. Rieke tested the rule with additions of baryta, beryllia, magnesia, ferrous oxide, and manganous oxide to a mol of china clay, Al₂O₃.2SiO₂.2H₂O, with a softening temp. of about 1790°. Using 0.25 mol of the base, the corresponding softening temp. were:

Li ₂ O	Na ₂ O	K ₂ O	CaO	SrO	BaO	BeO	MgO	FeO	MnO
1380°	1520°	1530°	1690°	1720°	1730°	1660°	1700°	1660°	1670°

With 0.25 mol TiO₂ and 0.25 mol ZrO₂ the softening temp. were respectively 1700° and 1690°. The results with still higher proportions of lime, strontia, and baryta showed that the oxide with the lowest mol. wt. lowered the m.p. most. Similarly with the alkali family. The effect with beryllia is less than with magnesia; and with ferrous oxide less than with manganous oxide. The atm. of the furnace was strongly reducing, and it was assumed that the last two oxides were in the lower state of oxidation. The general results show that the alleged law is inapplicable and the analogy with dil. soln. is invalid. A. S. Watts also made some observations on this subject.

Several observers—J. Burton,⁵³ F. W. Clarke, H. C. McNeil, J. M. Knote, H. E. Ashley, etc.—have attempted to find a **dehydration temperature**. E. Lovejoy said the dehydration temp. is near 630°; A. E. Brown gave 565°, and W. M. Kennedy, 475°, while A. B. Dick observed no loss of water with crystals of kaolinite at 275° or at 400°, and W. H. Hillebrand none at 330°. W. Vernadsky, and F. Hundeshagen affirmed that dehydration takes place in two stages: one half the water is said to be evolved at one temp. and the other half at a higher temp. Hence, J. M. van Bemmelen, and S. J. Thugutt inferred that one half the water is Si-hydroxyl, and the other half Al-hydroxyl, and they wrote the formula H₂Al₂Si₂O₈.H₂O. E. Löwenstein considered that 0.5 mol is driven off at the lower temp. and 1.5 mol at the higher temp., and he wrote the formula 2Al₂O₃.4SiO₂.3H₂O+Ag. There is, however, no satisfactory evidence of the evolution of water in two stages. J. W. Mellor and A. D. Holdcroft found that above 300°, the evolution of water is a continuous process, and that the rate which the water is expelled rises with the temp. Thus, the percentage losses were:

		300°	400°	425°	450°	500°	556°	600°
China clay	Vacuum	0.24	0.89	1.43	3.38	8.48	—	—
	Atm. press.	0.26	0.57	0.68	0.80	1.19	—	11.92
Kaolinite	Vacuum	1.66	1.70	1.80	2.72	4.96	8.20	11.58
	Atm. press.	1.82	1.91	—	—	2.41	6.00	10.08

The 13-14 per cent. of combined water is rapidly given off as the temp. rises beyond 500° under ordinary atm. press., although most is given off below this temp. under reduced press. It requires a high temp. to expel the last traces of water. The decomposition of the mineral which is attended by the evolution of water is an endothermal reaction and produces a terrace in the heating curve. D. Tschernobéeff, and J. W. Mellor and A. D. Holdcroft's rough estimates of the **heat of dehydration** range from 11-28 Cals. per mol, and D. Tschernobéeff's estimate of the **heat of formation** of kaolinite is $(\text{Al}_2\text{O}_3, 2\text{SiO}_2, 2\text{H}_2\text{O}) = 43.8$ Cals., but these data are of little value. E. Löwenstein measured the **vapour pressure** of a number of clays at ordinary temp., and J. W. Mellor and co-workers found that with a partial press. of water-vap., *p* mm., when confined over sulphuric acid, the loss in weight for crystals of kaolinite, china clay, ball clay, and halloysite was at 25°:

<i>p</i>	. . .	18.0	13.5	8.8	4.3	1.8	0.6	0.0 mm.
Kaolinite	. . .	0.06	0.08	0.12	0.18	0.24	0.38	0.46
China clay	. . .	0.01	0.06	0.13	0.16	0.23	0.36	0.50
Ball clay	. . .	0.08	0.24	1.63	2.31	2.44	3.29	3.54
Halloysite	. . .	0.06	0.44	1.67	1.96	3.26	3.62	4.03

The water is restored when the clay is exposed to a moist atm. L. Navias measured the velocity at which clays give off their combined water, and he suggested that the evolution of water is rapid at 745°, and the speed falls in a decisive manner, while the temp. rises 200°-300° more. Only clays containing organic matter develop an appreciable press. between 900° and 1200° in air. V. Agafonoff and W. Vernadsky raised the objection that the product obtained by dehydrating clay below 550° is homogeneous, because it cannot be separated into parts by separating liquids, and it appears homogeneous under the microscope. Neither test is at all an adequate proof of the conclusion. W. T. Schaller and R. K. Bailey described hexagonal plates of a kaolinite from Oklahoma which, unlike ordinary kaolinite, intumescenced strongly when heated.

H. le Chatelier observed a retardation in the heating curve of crystalline kaolinite ending at 770°, and a slight acceleration at 1050°; he also found a marked retardation with halloysite ending at 700°, and a sudden acceleration at 1000°. As a matter of fact, the actual temp. observed under these conditions depends on the rate of rise of temp., the physical state of the powdered material, etc. It is also possible that the alleged halloysite was really colloidal clayite, since J. W. Mellor's observations show no marked retardation with halloysite at the above temp. J. W. Mellor and A. D. Holdcroft found that china clay and crystalline kaolinite give a terrace in the **heating curves** just over 500°, and a hump in the curves between 800° and 1000°; china clay, like the colloidal aluminosilicates gives a terrace at about 150°, indicating that it contains clayite as well as crystals of kaolinite (shown by the microscope). The hydrogels of silica and alumina also give a terrace just over 100°, and alumina gives a hump at 800°-1000°. The curves are illustrated in Figs. 119, 120, and 122. Endothermal reactions are represented by terraces; exothermal reactions by humps. There is a remarkable likeness in the 800°-1000° hump in the heating curves of the hydrated aluminium silicates in conformity with the suspicion that all are due to one cause—the polymerization of alumina. It is inferred from the chemical and physical properties of dehydrated kaolinite or clayite that it is decomposed into free silica and free alumina above 500°, and the uniformity in the hump between 800° and 1000° with all these minerals corresponds with the inference that a mixture of silica and alumina is involved. Confirmatory results were obtained by R. Rieke, G. Keppeler, R. Wohlin, C. E. Moore, H. S. Houldsworth and J. W. Cobb, R. Wallace, A. M. Sokoloff, G. Tammann and W. Pape, A. Zöllner, J. V. Samoiloff, and S. Satoh. At higher temp., in the vicinity of 1200°, cristobalite, and sillimanite crystals are formed—presumably by the recombination of silica and alumina. If the clay breaks down into water and a disilicate, $\text{Al}_2\text{O}_3, 2\text{SiO}_2$, it is necessary to assume that this compound has properties

parallel with those of alumina, and that it breaks down at higher temp. into sillimanite (fibrolite) and silica (cristobalite). W. Vernadsky calls this residue leverrierite, and invests it with all the properties required to explain the assumption that the final products of the reaction are $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 + 2\text{H}_2\text{O}$. O. Rebuffat supports this hypothesis. The above-mentioned observations on the vap. press., coupled with the low temperature dehydration of clays in vacuo, probably mean that the clay loses its water before breaking down into free silica, and alumina (possibly sillimanite). J. Matejka went further than G. Tammann and assumed that several aluminium silicates are formed; he also used the break on the heating curve as a means of detecting kaolinite in soils. A. V. Henry found the **electrical resistance**, R ohms per c.c., of china clay—*vide infra*, pottery—with a 45-volt, 1000-cycle alternating current, to be

	300°	500°	700°	900°	1100°	1300°	1500°
R	133×10^5	269×10^3	302×10^2	7440	2350	1060	681

Clays in suspension in water are rapidly flocculated and made to settle by carbon dioxide, hydrochloric acid, many ammonium salts, the sulphates and chlorides of the alkalis and alkaline earths, ferrous and ferric sulphates, zinc chloride, etc. On the contrary, humic matters, sodium carbonate, water-glass, sodium and potassium phosphate, borax, potassium or ammonium oxalate, etc., have the converse effect, for they deflocculate clays and retard their settling. This subject has been discussed by W. Durham,⁵⁴ and many others. The observations of J. Murray and R. Irvine show that the clay matters carried by rivers to the sea are quickly deposited on reaching salt water, and only a small fraction is carried to deep waters. O. M. Smith found that salts containing bivalent ions aided the flocculation of clay suspensions by alum, but that it was hindered by sodium hydroxide or carbonate. N. M. Comber showed that clay suspensions were flocculated most readily in an alkaline medium, but that the degree of alkalinity above that of $0.005N\text{-NH}_4\text{OH}$ had no effect; he also determined the relative flocculating powers of different electrolytes by observing the rate of settling of the coagulum formed by a decided excess of the electrolyte. Observations by O. Arrhenius, E. F. Burton, etc., show that the addition of certain electrolytes in excess of the minimum required for flocculation yields a coagulum that settles much more slowly than that obtained when just enough is added to bring the colloid to its iso-electric point. R. Bradfield found that with an amount of potassium hydrophosphate just below that required to cause flocculation, the addition of a larger amount of other electrolytes is required to cause coagulation than is the case with the untreated clay. The protective action may be due to an absorption of negative phosphate ions and hydroxyl ions by the negative clay particles, thus increasing the negative charge, and consequently also the amount of positive ions required to bring it to the iso-electric point. The protective action may also be due to the higher conc. of the potassium hydrophosphate required for flocculation when used alone might be due to its weakly basic reaction, larger quantities being required to bring the colloid to its critical value than is the case with a strong base like potassium hydroxide. M. A. Rakuzin and A. N. Nesmejanoff found that mercuric chloride is not adsorbed by china clay. R. Bradfield measured the effect of the acidity of a soln. on the flocculation of clay in suspension, and found that hydrochloric, sulphuric, phosphoric, and acetic acids flocculate the clay at about the same H^+ -ion conc., but a greater acidity is needed with citric acid. Flocculation involves a decrease in the electric charge; peptization an increase. The acidity or hydrogen ion conc. of clays was found by F. P. Hall to range from $10^{-3.1}$ to $10^{-7.27}N$, when results with clays containing appreciable quantities of soluble salts are rejected. The iso-electric point with clays corresponds with a hydrogen ion conc. of $10^{-2.7}$ to $10^{-4.0}N$. The maximum electric charge acquired in the presence of soluble salts represents maximum deflocculation; and the maximum rate of settling takes place at the iso-electric point. R. Schwarz

said that flocculation occurs only when the acidity is eq. to an hydrogen ion conc. of $10^{-4.5}$ to $10^{-5.2}N$. This subject has been discussed by S. E. Mattson. A. Fodor and B. Schönfeld, and F. P. Hall also studied the effect of acids on clays.

The hygroscopicity of china clay—i.e. the property for absorbing moisture from humid air—is greater if it has been pre-heated to between 500° and 800° , than if the raw clay be used, and, like alumina, it loses this property if it has been calcined over 800° . L. Gurvich⁵⁵ measured the heat of wetting clay, and he found that oxygen compounds have a greater heat of wetting and are more adsorbed by adsorbents containing oxygen—or they are *oxyphilous*, while hydrocarbons are more attracted by charcoal and are *carbophilous*. With increasing mol. wt. in a series, the oxyphilous effect decreases to a minimum, and increases again with increasing mol. wt.—*vide* charcoal. E. Reichardt and E. Blumtritt found that 100 grms. of dry and moist clay respectively absorbed 33 and 29 c.c. of gas from the atm., and the gas contained respectively 65 and 60 per cent. nitrogen; 21 and 6 per cent. oxygen; and 14 and 34 per cent. carbon dioxide. A. von Dobeneck showed that 100 grms. of china clay absorbed 0.023 gm. of carbon dioxide at 0° , and practically the same amount at 10° , 20° , and 30° . In 1825, M. Faraday noted that china clay which has been heated to redness and exposed to the air for a week, absorbs, during that time, much ammonia from the air. B. von Ammon observed that china clay at 20° absorbed 0.42 per cent. of its dry weight of ammonia, and he, and A. von Dobeneck found the amount absorbed is less the higher the temp. above zero. R. E. Wilson and T. Fuwa found that with

Humidity of air	15	30	50	70	90	per cent.
Moisture in clay	0.30	0.60	0.92	1.06	1.27	„

According to W. Suida, china clay absorbs the colouring matter from aq. soln. of acid and basic aniline dyes. E. Dittler and C. Doelter observed that an alcoholic soln. of fuchsin does not dye kaolin. 2.5 grms. of a kaolinized granite containing about 70 per cent. of china clay absorbed 0.0176 gm. malachite-green, 0.0211 acid fuchsin, and 0.0211–0.0218 gm. of methylene blue from a litre of the soln. containing half a gram of the dye, and H. E. Ashley proposed to estimate the plasticity of clays by measuring the amount of malachite-green adsorbed by a given quantity of clay from a standard soln. of the dye. The adsorption of salts from their aq. soln. has been studied by F. Rautenberg, E. C. Sullivan, M. Rakuzin, S. Wosnessensky, H. Hirsch, T. O. G. Wolff, G. Moreau, A. S. Cushman, E. Kohler, J. M. van Bemmelen, A. Fodor and B. Schönfeld, K. Kobayashi, T. Okazawa, A. Bencko, H. Kohl, R. Bradfield, and others. E. Kohler, and E. C. Sullivan showed that when an aq. soln. of copper sulphate or lead nitrate is filtered through china clay, the basic constituent is largely retained by the clay. Neutral soln. of sodium chloride or sulphate, or of magnesium sulphate or chloride, give a filtrate which is distinctly acid. The acidity is thought to be partly due to the exchange of the bases for the aluminium (and iron) of the clay; and partly to the greater speed of the acid component when the salt is hydrolyzed, $MgSO_4 + 2H_2O = Mg(OH)_2 + H_2SO_4$. E. C. Sullivan studied the action of cupric sulphate and silver sulphate soln. on clay. P. Rohland described a clay which was permeable to crystalloids—e.g. sodium chloride, barium chloride, cupric sulphate, potassium dichromate, etc.—and impermeable to colloids—e.g. ferric hydroxide, silicic acid, dissolved starch, etc. S. Lagergren found that china clay, dried at 160° , increased the conc. of soln. of chlorides and bromides—in some cases as much as one per cent. The results require confirmation. H. Udluft showed that clay adsorbs ferric oxide and manganese dioxide from the colloidal sol; both the clay and manganese dioxide sols are negatively charged.

J. Lemberg's observations showed that sodium silicates or aluminosilicates are less stable in aq. soln. than the corresponding potassium salts. The replacement of potassium by sodium in the silicates does not proceed nearly so readily

as the reverse reaction. He also noted that the displacement of magnesium by calcium is more difficult than the reverse change. O. G. C. Bischof, and J. Lemberg suggested that the need of plant life for potassium rather than sodium may be due to the fact that the potassium salts are held more tenaciously by soils than those from sodium salts; and accordingly the plant finding more potassium than sodium available in the soils, has developed the habit of assimilating potassium rather than sodium. Again, the reason sodium salts accumulate in the ocean has been explained by showing that the potassium salts are retained more tenaciously by the soil while the sodium salts are washed into the rivers and seas.

J. M. van Bemmelen found that 100 grms. of china clay adsorbed 2.3 eq. of potassium chloride from 250 c.c. of a soln. containing 10 eq. of the salt; and H. Hirsch, that 100 grms. of clay adsorbed w grms. of barium chloride from a litre of soln. containing C grms. of salt:

C	. 0.1	0.5	1.0	3.0	5.0	10.0	15.0	20.0	25.0
w	. 0.096	0.424	0.701	1.087	1.231	1.412	1.527	1.535	1.551

R. Gallay found that clay with adsorbed bivalent ions is more sensitive to coagulation than clays with adsorbed univalent ions. The clay with adsorbed bivalent ions is more sensitive towards univalent ions than is a clay with adsorbed univalent ions towards bivalent ions. This indicates that the bivalent ion released by exchange from the clay exerts a coagulating influence; and that coagulation is complementary to adsorption. In 1859, C. Bödeker concluded from his observations that the amount of adsorption is proportional to the sq. root of the conc. T. O. G. Wolff said that the final, not the initial, conc. of the salt should be alone considered in discussing this relation, for a soln. percolating through a colloid will give up the solute to the colloid until equilibrium is attained, and it will then pass through unchanged. Conversely, a more dil. soln. will abstract salt from the colloid until equilibrium is attained. W. Ostwald, and H. Freundlich showed that the form of the function connecting adsorption with conc. will be exponential. For further work on the relation between adsorption and conc., *vide* carbon.

The plasticity of clay.—The fictile qualities of a clay are primarily dependent on its plasticity. Plasticity is a property of wet clay which enables it to change its shape without cracking when it is subjected to a deforming stress. The elasticity of the wet clay is negligibly small. Clay is peculiar in possessing another quality which is as important as plasticity. It has a high binding power when dried and fired, so that the form impressed on the plastic clay is retained more or less persistently when the clay is dried and fired. As shown by A. Baumé,⁵⁰ G. Vogt, S. Kasai, E. Bourry, E. Orton, F. F. Grout, A. Leppla, H. A. Wheeler, etc., very fine powders—barium sulphate, glass, quartz, etc.—acquire a kind of plasticity when wetted, but when dried, the binding power is exceedingly small. They are plastic, but their plasticity cannot be used in the fictile arts because the second quality is wanting. Many definitions of plasticity confuse these two distinct properties, and assume that the binding power of the dried clay is implied in the term plasticity. Indeed, many methods proposed for measuring plasticity are based on the binding power of the dried clay—*e.g.* those of W. Olzschewsky, and H. A. Wheeler. It is assumed that the tenacity of the dried clay is proportional to the plasticity of the wet clay. This is generally, but not always, true. No known property of the *dry* clay can be used as an infallible index of the plasticity of the *wet* clay, and measurements of plasticity dependent on some property of the dried clay can therefore be dismissed, because even though they may measure an important property of clay, that property is not plasticity.

It is really difficult to measure the plasticity of clay because the property is somewhat complex. In 1844, A. Brongniart recognized its elusive character. He said: *On a souvent parlé de cette propriété, on semble la connaître, mais on n'en a qu'une vague idée.* The potter's thumb under working conditions is one of the most sensitive tests at present known, but that is not always decisive. B. Zschokke

regarded plasticity as a complex property which could be analyzed into four simpler qualities: (i) the deformability; (ii) the cohesion; (iii) the adhesion; and (iv) the viscosity or internal friction of the clay. A. Martens assumed that the plasticity, P , is proportional to the toughness, T , of the material, and inversely as the modulus of rupture, R , such that $P \propto T/R$; and H. Fischer added that the plasticity also varies inversely as the elasticity, e , of the material, so that $P \propto T/eR$. The subject was discussed by H. Fischer, A. Rejtö, F. Kick, H. Tresca, and L. von Tetmajer. In estimating plasticity there is first the internal friction which can be otherwise represented as the resistance which the clay offers to changing its shape; and second, there is the cohesion, i.e. the amount of deformation which the clay can suffer without cracking. F. F. Grout worked on these lines; he assumed that, with suitable units, the product of (1) the resistance the clay offers to deformation, Fig. 115; and (2) the amount of deformation the clay can suffer without cracking, Fig. 116; represents the plasticity, Fig. 117. E. C. Bingham regards plasticity as a complex property involving a definite shearing stress and the viscosity determined by measuring the quantity of clay flowing through a capillary tube at various pressures. The subject has also been discussed by F. P. Hall, and A. de Waele.

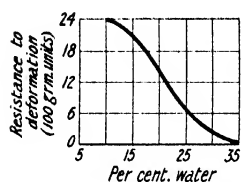

FIG. 115. Relation between Water Content and Resistance to Deformation.

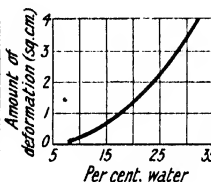

FIG. 116. Relation between Water Content and the Amount of Deformation.

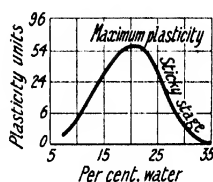

FIG. 117.—Relation between Water Content and Plasticity.

The plasticity of a clay varies with the proportion of water in a curious way. As water is progressively added to a dry clay, the plasticity continually increases and attains a maximum value. Any further addition of water reduces the plasticity; the clay acquires another quality. The particles no longer have a marked tendency to cohere together, rather does the clay become "sticky," and it adheres to anything it touches which water can "wet." In the sticky stage the clay is no longer workable. This represents a break in the continuity between plasticity and viscosity. As more and more water is added, the clay assumes the form of slip, and can then be poured like a liquid. J. W. Mellor and A. D. Holdcroft were able to restore a small proportion of water to completely dehydrated clay by heating it under pressure in steam. It was assumed that the silica and alumina of the decomposed clay are hydrated. J. S. Laird and R. F. Geller repeated the experiment and obtained analogous results. The restored plasticity is of a totally different kind to that possessed by the original clay.

There are different qualities in plasticity. The deformation pressures of some clays are greater than others, and such clays are said to be "stiff" or "strong." Some strong clays offer a high resistance to changing their shape and yet cannot be deformed very much without cracking. In other words, the clay is "strong" and "short"—e.g. London clays. There are other clays which have a low deformation pressure, and can suffer little deformation without rupture. They are "weak" and "short"—e.g. many siliceous pipe-clays. Other "fatty" clays offer a low resistance to change of shape, and yet suffer a comparatively large deformation without rupture—e.g. the black ball-clays.

Plasticity is a mechanical property, the resultant effect of a deformation and a pressure.—The deformability of a clay is probably determined by the distances the particles can move without loss of cohesion; and the deformation pressure represents the magnitude of the cohesive or attractive forces as shown by the

resistance offered by cohesion to the movements of the particles under the influence of an impressed force. The deformability of the clay is then conditioned by the size and shapes of the particles; and the deformation pressure is determined by the magnitude of the cohesion between the clay particles and the water, and by the thickness of the water film.

Until it has been shown that plasticity is a definite function of some other quality—salt-absorbing property of H. Hirsch, dye-adsorbing property, viscosity of slip, etc.—it cannot be assumed without reservations that measurements of these qualities measure plasticity. The claims made on behalf of such indexes of plasticity are examples of the logical fallacy *circulus in probando*. Take the dye-absorbing test. Plasticity is assumed to vary with the amount of colloid in a clay; the amount of colloid in the clay is then assumed to be proportional to the amount of dye the clay can absorb from a standard soln. Hence, dye-absorption measures plasticity. The viscosity test—used by M. Simonis,⁵ M. Chatenet, F. P. Hall, R. F. MacMichael, E. van der Bellen, etc.—is another example. Some methods which have been proposed for measuring plasticity really measure only one of the two components—deformation and pressure—into which plasticity has been resolved. For example, L. J. Vicat's needle test—used by P. Langenbeck; A. Brongniart's wad-box test—used by C. Bischof, R. Biedermann and H. Herzfeld, E. C. Stover and J. Lindley, etc.; G. E. Ladd's tensile test; P. Jochum's bending test; and K. Dummier's spiral test, ultimately measure deformation, not pressure; and they give comparable results under constant conditions for a particular type of clay when the pressure is constant, but not necessarily so for different types of clay.

The plasticity of a clay was assumed by G. Keppeler, and others, to be inversely proportional to the grain-size. H. E. Ashley made this an essential part of his formula. The observation has been qualitatively recognized for a couple of centuries. In 1770, A. Baumé attributed the high plasticity of clays to their extremely fine state of subdivision, and to their containing some saline matter. He said:

On doit attribuer le liant des argilles à l'extrême division de leurs parties qui les rend propres à retenir l'eau, et à leur état salin qui leur donne la faculté d'être presque dissolubles dans l'eau. Leurs molécules sont beaucoup plus dans l'état de division, que celui qu'on pourroit procurer à une pierre quelconque par des moyens mécaniques.

A. Baumé's *l'état salin* approaches near to the modern idea of matter in a colloidal state. The meaning is clear; superposed on the plasticity exhibited by fine grained powders, clays have a plasticity in virtue of their contained saline or colloidal matter. A. Baumé's assumption thus approximates to that made by T. Way, T. Schlösing, H. Kaul, F. Förster, E. W. Hilgard, E. Podszus, S. Odén, A. Benecke, E. van der Bellen, W. H. Brewer, A. S. Cushman, R. C. Wallace and J. E. Maynard, A. Bigot, G. Keppeler, P. Rohland, and by H. E. Ashley, that plasticity is connected with the amount of colloidal matter in the clay—*l'argile colloïdale* of T. Schlösing—and inversely as the state of subdivision. If, as appears highly probable, the plasticity of clay is proportional to the amount of colloidal matter in the clay, the dye-absorption test is probably invalid because there is nothing to show that the colloidal matters in different clays have the same absorption power. It is fairly certain that the colloidal matter in different clays—say ball clay and china clay—is not the same, for this must be largely determined by the nature of the organic matters associated with the clay at the time of its deposition, or which have been afterwards acquired from extraneous sources. Neither J. Spichal, nor C. D. B. y Escuder found the dye-absorbing test to be a satisfactory method of measuring plasticity. Clays have qualities which might be predicted from the known properties of matter in the colloidal state. It is therefore assumed that clays contain x per cent. of colloidal matter possessing qualities like those possessed by the clay itself.

The evidence for the statement that plasticity is inversely proportional to grain-

size is not to be accepted without reservations. B. Zschokke, and F. F. Grout have both shown that the plasticity of some clays is not always influenced by finer grinding, and that the plasticity of other clays may be lessened by fine-grinding. This shows that close-packing is also concerned in the action. It follows that closer packing is possible with mixed fine and coarse grains than with all fine or all coarse grains, and V. Alexieff, and P. A. Schemjatschensky have shown that both extremely fine-grained and extremely coarse-grained clays are less plastic than clays containing mixed fine and coarse grains. Hence, if grinding makes the particles more uniform in size, the clay will become less plastic; and it is probable that, other things being equal, the distribution of grain-sizes which permits the closest packing of the particles, will be the most favourable to high plasticity.

Plasticity *per se* can be readily explained by the known properties of films of water, and theories have been devised which postulate special shapes for the predominant particles in the clay; e.g. H. le Chatelier, R. Biedermann and H. Herzfeld, G. H. Cook, A. Leppla, H. A. Wheeler, R. F. MacMichael, G. Vogt, S. W. Johnson and J. M. Blake postulated flattened particles; J. Aron, and E. Linder, spherical particles; and W. Olzschewsky, spongy particles. There are, however, a number of cognate properties possessed by wet clays, which are of assistance in the clarification of the concept of plasticity. For example, the slow development of plasticity during the weathering or ageing of clays; the action on clay-slip of alkalis, hydrolysable salts, acids, and certain organic compounds like tannin; the high tenacity of dried clays, etc. H. A. Seger emphasized that the increased plasticity due to ageing is accompanied by an increased acidity in the clay. The acidity is due to the decomposition of the organic matters in the clay. It does not necessarily follow, as E. Rohland supposed, that increasing the acidity—i.e. the conc. of the H⁺-ions—will increase the plasticity of clays. It might be anticipated that the bacteria which decompose the organic matters may accelerate the development of plasticity by ageing and weathering. E. G. Stover said that the *bacillus sulphureus* is the active agent, but this is not proved. The subject was discussed by O. Beck, and F. F. Grout, etc. The facts connected with the action of alkalis, etc., on clay-slip have been worked out by many investigations on the sedimentation of clay, etc., suspended in water. It has been observed that there are three classes of substances concerned in these effects: *I. Flocculants*—Acids, acid salts, lime, calcium sulphate, sodium chloride, and most neutral salts cause the fine particles in suspension to flocculate or coagulate into groups and settle; these agents also enhance the plasticity of clays. *II. Deflocculants*—A small proportion of ammonia, alkali hydroxide, alkali carbonate, borate, silicate, or a salt of other weak acids deflocculate, decoagulate, or peptize the clay, causing it to assume a more finely divided condition than in water, and thus to remain in suspension for a longer period. These agents also diminish the plasticity of clays. *III.* An excess of the deflocculating agents may produce the converse effect giving the same result as if an acid had been added; and perhaps also with some flocculants.

The attractive forces exerted on the molecules at the surface of a liquid are smaller than on a molecule in the interior, so that there is a tendency for the surface mols. to move inwards. The general result is that the surface tends to contract so as to leave the smallest number of molecules on the surface. K. Fuchs, M. Whitney, and W. J. A. Bliss have pointed out that with fine-grained particles of a solid suspended in a liquid, when the surface attraction of the liquid for the liquid predominates over that of the clay for the liquid, the shell of liquid about the clay will diminish, and flocculation will set in. This case is characterized by acids and other flocculants of the first class. When the surface attraction of the clay for the liquid predominates over that of liquid for liquid, the shell of liquid about the clay will enlarge, and the grains of clay will be kept apart and deflocculation will occur. This case is typical of dil. soln. of the alkalis, and other deflocculants of the second class. The behaviour of substances in the third class shows that there is a critical concentration below which the surface attraction of

clay for the liquid predominates, and above which the attraction of liquid for liquid is predominant.

The effect of alkalies on clay suspended in water is to keep the clay particles apart, the effect of acids is to make them form aggregates. The result is rather remarkable. Clay-slip prepared with about 0.3 per cent. of a mixture of sodium carbonate and silicate, can be readily poured in casting operations, and yet it may contain less water than a stiff mass of clay without the alkali. The addition of a little acid to the former so as to neutralize the alkali is attended by an immediate "solidification" of the slip. The vessel can then be turned upside down without interfering with the contents. The addition of more alkali will again make the slip pour readily. The amount of the alkali mixture required to give the maximum fluidity with the minimum proportion of water varies from clay to clay. The phenomenon has important industrial applications. It has been discussed by C. Goetz, A. Schmidt, A. Johnson, M. Simonis, O. M. Smith, J. W. Mellor, E. Weber, H. E. Ashley, B. Kosmann, A. V. Bleining and C. E. Fulton, G. Keppeler, M. Rosenoff, M. Böttcher, H. Hirsch, A. Spangenberg, H. G. Schurecht, S. Woessnessensky, A. Fodor and B. Schönfeld, R. C. Wallace and J. E. Maynard, etc.

The above hypothesis shows how the plasticity of a clay can increase with increasing proportions of water so long as the average thickness of the surface films of water on the particle of clay is not greater than the average range of the mol. attraction of the clay for water. When enough water has been added to produce thicker films, part of the water will be outside the range of this attraction, and the clay will be less coherent, and become "sticky." The high surface attraction of clay for water is illustrated by the magnitude of the **Pouillet effect** observed by C. S. M. Pouillet, C. G. Jungk, F. Meissner, and S. Lagergren. According to A. Mitscherlich, with approximately the same surface area, the maximum effect is nearly 1.50 cal. per gram with china clay; 0.03 cal. with ground quartz; and 0.01 cal. with ground flint. J. G. Bouyoucos found the heat of wetting quartz sand is zero; with fine sand, 0.8 cal. per 50 grms. of material; and 607.5 for clay. The heat of wetting is reduced when the materials are preheated, and this the more the higher the temp., until, at 750°, the effect with soils vanished. Attempts by J. Aron, B. Kosmann, O. Bock, W. H. Brewer, P. Rohland, E. Orton, A. Scheid, H. A. Seger, F. Kraze, etc., to refer plasticity to the hydration of the clay mols. have not been very successful because no direct relation has been observed between the plasticity and the water of hydration *per se*. It is, however, noticeable that the greater the plasticity of the clay, the greater the proportion of water required to develop maximum plasticity. Thus, a highly plastic clay may take up 30 per cent. of water before becoming sticky, while less plastic clay requires 20 per cent., and a short clay may become sticky after 10 per cent. of water has been added. O. Ruff contrasted the plasticity obtained by kneading a solid in a viscous fluid—e.g. putty—with the plasticity obtained by the concentration of lyophile substances—e.g. clays—thus attributing the plasticity of clays to the affinity between the clay particles and the water. F. Bourry, and R. Biedermann and H. Herzfeld showed that liquids like absolute alcohol, ether, petroleum, benzene, turpentine, olive oil, glycerol, etc., do not make dry clays plastic in the same sense that water makes them plastic.

In analyzing the effect of acids, bases, and salts on clays, it is necessary to take adsorption into consideration. The relation of the clay particles to the liquid may be drastically modified when the clay particles contain adsorbed salts, acids, etc. R. C. Purdy specially emphasized the function of adsorbed salts. This, however, does not affect the qualitative explanation of the effects just outlined; nor is it necessary to make any assumption as to the nature of the attractive forces. The gravitational attraction of solid for solid has been neglected because it can be regarded as a constant under these conditions. L. Wolf has built an explanation based on T. Schniedel's application of the gravitational law to molecular attraction. C. Tomlinson made a similar hypothesis. The particles of clay are assumed

to attract one another according to the gravitational law; but any other assumed law of attraction would apply equally well.

The remarkable effects of gum and other mucilages in enhancing the plasticity of clay has been utilized by potters for an indefinitely long time. In 1903, E. G. Acheson patented the use of aq. soln. of the tannins and gallotannins, e.g. decoctions of oak-bark, etc.; and in 1918, G. Keppler, and A. Spangenberg patented the use of decoctions of humic acid, peat, etc. These plasticizing agents probably act indirectly by adsorption. The clay particles adsorb the organic colloid, and, judging by results, this probably augments the surface attraction between the particles and the surrounding liquid. The plasticity of china clays, practically free from organic matter, shows that adsorbed organic colloids are not always the source of their plasticity. Clays which have been sodden with ground waters rich in organic matter are usually highly plastic; and those clays which can be shown geologically to have been deposited in swamps and bogs, or which have been in contact with such waters, are usually very plastic unless other metamorphic changes have occurred. Many such clays, however, are not plastic when freshly dug, but they become plastic during weathering. When first mined, some of the clays are hard, but if they be moistened and exposed to sunshine and frost they more or less quickly disintegrate and crumble to fine-grained plastic clays. Clays which are allowed to stand for a long time in contact with moisture become more plastic, or, as the workmen express it, more "buttery." Clays which have been boiled with water also become more plastic. Clays prepared by fast processes—filter-press—are not so "buttery" as when prepared by a slower process—slip-kiln. China clays prepared by the elaborate, apparently primitive Cornish process—by slow sedimentation and slip-kiln—are more plastic than when the process of dewatering the clay is accelerated by filter-press. There is thus an intimate connection between the plasticity of a clay and its past history with respect to water. All this looks as if the clay in contact with water is being hydrated to form a colloidal gel.

Attempts have been made to establish the colloidal theory of plasticity by adding artificially-prepared colloids to feebly plastic clays. A. S. Cushman, for example, found that when colloidal silica is added to such a clay, the air shrinkage and the tensile strength of the clay are increased, but not the plasticity; but with colloidal alumina, neither the air shrinkage nor the tensile strength were increased but the plasticity was augmented. F. F. Grout, however, pointed out that unlike the plasticity of clays, the plasticity acquired by the addition of colloidal alumina is lost when the clay is dried. Similar remarks apply to the colloids prepared by precipitation from a mixed soln. of alum and water-glass. If the plasticity of clays is due to the presence of a colloidal aluminosilicate, it is therefore necessary to assume that it is due to a form which has not yet been recognized. J. Stewart assumed that an organic aluminium component is the colloid, but this is unlikely. From his study of the action of acids and alkalis on the colloidal fractions of clay, R. Bradfield inferred that the colloid is a complex aluminosilicate and not a mixture of hydrated oxides. The properties of T. Schloesing's *l'argile colloïdale* simulate, in a highly exaggerated form, the behaviour of clays on drying, and it is probable that the colloid plays an important part in the drying of clay. The "felting" action *per se* of the particles of the drying clay is scarcely an adequate explanation of the comparatively high tenacity of dried clays. The impermeability of wet puddled clay to water is also difficult to understand on the "felting" hypothesis *simpliciter*.

Clay suspended in water is negatively charged. W. S. Jevons,⁵⁷ and W. Durham said that the electrification is excited by the friction of the clay particles falling in the water, and the water in the vicinity acquires an equal and opposite charge. Hence water and clay are mutually attracted. The latter said that the dissipation of the charge is prevented by the non-conductivity of the water. In the presence of acids or salts the water becomes a good conductor, the charges are neutralized,

and the clay settles. This does not explain the action of peptizing agents which make the water a good conductor and yet keep the clay in suspension—*vide* 3, 23, 8. The acceleration of the sedimentation of clays by electrification whereby the clay is deposited on the anode has been discussed in connection with hydrated silica. The action has also been examined by A. V. Bleining and C. S. Kinnison, R. D. Kleeman, A. Muentz and H. Gaudechon.

Some chemical properties of clays.—According to F. Cornu,⁵⁸ moist kaolinite reacts more or less acid to litmus. H. F. Kriege studied the rate of chlorination of different clays when mixed with carbon and heated in chlorine gas. According to R. van der Lieden, china clay from Zettlitz is slightly soluble when shaken with distilled water at room temp., but it is possible that a colloidal suspension was mistaken for a soln., or the clay was impure, and it is doubtful if china clay is really soluble in water. The attempts made to find the constitution of kaolinite by the action of acids and alkali-lye have been previously discussed; and the action of sulphuric acid in connection with the preparation of alum—5, 33, 20. H. St. C. Deville⁶⁰ examined the solubility of china clay in soda-lye; and he also found that the clay is decomposed by hydrofluosilicic acid (*q.v.*) so that alumina passes into soln. He also removed iron and pyrites from clays by means of hydrochloric acid. China clay is slightly soluble in acetic and hydrochloric acids at ordinary temp.; the former dissolved 1.26 and the latter 0.34 per cent. China clay is still more soluble in hydrochloric or nitric acid at the b.p. when the former dissolved 3.91 and the latter 1.37 per cent. More alumina is dissolved than silica so that the clay is partially decomposed by the acid. Hot conc. sulphuric acid breaks down the clay completely and aluminium sulphate can be obtained from the soln. The action of sulphuric acid was considered by S. Kasai. If the china clay has been heated at temp. between 500° and 800°, it becomes much more soluble in acids. If the calcination be higher than 800°, the

solubility again decreases. R. van der Lieden studied the action of acetic acid. The solubility curve of kaolinite calcined at different temp., Fig. 118, is by A. M. Sokoloff. Alumina also becomes much more soluble after it has been preheated to between 500° and 800°, and less soluble after heating above 800°. The solubility curve for alumina alone is analogous to that for china clay at these temp. A. Geymunt studied the ionic conc. of china clay in soln. of sodium chloride; and R. Bradfield measured the H⁺-concentration of

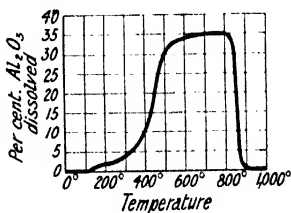

FIG. 118. Hydrochloric Acid Solubility of Kaolinite Calcined at Different Temperatures.

colloid clay. K. D. Glinka studied the action of boiling soln. of potassium hydroxide. J. Lemberg, and S. J. Thugutt found that with a soln. of sodium carbonate, cancrinite is formed; with potassium carbonate, a potassium aluminium silicate; and with a soln. of sodium silicate, analcite is produced. H. Schneiderhöltn studied the action of various salt soln. on china clay. J. H. Davidson, and W. E. S. Turner studied the solubility of clay in molten glass, and G. V. Wilson showed that crystals of feldspar, magnetite, and biotite may be formed in the soln. W. E. S. Turner and co-workers studied the action of fused glasses on fireclays. The disintegrating influence of furnace gases *e.g.* carbon monoxide—on firebricks was investigated by B. M. O'Harra and W. J. Darby, T. Holgate, F. Firmstone, J. Pattinson, L. Bradshaw and W. Emery, J. W. Mellor, C. E. Nesbitt and M. L. Bell, R. M. Howe, L. P. Ross, and A. C. Fieldner and co-workers. The absorption of sulphurous gases by clays was studied by F. G. Jackson; and the adsorption of ammonia from the atmosphere, by J. Bouis, and M. Faraday. For the action of the vapours of ammonium or sodium chloride, *vide* silica. H. Ota and M. Noda found that china clay does not show the indophenol reaction. The polymerizing

effect of healed clay on some unsaturated hydrocarbons was discussed by S. W. Lebedeff and E. P. Filonenko, and L. G. Gurvitsch. H. Freundlich and F. Oppenheimer found that the presence of particles of china clay increased the rate of crystallization of water, and various aq. soln. The subject was also studied by A. Brann and co-workers.

R. N. Brackett and J. F. Williams⁶⁰ found a soft white mineral, occurring as plates or leaves resembling mountain leather, in the sandstone of the Blue Mountain, Arkansas. They called the mineral **rectorite**—after E. W. Rector. The folia are flexible and inelastic, separating with an easy cleavage; and they are softer than talc. The crystals are possibly monoclinic; they are biaxial, and have the optical axial angle $2E=5^{\circ}-20^{\circ}$. The refractive index is low. The composition of the mineral dried at 110° is, $Al_2O_3 \cdot 2SiO_2 \cdot H_2O$. F. W. Clarke wrote $Al_3(SiO_4)_3H_3$. The mineral is sometimes stained with iron oxide. R. N. Brackett and J. F. Williams also found at Sneed's Creek, Newton, Arkansas, soft compact masses of a white powder which they called **newtonite**. The powder consists of minute rhombs with angles $88^{\circ}-89^{\circ}$. The extinction is parallel to the diagonals of the rhombs, and the crystals are thought to belong to the trigonal system. The composition approximates $Al_2O_3 \cdot 2SiO_2 \cdot 5H_2O$. F. W. Clarke wrote $Al(OH)_2(H_3SiO_4)$. The sp. gr. is 2.37. Newtonite resembles halloysite in many respects. It is slightly soluble in hydrochloric acid; decomposed by sulphuric acid with the separation of gelatinous silicic acid; decomposed by boiling soda-lye, leaving a residue insoluble in hydrochloric acid. These two minerals have not been closely investigated, and their relation to the better-known hydrated aluminium silicates remains to be elucidated.

P. Termier⁶¹ described a clay-like, colourless or brown mineral which he called **leverrierite**—after U. J. J. Leverrier. Analyses made by A. Carnot, P. Termier, and E. S. Larsen and E. T. Wherry, do not agree. P. Termier gave $Al_2O_3 \cdot 5SiO_2 \cdot 5H_2O$, as the best representative value; W. Vernadsky gave $Al_2O_3 \cdot 2SiO_2$, corresponding with calcined kaolinite. Leverrierite occurs in vermiculate aggregates in the black shales of the Departments de la Loire, France. The crystals are hexagonal prisms—possibly rhombic. The form and twinning resembles that of the micas. The sp. gr. is 2.3–2.598; the hardness 1.5; the indices of refraction $\alpha=1.554$, and $\gamma=1.582$; the dispersion $\gamma-\alpha=0.028$; and the optical character is negative. E. S. Larsen and E. T. Wherry gave $\omega=1.470$, and $\epsilon=1.515$. F. W. Clarke, and E. S. Larsen and E. T. Wherry regard the group of minerals leverrierite, batchelorite, kryptolite, and delanouite as belonging to the same family—probably the micas. According to W. F. Petterd, **batchelorite** is a green, foliated, clay-like mineral from the Mt. Lyell mine, Tasmania, which was named after W. T. Batchelor; its composition approximates to that of rectorite: $Al_2O_3 \cdot 2SiO_2 \cdot H_2O$.

There is usually a difficulty in assigning formulae calculated from the analyses of the hydrated aluminium silicates because the minerals are so often contaminated with silicic acids, aluminium hydroxides, etc. These hydrates are often colloidal or amorphous. Many of them have been given specific names owing to trifling and accidental differences such as the occurrence in a different locality, or a variation in the colour, state of aggregation, etc., without any attempt being made to correlate the essentials with those of other known minerals. This may be due to excessive zeal in the discovery of new minerals. To the onlooker of descriptive mineralogy it would appear as if the co-ordination of facts has not always been kept in view as the ultimate goal. The colloidal hydrated aluminium silicates have generally been formed by the weathering of crystalline aluminosilicates to which they are related much as china clay is related to felspar. Many of the hydrated aluminium silicates are mixtures of the hydrogels of silica and alumina, and many of them have been artificially synthesized by the simultaneous precipitation of these two gels from aq. soln. of their salts. J. Splichal⁶² measured the refractive index of various mixtures of the hydrogels of silica and alumina after calcination, and found for the $SiO_2 : Al_2O_3$ ratio:

$SiO_2 : Al_2O_3$	0.9 : 1	1.9 : 1	2.8 : 1	4.3 : 1	6.5 : 1
Ref. index	1.580–1.595	1.535–1.545	1.520–1.535	1.495–1.505	1.48–1.49

when 1.68 was obtained for alumina alone, and 1.480–1.485 for silica alone. The

three minerals halloysite, allophane, and montmorillonite may be regarded as types of colloidal or gel minerals. P. Groth, for instance, suggested that allophane and montmorillonite are "loose" compounds of colloidal silicic acid and colloidal aluminium hydroxide, and S. Kasai found that mixtures of these two gels have properties like those of allophane. The work of B. Aarnio, F. Cornu, R. Gans, T. A. Nikolajewsky, H. Stremme, and G. Wiegner shows that these minerals are adsorption compounds of silica gel and alumina gel, although S. J. Thugutt, and E. Löwenstein hold the view that they are definite compounds.

H. le Chatelier examined the thermal changes which occur when halloysite, allophane, and montmorillonite are heated, and considered that each curve is specific and characteristic. J. W. Mellor showed that the heating curves of all three minerals are the same if allowance be made for the presence of kaolinite impurities, and for small variations in the position of the critical points due to differences in the lag determined by differences in the rates of heating. A terrace in the heating curve at about 150° is a characteristic of colloidal silicates and silicic acid; a terrace at about 500° is characteristic of kaolinitic clays (kaolinite or clayite); and a hump in the curve at about 900° is characteristic of alumina (Figs. 51-5, 33, 10) and of aluminium silicates, which are assumed to have broken down at some lower temp. into free silica and free alumina (Figs. 119-120, *vide supra*). Variations in sp. ht.,

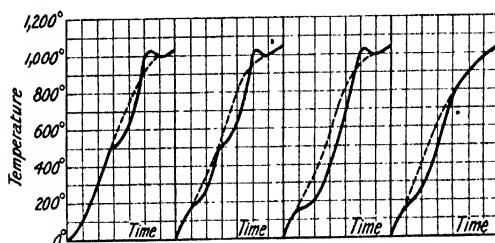

FIG. 119.—Crystals of Kaolinite.

FIG. 121.—Halloysite, Allophane, and Montmorillonite.

FIG. 122.—Silicic Acid.

thermal conductivity, and compactness of the mineral may produce small variations in the positions of the singularities on the heating curves. There is no terrace at 500° with silicic acid, opal, aluminium hydroxide, halloysite, allophane, indianite, lenzinite, schrötterite, collyrite, smectite*, montmorillonite, severite*, cimolite*, razoumoffakite*, anauxite*, and confolensite*. Those marked with an asterisk showed a faint terrace, presumably owing to the presence of impurities; and all of them showed the colloid terrace near 150° , and the alumina hump near 900° . This is in agreement with H. Stremme's suggestion that halloysite, allophane, and montmorillonite are mixtures of hydrogels of silica and alumina; and not chemical individuals. With these views of the nature of these hydrates, the graphic formula representing them as aluminosilicates lose their significance. Summarizing these results, the heating curve of these hydrated aluminium silicates has

Hump at 900'	{	Terrace near 500°	{No terrace about 150'	. Kaolinite.
			{Terrace about 150' .	. Clayite.
		No terrace near 500°	{Terrace about 150' .	. Halloysite, etc.

The so-called *clay-base* or *clay substance* may contain one or more of these constituents.

P. Berthier⁶³ described a friable hard mineral from Angleur, etc., which he called **halloysite**—after J. B. J. d'Omalius d'Halloy, who first noticed the

mineral. Its colour is white, grey, bluish-green, yellow, red, or brown according to the nature and proportion of impurities which are present. The more pure varieties are sometimes translucent particularly near the edges, and the translucency is more pronounced when the mineral is wet. Halloysite occurs massive and earthy. It has a soapy feel. The sp. gr. ranges from 1.92-2.20; and P. Philipenko gave 2.45 at 19°. The hardness is 1-2, and P. Philipenko gave 2.5-3. J. Spichal gave for the index of refraction 1.54-1.57, and after calcination, 1.555-1.595.

Analyses of halloysite were reported by P. Berthier, P. A. Dufrénoy, P. Philipenko, F. Ostwald, V. Monheim, C. Sauvage, M. Thomson and M. Binney, H. le Chatelier, R. Helmhacker, F. Pisani, C. F. Rammelsberg, C. von John, F. W. Clarke and T. M. Chatard, M. F. Heddle, D. Pedro, F. Koch, F. L. Ransome, E. S. Simpson and C. G. Gibson, A. F. Rogers, and H. Stremme. The results are divergent, but the best representative value approximates to $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot n\text{H}_2\text{O}$, with n varying from 3 to 5, usually nearer 3. An air-dried sample from Styria contained 22.42 per cent. of water of which 9.43 per cent. was lost at 110°, and the remainder was lost as the temp. rose gradually above 300°. Air-dried halloysites from various localities were found by A. Lacroix to have from 17.6 to 26.5 per cent. of water. The possible constitutional formulae are as varied as in the case of kaolinite. E. S. Larsen and E. T. Wherry regard halloysite as an amorphous mineral corresponding with kaolinite, but holding extra water either by adsorption or capillarity. As an example of a possible constitution, assuming that halloysite is a chemical individual, the following may be quoted, $\text{O} : \text{Al}_2\text{O}_3 \cdot \text{Si}(\text{OH})_3$. H. le Chatelier found that halloysites lost between 3.5 and 12.5 per cent. of water when heated to 250°. The heating curve shows a rapid evolution of water between 150° and 200°, Fig. 121, and the residue has the composition $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, the same as kaolinite; but the loss of the remaining water at about 500° does not show the kaolinite terrace. There is the alumina hump at about 900°. H. le Chatelier believes that the sedimentary clays do not contain kaolinite, but rather halloysite. J. W. Gregory, and D. P. McDonald adopted a similar hypothesis. J. W. Mellor showed that the results are better interpreted by assuming that these clays contain colloidal kaolinite, *i.e.* clayite, because the heating curves have the kaolinite terrace at about 500°. E. Löwenstein found that when confined at 25° over sulphuric acid of vap. press. p mm. of mercury, the molar loss of water for equilibrium was as follows:

p	23.55	19.60	13.45	4.41	0.56	0.18
Halloysite	0	0.25	0.91	2.32	3.34	3.44
Collyrite	0	0.14	0.42	0.71	0.98	1.14
Montmorillonite	0	1.05	1.93	3.41	4.74	5.16

J. W. Mellor and co-workers obtained analogous results with halloysite. A. B. Dick found the refractive indices of the opaline halloysites ranged from 1.522 to 1.544. When boiled in water, and afterwards dried spontaneously in air, their refractive indices were not changed; but if dried for a fortnight at ordinary atm. press., over conc. sulphuric acid, the refractive index rose to 1.555. Dry air decomposes the minerals because, when placed in damp air for some days to regain the lost water, they do not regain their original refractive index. There are some museum specimens of halloysite with a refractive index a little over 1.56. They have a cryptocrystalline structure and a faint double refraction. A. B. Dick said that these specimens may be kaolinite or rectorite, or an alkaline earth silicate. J. Spichal gave 1.54-1.57 for the refractive indices of the halloysites from Angleur, Belgium, and Radzionkow, Silesia; and after ignition, 1.555-1.595. Halloysite is partly decomposed by cold conc. hydrochloric acid, and completely decomposed by the boiling acid. Similarly also with sulphuric acid.

A. Breithaupt called ordinary compact halloysite from Angler, *galapectite*, and a dense gum-like variety which does not adhere to the tongue, *gummite*. A gum-like clay from Budapest was called halloysite by F. Koch. P. A. Dufrénoy's *argile chimique* is probably halloysite. A compact, earthy, white, translucent variety of halloysite from La Vilate, France, was called by J. F. John, *lenzinite* or *lenzite*—after D. G. J. Lenz; its composition

is $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$; and a brownish variety from Call, Eifel, had a composition $3\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2 \cdot 11\text{H}_2\text{O}$. C. C. von Leonhard regarded it as a decomposed semipal. It is said not to gelatinize with acids. For the heating curve, *vide* Fig. 121. The term lenzinite has also been applied to white clay with a large proportion of silica. The lenzinite from St. Séverin was called by F. S. Beudant *séverite*. It was analyzed by J. Pelletier; and discussed by C. von Hauer. For the heating curve, *vide* Fig. 121. A white clay with a conchoidal fracture from Lawrence, Indiana, resembling halloysite, was called by E. T. Cox *indianite*. The sp. gr. is 2.31–2.53, and the hardness 2–2½. Indianite was discussed by W. N. Logan, A. M. Gibson, H. A. Wheeler, etc. For the heating curve, *vide* Fig. 121. The term indianite has been also applied to a brown anorthite from India. A white or yellowish-white earth from Bergensreuth, Bavaria, was called by A. Breithaupt *glagerite*—from γλαγρός, milk coloured. There are two varieties, one is earthy, with a sp. gr. 2.355, and a composition $2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 6\text{H}_2\text{O}$; the other is compact, with a sp. gr. 2.331, and a composition $2\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 6\text{H}_2\text{O}$. Glagerite was analyzed by J. F. John, and A. Sajtzoff. A. B. Dick gave 1.544 for the refractive index. J. Fikenstein found that A. Breithaupt's glagerite is halloysite. A variety of halloysite from Condé-sur-Végre, France, was called by A. Salvétat, *smectite*—from σμῆξις, detersive earth. It has a greenish colour, and a greasy appearance; and in certain states of humidity appears almost transparent and gelatinous. It was examined by L. A. Jordan. For the heating curve, *vide* Fig. 121. A. Breithaupt applied the term smectite to a kind of fuller's earth from Styria. C. U. Shepard called a milk-white variety of halloysite from Dade, Georgia, *glossacolite*. It was analyzed by F. Pisani. M. Thomson and M. Binney applied the term *pseudoscatite* to an impure green halloysite from Bathgate, Scotland. A white or bluish-white earth obtained at Nertschinsk was called *neretschinskite* by E. F. Glocker, who considered it to be a variety of lenzite. E. Tietze called a white earth from Maidanpek, Serbia, *milanite*. An opaque milk-white slightly lustrous clay from the red sandstone on the banks of the Tweed, Scotland, was called by T. Thomson *tuesite*—from the Latin *Tuesis*, the Tweed. C. F. Rammelsberg gave a number of analyses. The sp. gr. is 2.434–2.624. P. A. Dufrenoy, J. Niol, and J. W. Gregory regard *tuesite* as a variety of halloysite. It is amorphous and practically isotropic.

Cimolian earth referred to by Theophrastus⁴⁴ as κίμωλία; by Pliny as *cimolia*; and by M. H. Klaproth as *cimolite*, is a greyish-white clay when freshly dug, but it acquires a reddish tint on exposure to air. It was originally obtained from Kinlos, i.e. the island of Argentiera, and a similar earth has been reported from other localities. Cimolian earth has a slaty fracture; and is difficult to powder. E. Dittler and J. E. Hibsch gave $2\text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 6\text{H}_2\text{O}$ for the formula. Cimolite is a structureless powder. Its sp. gr. is 2.18–2.30. It sticks to the tongue, and on immersion in water, it splits into flakes and forms a cream-like slip when ground with water. In this form it has been used for removing oils and fats from wool and silk. Analyses were reported by M. H. Klaproth, C. F. Rammelsberg, R. B. Riggs, F. W. Clarke, R. Scharizer, and A. Laversidge; the results are not concordant; the average approximates $2\text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 6\text{H}_2\text{O}$. The mineral is probably a mixture of the hydrogels of silica and alumina. For the heating curve, *vide* Fig. 121. F. W. Clarke gave for cimolite, $\text{Al}(\text{Si}_2\text{O}_5)_2 \cdot 6\text{H}_2\text{O}$. A. Breithaupt described a greenish-white cimolite in the weathered basalt of Bilin, Bohemia, which he called *anauzite*—from ἀναύζειν, not softening—in allusion to its behaviour in the blowpipe flame. Its sp. gr. is 2.26; E. Dittler and J. E. Hibsch gave 2.524. It was analyzed by C. von Hauer. E. Dittler and J. E. Hibsch gave the formula $3\text{Al}_2\text{O}_3 \cdot 10\text{SiO}_2 \cdot 8\text{H}_2\text{O}$. They say the crystals are rhombic and unlike those of kaolinite. The heating curve is shown in Fig. 121. The *pelikanite* of N. Ouchakoff is a mixture of cimolite and quartz found at Kieff, Russia. The *hunderite* of S. Haughton is a similar earth.

J. J. Nöggerath described a rose-red earth from the trachyte of the Siebengebirges which he called *ehrenbergite*. It is almost gelatinous when freshly dug, and it becomes fragile and pulverulent when dried. It swells up like boiled starch when placed in water. W. C. Knight⁴⁵ discovered a soft fine-grained clay in the Benton formation of Wyoming, and he first named it *taylorite*—after W. Taylor—but the name was afterwards altered to *bentonite* when it was found that taylorite was already in use for something else. The mineral was also reported in other localities by N. H. Darton, C. E. Siebenthal, etc. In some respects bentonite resembles ehrenbergite. It is supposed in some cases to have been formed by the weathering of labradorite; in other cases, as shown by E. T. Wherry, and C. S. Ross and E. V. Shannon, it is considered to be derived from volcanic ash which has sometimes been reworked and mixed with detrital matters. Often it is made up of varying proportions of volcanic rock, phenocrysts, and a devitrification product of glass. There are, however, several varieties probably derived from different sources. The composition approximates $\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. H. G. Schurecht and H. W. Doude consider that bentonite is a mixture of colloidal silicates and fine-grained kaolinite. The colour when freshly dug is yellowish-green, which changes to a pale cream on exposure to air. The sp. gr. is 2.132–2.180. When placed in water some varieties absorb more than three times their weight or up to eight times their own volume of water, swelling considerably, and producing a jelly-like mass which recalls some of the adhesive pastes. According to W. A. Nelson, when bentonite is boiled with sulphuric acid, nearly all the alumina passes

into soln. Bentonite has been used in the manufacture of soap, as a filler for paper, as a sizing for yarn, as a diluent for certain drugs, and as a raw constituent of glazes to help in keeping the materials suspended in water. Numerous possible uses have been suggested. It has high adsorptive powers resembling those of diatomaceous earth. H. F. Coward found bentonite is a typical negative suspensoidal colloid in that the particles are negatively charged, and the charge decreases with increasing quantities of electrolytes—acids, alkalies, or salts—until, with a sufficient concentration, the whole is sedimented in a gelatinized form. The flocculation is reversible.

Many kinds of clay-like substances have been called **fuller's earth**, in allusion to the fact that they have long been used for "fulling" or removing grease from woollen goods. Fuller's earth corresponds with the description of the *creta cimolia* or *cimolian earth* of Pliny's *Historia naturalis* (17. 4; and 35. 57). The earth was used by the Romans for scouring cloth. The Metilian Law of the Romans had to do with the *ars fullonia*. In ancient times, the cloth was washed by stamping it with water and *creta fullonia* which acted partly by scouring and partly by absorbing greasy dirt. According to J. Beckmann,⁶⁶ the mill where cloth was scoured as it came from the loom was formerly called *fullencium*, or *molendium cum fullione*. A. G. Werner, L. A. Emmerling, etc., called a clay of this kind *Walkererde*, *Walkthon*, or *Walkerde*; A. J. M. Brochant, *la terre à foulon*; J. G. Wallerius, *smectis*; R. J. Haüy, *argile smectique*; and A. Breithaupt, *walkerite*, *smectite* (*vide halloysite*), and *malthacite*. Fuller's earth has been worked in Great Britain for very many years—at Reigate and Nutfield, Surrey; Bath, Somerset; etc. Various other occurrences have been reported by J. Woodward, J. C. Branner, A. E. Fersmann, A. H. Cox, G. M. Davies, J. Middleton, H. D. Miser, P. G. Morgan, F. J. Bennett, H. Ries, H. K. Shearer, R. Tate, D. J. Day, A. C. G. Cameron, J. T. Porter, T. W. Vaughan, E. H. Sellards and H. Gunter, L. E. Aubury, A. Duessen, W. C. Alden, O. Veatch, E. Sloan, etc. In the eighteenth century, a special Act was passed prohibiting its export from England; after the repeal of the Act, England was the chief producer for the world, but in recent years has been outstripped by the United States. The mining of fuller's earth is like that of other clays. The earth may or may not be washed by levigation as in the case of china clay. In the washing, the earth remaining suspended in water after the grosser impurities have settled, is finally dried in kilns. The drying temp. must be low, or the adsorbent qualities are impaired. The preparation of fuller's earth for the market was described by H. B. Woodward, W. C. Phalen, A. C. G. Cameron, C. L. Parsons, etc.

The first analysis was made by T. Bergman, and analyses were afterwards reported by M. H. Klaproth, T. Thomson, R. Sachse and A. Becker, H. B. Woodward, J. G. Sanford, H. Ries, J. Brierley, L. A. Jordan, J. T. Porter, etc. The results range from 44.00–72.00 per cent. SiO_2 ; 5.00–33.38, Al_2O_3 ; 4.89–24.95, H_2O ; 1.26–14.87, Fe_2O_3 ; 0.33–7.40, CaO ; 0.43–4.36, MgO ; alkalies, 0.45–5.00; with small amounts of organic matter SO_3 , P_2O_5 , and TiO_2 . The variations in composition are so great that analysis alone does not determine whether a particular clay is to be classed as a fuller's earth. Fuller's earth contains hydrated aluminium silicates, incompletely decomposed mineral matters, and various detrital minerals. The petrology of fuller's earth has been discussed by A. H. Cox, and T. Crook. H. Ries said that hydrated silica is usually present. A. Breithaupt supposed *smectite*, $\text{Al}_2\text{O}_3 \cdot 7\text{SiO}_2 \cdot 12\text{H}_2\text{O}$, and *malthacite*, $\text{Al}_2\text{O}_3 \cdot 7\text{SiO}_2 \cdot 16\text{H}_2\text{O}$, to be primary constituents. The conclusion, however, is not very convincing. The origin of fuller's earth has not been elucidated. H. Credner said that while kaolinitic clays are derived from the decomposition of felspathic rocks, fuller's earth is probably derived from hornblende, amphibole, and augite rocks—e.g. gabbros, diorites, diabases, and basalts.

The colour of fuller's earth may be white, grey, green, or brown. It does not adhere to the tongue and it softens when placed in water. The sp. gr. ranges from 1.9–2.1. Some fuller's earths have an acid reaction, others are neutral. The so-called *Kambara clay* of Japan is like an acidic fuller's earth. Its properties were described by K. Kobayashi, and S. Veno. The adsorbent quality of fuller's earth is determined by the constituent colloidal aluminium silicates. Most of the fuller's earths contain much water, but, as C. L. Parsons showed, some of the earths adsorb as well after the water has been expelled as they did before; others have their adsorbent power much weakened. Although still used as a kind of *argile savonneuse* in cleaning cloth, washing woollens, and fine-dyed goods, fuller's earth is still more extensively employed in refining oils, fats, lard, etc. J. E. Gilpin and O. E. Bransky found that the selective adsorption by fuller's earth is greatest for oils of high sp. gr. and viscosity, for unsaturated hydrocarbons, and for sulphur compounds. E. K. Rideal and W. Thomas believe that with the earths from Surrey, Somerset, and Florida, the adsorption of methylene blue from aq. soln. is approximately proportional to the sp. surface of the earths, while the catalytic activities in decomposing hydrogen dioxide are not dependent on the adsorption and may depend on the iron content. The specific adsorbent qualities of fuller's earth have been discussed by V. F. Herr, J. E. Gilpin and co-workers, L. G. Gurvitch, D. Wesson, W. R. Jewell, T. G. Richert, A. Seidell, C. L. Parsons, J. J. Vollertson, etc. A little is used as a pigment for wall-papers, and the finest grades in toilet preparations.

F. Stromeyer and J. F. L. Hausmann⁶⁷ applied the term **allophane** to a mineral

occurring in cavities in a marl near Saalfeld, Thuringia. The name is derived from *ἄλλος*, other; *φαίνεσθαι*, to appear, in allusion to the change in the appearance of the mineral before the blowpipe flame. A. Breithaupt called it *riemannite*. Allophane is a hard, brittle, opaque, non-crystalline earth; the edges of the fragments are sometimes translucent. The colour may be white, but more commonly sky-blue, green, red, or brown. The fracture is conchoidal, and the lustre vitreous. The sp. gr. is 1.89–2.02. J. Spical gave for the index of refraction 1.480–1.490; and after calcination, 1.505–1.570. The mineral has been found in different localities and described by W. D. Herman, J. Morris, J. Prestwich, R. H. Chandler, G. vom Rath, P. Berthier, A. B. Northcote, C. T. Jackson, B. Silliman, etc. Analyses were reported by F. Stromeyer, F. A. Walchner, J. Guillemin, R. Bunsen, P. Berthier, A. B. Northcote, B. Silliman, C. T. Jackson, E. F. Smith, J. Gamper, A. F. Rogers, C. F. Rammelsberg, F. Kretschmer, G. d'Achiardi, S. Kasai, A. Nikolavsky, etc. The results approximate to $Al_2O_3 \cdot SiO_2 \cdot nH_2O$, where n may be 4, 5, or 6. F. W. Clarke gave $\{Al(OH)_2\}_2 \cdot H_2SiO_4 \cdot 3H_2O$, or, analogously to andalusite, $Al_2(SiO_4)_2 \cdot \{Al(OH)_2\}_2 \cdot 12H_2O$. According to S. J. Thugutt, and H. Strenme, the mineral is probably a mixture of the hydrogels of silica and alumina. For the heating curve, *vide* Fig. 121. J. Spical found the refractive indices of samples of allophane from Hromice, Bohemia; Bogsan, Banat; and Borovec, Moravia, to range from 1.480–1.490 before calcination, and after calcination, 1.505–1.570. Allophane is partly decomposed by cold conc. hydrochloric acid, and completely decomposed by the boiling acid. H. Schneiderhölml studied the action of various salt soln. on allophane; and R. van der Lieden, the action of acetic acid.

The blue variety looks like a copper ore, and presumably contains chrysocolla; the green variety contains malachite. C. Schnabel found a sample with nearly 19 per cent. CuO ; and the yellow and brown varieties, iron oxides or hydroxides. B. Silliman found a sample with admixed gibbsite. The yellow variety from Kornwestheim contained aluminite, and M. van Groningen and A. Oppel called the mineral *siliceous aluminite*; L. Muck designated a similar variety from Schwelm, Westphalia, *sulphatellophane*; and L. Bombicci named a variety from Mt. Vocchio, Sarlinia containing a little lead, *plumb-allophane*. A. L. Sach found a reddish allophane at Friesdorf, Bonn, and called it *chrysurite*; it was described by E. F. Glocker, and R. Bunsen. F. L. Sonnenschein applied the term *carolithine*—after Prince Carolath—to a yellow allophane from Zabrze, Silesia. The white or yellow allophane found by J. D. Dana as stalactites and stalagmites in the lava caverns on the island of Upolu, Samoa, was styled *samoite*. F. W. Clarke gave the formula $Al_2(SiO_4)_2 \cdot 12H_2O$. V. von Zepharovich reported a ferruginous variety. J. D. Dana considered that the samoite of B. Silliman is probably a labradorite.

D. L. G. Karsten⁶⁸ employed the term *collyrite*, for the white clay which he found near Schemnitz, Hungary, because it agrees well with Dioscorides' description of the Samian earth *καλλύριον*, and Pliny's *collyrium*. J. C. Freiesleben called it *Salpeter*, and M. H. Klaproth, *natürliche Alaunerde*. Collyrite is very like allophane in its general properties. Occurrences were reported by W. V. Vernon, A. Brongniart, J. C. G. de Marignac, J. Jacobson, etc. Analyses of collyrite were made by M. H. Klaproth, P. Berthier, C. M. Kersten, and J. H. and G. Gladstone. The best representative value is $2Al_2O_3 \cdot SiO_2 \cdot 9H_2O$ —F. W. Clarke gave $(AlO)_4 \cdot SiO_4 \cdot 6H_2O$. It is probably a mixture of the hydrogels of silica and alumina. G. Vogt regarded the clay of Hesdin, France, as a mixture of 30 per cent. allophane and 70 per cent. kaolin. H. le Chatelier called the same clay collyrite. The collyrite found at Scarborough, Yorkshire, was called by W. V. Vernon, *scarborovite*; its nature was discussed by J. F. L. Hausmann. A greenish or yellowish clay resembling allophane, and found by A. Schrötter near Freienstein, Styria, was called *opaline allophane*; E. F. Glocker named it *schrötterite*. It was analyzed by A. Schrötter, and J. W. Mallet. Its composition is variable, for the ratios $Al_2O_3 : SiO_2 : H_2O$ range over 8 : 3 : 30, 7 : 3 : 36, and 5 : 2 : 20. The index of refraction is 1.584. F. Zambonini regarded a sample from Saalfeld as a mixture of $3(Al_2SiO_5 \cdot 8H_2O) + 8Al(OH)_3$; and R. Helmhaecker believed a sample from Freienstein to be a mixture of halloysite and variscite. F. W. Clarke gave the formula $\{Al(OH)_2\}_4 SiO_4 \cdot 6H_2O$. The heating curves—Fig. 121—show that collyrite is a mixture of the hydrogels of silica and alumina. The vap. press. of collyrite is indicated above.

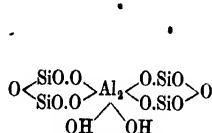

A. Selvetat⁶⁹ found a rose-red clay in pockets in the brown clay of Montmorillon, France, and he called it *montmorillonite*. The clay was reported from

other localities, and analyses have been made by A. Damour, L. Azénma, A. von Fersmann, D. Lovisato, H. Leitmeier, C. von Hauer, H. le Chatelier, R. Helmhacker, H. L. Wells, C. S. Ross and E. V. Shannon, and J. H. Collins. The analyses are not concordant, but the best representative value is $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 9\text{H}_2\text{O}$. The heating curve—Fig. 121—indicates that montmorillonite is a mixture of the hydrogels of silica and alumina. J. Splichal gave for the index of refraction 1.50; and after calcination, 1.510–1.525. H. Leitmeier kept the isotropic hydrogel from Zogora, Bulgaria, for three years when it had acquired a feeble birefringence, indicating that it had become crystalline, with an index of refraction 1.51. This may be a chemical individual, or a solid soln. of silicic acid and of a simpler aluminium silicate. The vap. press. of montmorillonite has been indicated above. According to A. Salvétat, an aq. soln. of sodium carbonate dissolves a little silica from montmorillonite; the mineral is partially decomposed by cold, conc. hydrochloric acid, and completely decomposed by the boiling acid.

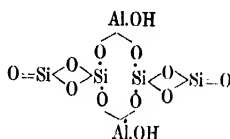

A number of varieties have been reported. A pale rose variety found at Confolens, and St. Jean-de-Cole (Thiviers), was called *confolensite* by A. P. Dufrénoy. It was analyzed by P. Berthier, and A. Salvétat. For the heating curve, *vide* Fig. 121. G. A. Kenngott, and C. von Hauer described a variety from Millac, France, and called it *delanovite*. It is rose-red when freshly dug, but the colour darkens on exposure to air. A. des Cloizeaux described white, yellow, or green varieties from Violet, and Poitiers, France; and he called this mineral *steargillite* or *steatargillite*. A yellowish clay, resembling steargillite, found in the basalt of Stolpen, Saxony, was called *stolpenite*, or the *bole of Stolpen*, by G. A. Kenngott, C. F. Rammelsberg, A. von Fersmann, D. Lovisato, and C. F. Naumann. T. Thomson called a yellowish-red clay from Giant's Causeway, Ireland, *erinite*—from *Erin*, Ireland. A white or mottled green clay from the serpentine of Frankenstein and Kosmutz, Silesia, was called *razoumowskyn* by J. F. John and J. Zellner. R. Helmhacker reported a similar bluish clay from Lading, Carinthia. Some calcite and azurite were also present as impurities. For the heating curve, *vide* Fig. 121. J. Nickles applied the term *saponite* to a white, plastic, soap-like clay occurring in the granite from which issues one of the hot springs at Plombières, France. R. P. D. Graham analyzed a sample from Montreal. C. F. Naumann named a similar clay *smegmatite*. This clay is one of a series called *mountain soap*, *pierre à savon*, or *Bergseife* referred to by C. F. Bucholz, H. O. A. Fiecinus, and S. J. S. Beckmann. There is also a variety of meerschaum, or soap-stone which is the true saponite. S. D. Villarelo described what he called *paramontmorillonite* from Michoagan, Mexico, as a mineral with the composition $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 5\text{H}_2\text{O}$, or $\text{H}_4\text{Al}_2\text{Si}_4\text{O}_{14} \cdot 2\text{H}_2\text{O}$. G. Friedel described a mineral from Miramont, France, which he called *termierite*; its composition approximates $\text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 18\text{H}_2\text{O}$. Its sp. gr. is 1.54; hardness, 2; and index of refraction, 1.403. The partially dehydrated mineral takes up ether, benzene, or methylene iodide; but these are readily displaced by water.

M. H. Klaproth⁷⁰ employed the term *agalmatolite* for a talc-like mineral; C. A. G. Napione used *pagodite*, and for the Chinese mineral A. Breithaupt used *gemmahuji*. Some of the agalmatolites are not hydrated aluminium silicates, but rather nephelites, and hydrated magnesium aluminium silicates (*q.v.*). R. Hermann received a sample of the supposed talc from Ural, and showed that it is really an aluminium silicate which he designated *pyrophyllite*—from *πῦρ*, fire; and *φύλλον*, a leaf. K. G. Fieldler found a similar mineral at Berjosowsk, Ural. A. Breithaupt proposed to use the term *pyrauxite*—from *πῦρ*, fire; and *αἴξω*, to increase—in allusion to its behaviour when heated. The occurrence of pyrophyllite in various localities has been indicated by G. Rose, L. L. de Koninck, L. J. Igelström, H. Sjögren, E. Schumacher, G. A. Kenngott, H. Gorceix, G. J. Brush, F. A. Genth, V. von Zepharovich, R. Helmhacker, M. F. Heddle, W. I. Macadam, A. Frenzel, P. Groth, and F. von Richthofen. Analyses were made by R. Hermann, C. F. Rammelsberg, L. L. de Koninck, H. Sjögren, L. J. Igelström, H. Gorciex, J. L. Smith, G. J. Brush, F. A. Genth, A. H. Church, M. H. Klaproth, J. F. John, E. Walstedt, M. F. Heddle, W. I. Macadam, C. W. von Gümbel, F. Dewalque, F. W. Clarke, J. Samojloff, J. Morozewicz, J. H. Pratt, T. Löwinson-Lessing, A. Huntzelmann, and A. Damour. The relation between agalmatolite and pyrophyllite was shown by G. J. Brush. The best representative formula was given by G. A. Kenngott, $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O}$, or $\text{H}_2\text{Al}_2\text{Si}_4\text{O}_{12}$, or HAlSi_2O_6 . Other

formulae were suggested by J. Morozewicz, and T. Löwinson-Lessing. The latter regarded the pyrophyllite of Pyshminsk as a mixture of pyrophyllite, $3\text{Al}_2\text{O}_3 \cdot 11\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, which is optically negative, and *pseudo-pyrophyllite*, $3\text{MgO} \cdot 4\text{Al}_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 8\text{H}_2\text{O}$, which is optically positive. F. W. Clarke and G. Steiger, and H. C. McNeil proposed $\text{HO} \cdot \text{Al} : \text{Si}_2\text{O}_5$; and R. Scharizer, and W. Vernadsky gave respectively:

R. Scharizer's formula.

W. Vernadsky's formula

K. von Chroustschoff claimed to have obtained a zirconiferous pyrophyllite by heating a mixture of silicic acid, water, alumina, and zirconia to dark redness; and E. Baur, and M. Schläpfer, pyrophyllite, by heating a mixture of silicic acid, alumina, and potassium silicate in an autoclave. Pyrophyllite is a crystalline mineral belonging to the rhombic or monoclinic system. It occurs as a compact mass of small crystalline plates or radiating fibres. It is more or less translucent, and coloured white, grey, yellow, green, or brown. It has a greasy feel, and a dull matte or mother-of-pearl lustre. A. Michel-Lévy and A. Lacroix found the refractive index is 1.58; and the double refraction, 0.041. A. des Cloizeaux showed that the axial angle $2V=62^\circ$; and $2E=110^\circ 28'$ at 170° , and this diminished with a rise of temp. to $105^\circ 30'$ at 135° . The hardness is nearly 1; and the sp. gr., 2.8–2.9. H. le Chatelier observed the variations of temp. when the mineral is heated; and J. W. Mellor's heating curve is indicated in Fig. 123. R. Wohlin, and J. L. Stuckey obtained a similar curve. Pyrophyllite loses an appreciable quantity of water at about 500° ; thus after heating 2 hrs. at 500° the mineral lost 0.33 per cent., kaolinite under the same conditions lost nearly all its combined water. The combined water is given off at about 700° . G. Tammann found that when confined over sulphuric acid with a partial press. p of water vap., pyrophyllite lost the following percentage amounts of water:

p	15.72	14.55	12.48	9.11	6.05	2.93	0.11
Loss	0.000	0.027	0.035	0.039	0.050	0.059	0.060 per cent.

J. W. Mellor and co-workers obtained higher values. Pyrophyllite swells to twice its bulk when heated. A. Johnsen studied the optical properties of the mineral. E. S. Larsen gave for the indices of refraction $\alpha=1.552$, $\beta=1.588$, and $\gamma=1.600$. F. Cornu found that the moist powder reacts alkaline to litmus. The mineral is but slightly attacked by aq. soln. of sodium carbonate, but, according to F. W. Clarke and G. Steiger, and H. C. MacNeil, when the pyrophyllite has been calcined, about 2.84 per cent. of the silica becomes soluble in that menstruum; and when calcined in ammonium chloride vap., about 6 per cent. becomes soluble. K. D. Glinka studied the action of potassium hydroxide on pyrophyllite. Pyrophyllite is but slightly affected by hydrochloric acid; while sulphuric acid decomposes it with the separation of gelatinous silica. Some varieties of agalmatolite were employed by the Chinese for carving figures; it has also been used for making slate-pencils since it leaves a white trace on slate—hence the name *pencil-stone*.

T. Scheerer¹¹ applied the term *lardite* to a greenish agalmatolite analyzed by T. Thomson. A light greenish-white variety of pyrophyllite was found by C. W. von Gümbel at Nord-

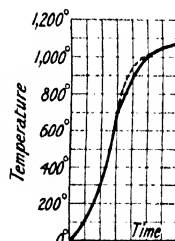

FIG. 123.—The Heating Curve of Pyrophyllite.

halben, Oberfranken. The mineral was analyzed by F. von Kobell, and A. Terrell, and named *gambelile*. C. W. Blomstrand found reddish fibrous aggregates in the pyrophyllite of Vestana, Sweden, and named the mineral *vestanite* or *westanite*. The composition approximates $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$, and P. Groth regarded it as a hydrated andalusite. K. F. Peters found a granular microcrystalline mineral in the limestone of Biharberg, Hungary, and named it *biharite*. W. Haidinger considered it to be a variety of agalmatolite. A fibrous variety of agalmatolite was found by T. S. Hunt at Stanstead, Canada, and named *neuroilite*—from *vetpor*, a fibre or tendon. T. S. Hunt, and T. Thomson analyzed the mineral, and the results show that it approximates in composition to pyrophyllite. A. H. Church described a massive greyish-green agalmatolite-like mineral from the Restormel Mine, Cornwall. He called it *restormelite*. The hardness was 2, the sp. gr. 2.58, and the analysis 45.66, SiO_2 ; 35.10, Al_2O_3 ; 1.11, FeO; 0.85, MgO; 2.30, K_2O ; 4.39, Na_2O ; 11.68, H_2O .

§ 36. Pottery

The potter's art has been so universally practised that there is probably no nation, whether barbarous or civilized, which could not contribute some interesting pages to a general history of pottery; whilst in almost every country it would be found that the state of this art at any particular time is a tolerably fair test of the degree of civilization to which its people had attained.—S. W. BAKER.

The potter's art, in its more primitive forms, has been practised from the remotest of prehistoric times in various parts of the earth. Only a few peoples have been found to be unacquainted with the fictile art—e.g. the natives of Australia, New Zealand, and some Polynesian islands; the nomadic tribes of Siberia; the natives of the extreme south of South America, and South Africa; and of the north-western region of North America. The art as practised to-day in some parts of Africa represents a very early stage in the manufacture of pottery.

The *fossil pottery* found in the soil of the country from Hanover to Thuringia, and Bohemia, was once thought to grow naturally like truffles in the ground. J. Matthesius,¹ B. A. Balbinus, and others had no doubts and they quoted irrefutable proofs, if such were needed, that these pots, *olla fossiles* as B. A. Balbinus called them, were the result of nature's parturient forces. It was argued that to question the fact was nothing short of heresy; did not the Psalms (139. 15) refer to "the vessels formed within the earth"? It was some time before the sceptics were able to show that the *olla fossiles* were really cinerary urns from the burial ground of indigenous tribes living in North Germany long before the Roman invasion. Those vessels represent an early stage in the manufacture of pottery. According to L. von Ledebur, in 1838, about two thousand pamphlets and books had been written on the cinerary urns of Germany.

Fragments of fired bricks have been found by borings in the Nile basin. From their depth, and assuming that the rate of deposition of the Nile mud has been continuously the same in past times as it is at present, it has been estimated that the bricks are over ten thousand years old. The tombs of ancient Egypt,² however, furnish the earliest definite evidence of a refining of the technique of this fictile art. Terra-cotta vessels, common to most primitive civilizations, have been found in the tombs of Memphis, and these are estimated to belong to the period 5000–3000 B.C. The Egyptians practised the compounding of bodies, glazing, and enamelling long before these arts were acquired by any other nation. Scenes from Egyptian life in the period 3000–1700 B.C. have been found depicted on the walls of tombs at Thebes representing the making, Fig. 124, and the firing, Fig. 125, of vases in

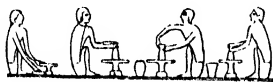

FIG. 124.—Throwing Pottery in Ancient Egypt.

FIG. 125.—Firing Pottery in Ancient Egypt.

ovens. Glazed earthenware, made in the period 3000–1700 B.C., has been found in the pyramid of Saggareh. The decorations of the temple of Tell-el-Yadouai, built by Rameses III, show that the potter's art was well advanced between 1700 and 500 B.C. The Egyptian potter's wheel is not essentially different from that employed to-day. According to H. le Chatelier, samples of pottery from Saggarah (Memphis) show that the Egyptians made real porcelain. The description and analyses, however, agree better with the assumption that the pottery in question was a more or less opaque glass. Some statuettes found in Egyptian tombs are usually thought to have been carved out of natural sandstone, and covered with a cupriferaous sodium silicate glaze. H. le Chatelier assumes that the body was artificially made. There are several biblical allusions to the potter's

art—e.g. *Jeremiah* 18. 1-6. It may be added that the potter's ovens depicted in Fig. 125 seem to be of a type similar to many of those used by the Romans; and these in turn pass by an easy transition to the intermittent ovens used at the present day.

The bricks from Chaldean and Assyrian ruins show that these peoples were adepts at the work, but whether or not their knowledge was borrowed from Egyptian sources no one can say. The ruins of Nineveh and Babylon furnish bricks sometimes coloured with blue, grey, or yellow glazes. The traditions of the Assyrian potters seem to have stimulated the Persians, who acquired great skill in the art of glazing. The beautiful turquoise-blue cupriferous glaze of the Persian tiles has never been surpassed. The potter's art was carried to Greece. The Mycenaean pottery is referred to in Homer's *Iliad* (18. 560).³ Although the Grecian potters produced some magnificent ware, they did not specially develop the methods of glazing so well employed by their neighbours, the Persians. The term *ceramic* comes from Greece. The potteries of Athens were located at Kerameis, and the inhabitants—mainly potters—were called Kerameis.⁴ The term *ceramic* thus came to be employed for the potter's art; and by an easy transition the term *ceramic art* was applied to the clayworker's art generally. In Pliny's time, beautiful pottery was made in several towns both in Greece and in Italy. The Roman potters were stimulated by contact with the Greeks, and are noted for the Etruscan ware made in Etruria, and the red *samian ware* used for domestic purposes.

The secrets of the art of glazing⁵ pottery passed from the Persians to the Arabians. The Moors carried the art into Spain, and it then passed on to the Island of Majorca. This gave rise to the name *majolica*—an old Tuscan name for the island. A similar kind of ware made at Faenza, Italy, in the thirteenth century, was called *faience*. The art of glazing pottery with plumbiferous and stanniferous glazes was practised in several places in Europe during the latter part of the Middle Ages. It has been suggested that in the twelfth-century Latin work, *De investigatione magisterii*, attributed to Geber, the instruction to evaporate a soln. of salt in *vase terreo plumbato* refers to an earthen vessel coated with a plumbiferous glaze. Albertus Magnus, in the thirteenth century, in his *De alchymia*, mentioned the use of red-lead for glazing pottery; in the fourteenth century, P. Bonus, in his *Margarita pretiosa* (1330), spoke of the use of tin and lead oxides in this connection; and in the sixteenth century, D. Agricola gave some glaze recipes; while J. B. Porta indicated the use of lead oxide in making glasses to imitate precious stones. According to B. Laufer,⁶ the production of glazes in Western Asia stimulated the Chinese to develop the idea. It is probable that the Chinese were making porcelain towards the end of the sixth century, and they had attained a very high skill in the art during the Tang, Sung, and Yuan Dynasties, 618-1367 A.D. The importation of Chinese porcelain into Europe by Eastern traders acted as a great stimulus on the European potters.

According to A. Foresi,⁷ the Venetian glass-makers imitated the Oriental ware by heating mixtures of an impure china clay, sand, and glass. R. A. F. de Reaumur likewise, in France, obtained an imitation by a similar method, and also by the devitrification of glass—*porcelaine par devitrification*. This subject was discussed by W. Lewis, A. Dartigues, and L. B. G. de Morveau. The discovery of the mode of manufacturing porcelain at Meissen early in the eighteenth century has been mentioned in connection with china clay. The two letters of Père d'Entrecolles, a Jesuit missionary in the pottery district of China, reached Europe about this time. The first letter is dated Sept. 1, 1712. These letters contained some acute observations on the methods employed for manufacturing porcelain in China. The art gradually spread through Europe in spite of the elaborate precautions at Meissen to keep the procedure a secret. The first clear description of the Meissen process was published by N. C. de Milly in his *L'art de la porcelaine*

(Paris, 1771). Experiments on the properties of the materials were made by J. H. Pott, L. L. B. de Lauraguais, J. P. J. d'Arcet, B. Palissy, J. E. Guettard, P. J. Macquer, etc. W. Cookworthy's discovery of china clay in Cornwall, about 1755, led to the manufacture of porcelain in England, about 1760.

The remains of Celtic pottery, made in England in pre-Roman times, consist mainly of sepulchral urns, drinking cups, vessels for food, and incense pots. The Romans established potteries in Kent, London, Essex, Buckinghamshire, Dorsetshire, Wiltshire, Hampshire, Norfolk, Cambridgeshire, Lincolnshire, Yorkshire, Shropshire, and Staffordshire. The ware produced in the different districts had its own characteristics determined largely by the character of the local clays. A red ware, sometimes called *English samian*, was made in Staffordshire, and in some other counties. After the departure of the Romans, the potter's art in England seems to have relapsed into its original barbarous state. The recovery was slow. About the middle of the seventeenth century, the importations of Oriental, Dutch, French, and German ware seems to have excited public taste and stimulated the curiosity of potters. The work of J. Dwight, J. P. and D. Elers, J. Astbury, J. Twyford, Josiah Wedgwood, etc., raised English pottery to the highest degree of excellence, which has ever since been maintained.

It is impossible to compile a set of mutually exclusive definitions of the various types of pottery, because one type merges into another by insensible gradations. Most types of pottery are made from mixtures of clay, felspar, and quartz. The right proportions of these components for the desired type of ware may occur naturally in the clays. Such clays are usually coloured buff or various shades of red, and in the latter case furnish the so-called *terra-cotta*, red and buff flooring tiles, flower-pots, varieties of *stoneware*, etc. The ware may or may not be glazed with a plumbiferous or with a leadless glaze, and certain colouring oxides may be mixed with the glaze to impart to it a desired colour. Drain-pipes, etc., may be glazed by introducing sodium chloride in the fire-mouths of the oven or kiln near the finish of the firing operation. The salt partly decrepitates and partly volatilizes; and part is hydrolyzed by the steam. The final result is to cover the ware exposed to the fumes with a glassy film—*salt-glaze*.

For white pottery, the scarcer white-burning clays are used. In one of the simplest cases, the clay may be intimately mixed with about twice its weight of felspar, moulded into the desired shape, and fired. This furnishes the so-called *parian* which has a translucent and vitreous body, and which may or may not be afterwards glazed. The body of English *earthenware* is made from a mixture of, roughly, Cornish stone, 15; flint, 30; ball clay, 25; china clay, 30. The colour of ball clay when fired is objectionable, but the clay is used because it is highly plastic. The available china clay is not sufficiently plastic if used alone. The Cornish stone contains enough felspar to serve as a flux or matrix. When the moulded and dried ware is fired in the biscuit oven in an oxidizing atmosphere to about 1100°, the flux acts as a cementing agent binding the whole into a durable body. The biscuit body may be decorated in suitable designs and colours—*underglaze decoration*—or it may be left white. The body is then dipped in a slurry or slip in which the powdered glaze is suspended. The molar composition of the glaze approximates:

according as a lead or leadless glaze is required. Some of the substances used in compounding the glaze are fritted with suitable proportions of some of the other materials. Part or all the "lead" may be included with the frit. The dried, and dipped ware is then fired in the glost oven at about 1500°. The glazed ware may be decorated by painting or printing on the glaze with mixtures of fusible frits and metal oxides to give the desired colour—*on-glaze decoration*. The ware is then

fired in muffles between 800° and 900°. Glazed ware may also be gilded with a kind of lustre-gold or with a form of gold which requires burnishing after being fired. *Lustres* may also be produced on the glaze by painting the glaze with bismuth nitrate, etc., suspended in a medium of oil, and afterwards firing.

As previously indicated in connection with china clay, *hard porcelain*, *porcelaine dur*, or *felspathic porcelain*, is made from a mixture of felspar, quartz, and clay in the approximate proportions 1 : 1 : 2. According to the analysis of W. L. Howat,⁸ the so-called *Marquart's porcelain* used for making pyrometer tubes, has the composition 35.12 per cent. SiO_2 ; 63.20 per cent. Al_2O_3 ; and 1.65 per cent. K_2O . F. H. Riddle based a process of manufacturing these tubes on this analysis. The moulded and dried porcelain ware is baked at about 900° usually by the waste heat from another oven. The baked ware is dipped in the glaze which approximates in composition to felspar. The body and glaze are fired together up to the required temp., 1400°–1600°. The atm. is reducing, and this imparts a very faint bluish tinge to the white colour of the ware; if fired under oxidizing conditions, the colour is cream or pale yellowish-red. In some cases, the maturing temp. of body and glaze is lowered by mixing a small proportion of lime with the glaze and body; in rarer cases, magnesia is used. The effect of lowering the firing temperature of the body with additions of lime is to narrow the margin of safety between over-fired and under-fired ware. Some of the early porcelains had steatite for a flux, and the same flux, or its equivalent, is used as a constituent of the body of sparking plugs and some similar types of ware. In the *jasper* body, barium sulphate or carbonate is used as a flux.

The so-called *soft porcelain*, *porcelain tendre*, or *fritted porcelain*, was once a speciality of the Sèvres factory. The body was made from a calcareous marl admixed with an alkaline frit, and glazed with a plumbiferous glaze. Practically all the English porcelain, or *bone china*, is made from a body containing rather less than 50 per cent. of bone ash in admixture with nearly equal parts of china clay and Cornish stone. The body is fired near to 1200° in an oxidizing atm. There are special phenomena connected with the decomposition of the calcium phosphate when the ware is a little over-fired, if an excess of clay is present, or if reducing conditions obtain. A lead or leadless glaze is applied to the biscuit and fired at about 1050°.

The silicate industries are usually concerned with certain reactions which are not allowed to pursue their full course, but which are arrested at definite stages of their progress. The success or failure of the industrial operations is determined by the arrest being made at precisely the right stage. These *arrested reactions* were discussed 4.31, 33.⁹ In the different kinds of pottery, the flux begins its work of dissolving the clay and quartz or flint in the vicinity of 1000°, and the speed of the action is greater the higher the temp. The result is that the particles of clay and quartz appear to be cemented together by a felspathic or other glassy matrix. The change has not progressed very far in earthenware and similar types of body, but in the porcelainic bodies, the proportion of glassy matrix is so large that it makes the body appear translucent in moderately thick layers. For the development of sillimanite crystals in pottery, *vide* aluminium silicate.

A series of so-called vitreous bodies come between porcelain and earthenware. These are represented by the *mortar bodies* used in making Wedgwood-ware mortars and pestles; *granite ware*; *ironstone-china*; *stone-ware*, *sanitary ware*; etc. The earthenware bodies are porous and absorb liquids, the porcelain bodies are glassy with a conchoidal fracture and are virtually non-absorbent. Those vitreous bodies approaching the porcelain stage pass the so-called red-ink test in which a drop of red ink placed on the body can afterwards be washed off without showing a stain. The distinction between the bodies of different types of ware is perhaps as much a question of time and temp. of firing, as of composition. Otherwise expressed, the different bodies represent different stages of progress in an arrested reaction. In order that the firing temp. may not be inconveniently high, and the time

inordinately long, the proportion of fluxes may be augmented. No particular value, however, can be attached to proofs that a given type of ware is porcelainic solely because its composition is like that of any particular type of porcelain. All the clay-felspar-quartz (or flint) bodies become porcelainic with the right firing conditions. The margin of safety represented by the percentage loss in manufacture may be greater with some mixtures than with others.

The measurements of some properties of what has been described as porcelain, probably refer to the less vitreous, more porous earthenware. The **colour** of porcelain depends on the nature of the atm. which obtains in the oven at different stages of the firing; and on the proportion of contained iron oxide. The effect of the small proportions of titanic oxide usually present in clays is not appreciable. A very small proportion of lime reduces the tinctorial power of iron oxide. The colour can be controlled by using blue smalt or its equivalent to mask the yellow colour produced by iron oxide in an oxidizing atm. K. H. Reichau, and others, have studied the minute structure of porcelain—*vide* sillimanite. The **specific gravity** of the porcelain body fired to about 700° is 2.60–2.62, but when fired at higher temp., the sp. gr. falls to about 2.3. This was shown by A. Laurent,¹⁰ G. Rose, etc. A. V. Bleining and J. K. Moore studied the sp. gr. of porcelain. The **hardness** of porcelain is nearly 7, and that of the glaze nearly 6. S. L. Bigelow measured the **permeability** of unglazed porcelain (earthenware) for liquids at different temp. and at different press.; and S. L. Bigelow and F. E. Bartell estimated the **size of the pores** in porcelain (earthenware). H. le Chatelier also made observations on the porosity. A. V. Bleining and J. K. Moore studied the **porosity** of porcelain. Glazed porcelain should be impermeable to gases at temp. as high as 1300°. A. V. Bleining and P. Teetor measured the **viscosity** of different porcelain bodies between 1100° and 1320° in terms of their deformation under tensile strain. According to R. M. Fries, and R. Rieke hard porcelain has a **tensile strength** equal to about 1000–2000 kgrms. per sq. cm. H. le Chatelier reported some measurements of the tensile strength. R. Rieke found china clay increased and felspar decreased the tensile strength of porcelain. E. Rosenthal studied the effect of composition on the **crushing strength** of porcelain. R. M. Fries, and R. Rieke found that the crushing strength is about 4000–5000 kgrms. per sq. cm.; the **compressibility** coeff., 1.4×10^{-6} or 1.8×10^{-6} ; and the **elastic modulus**, 54,000–71,000 kgrms. per sq. cm. H. le Chatelier reported some measurements of the coeff. of elasticity. The **velocity of sound** in porcelain approximates 5000 metres per sec. Many observations have been made on the **thermal expansion** of porcelain. H. St. C. Deville and L. Troost found the coeff. of cubical expansion of porcelain to be between 0.000016 and 0.000017 between 0° and 1500°. L. Holborn and W. Wien gave for the coeff. of linear expansion 0.0544. R. C. Purdy and A. P. Potts found the coeff. of expansion ranged between 0.0525 and 0.0565. A. Weinhold gave 0.05269 between 0° and 100°; F. Henning, 0.05177 between –191° and 16°; 0.05336 between 16° and 250°; 0.053645 between 16° and 500°; and 0.054340 between 16° and 1000°; and A. E. H. Tutton 0.052522 at 0°; 0.053265 at 50°; 0.054008 at 100°; and 0.054305 at 120°. This shows that the higher the temp. the greater the coeff. of thermal expansion. T. G. Bedford gave $(3.425 + 0.00214\theta)10^{-6}$ up to 830°; and L. Holborn and E. Grüneisen found for two different samples $(3.027 + 0.001177\theta)10^{-6}$, and $(3.188 + 0.00036\theta)10^{-6}$ up to 625°. R. Rieke observed no relation between the composition and thermal expansion. Observations were also made by L. Holborn and co-workers, K. Scheel, H. le Chatelier, E. Damour, M. Coupeau, and M. Chantepie. T. G. Bedford gave for the linear expansion at θ° between 0° and 600°, $l = l_0(1 + 0.03425\theta + 0.05107\theta^2)$; and for the cubical expansion, $v = v_0(1 + 0.010275\theta + 0.05324\theta^2)$. F. Singer and E. Rosenthal gave for the linear coeff. of Berlin porcelain 0.05177 between –191° and 16°; 0.05366 between 16° and 250°; 0.053645 between 16° and 500°; and 0.05434 between 16° and 1000°. Porcelain from other sources gave 0.05269–0.054305 from 0°–100°. R. Rieke also gave 0.05343 between 23° and 200°, and

0.0356 between 23° and 700°. J. W. Mellor found that the higher the firing temp. of floor-tiles the smaller the coeff. of thermal expansion, and G. Vogt, and R. Rieke made a similar observation with respect to porcelain. R. Rieke found that the coeff. of expansion is lowered by increasing the proportion of felspar and lowering the quartz or flint, and keeping the clay constant. The expansion coeff. of porcelain is smaller than that of glass, and in consequence, such porcelain resists abrupt changes of temp. better than glass—*vide supra*, clays. The **thermal conductivity** of porcelain is about 0.04 when that of silver is 100; and the conductivity on the absolute scale is 0.2. The thermal conductivity increases with a rise of temp.—*vide supra*, clays. W. Steger found the mean **specific heat** of porcelain between 20° and 200° to be 0.202, and between 20° and 400°, 0.221. J. A. Harker gave between 15° and 912°; 0.2563 between 15° and 958°; and 0.2539 between 15° and 1075°. F. Singer and E. Rosenthal gave 0.202 from 20°–200°, and 0.221 from 20°–400°—*vide supra*, clays. W. Steger discussed the **translucency** of porcelain. D. Hofmann, J. H. Pitt, and G. de Razurowsky noted the **triboluminescence** of porcelain.

The **electrical conductivity** of porcelain at ordinary temp. is extremely small. The temp. coeff. is large and positive. G. Fossereau found that the **electrical resistance** approximates 215×10^7 megohms at 50° and 651 megohms at 210°. The subject is important in the manufacture of insulators for high-tension currents. As the temp. rises, the resistance decreases rapidly. H. F. Haworth gave for the sp. conductivity c of porcelain at different temp.

	1.03°	20.50°	30.87°	40.02°	50.40°	59.12°	64.80°	81.93°
$c \times 10^{10}$	0.49272	1.9883	5.0210	11.288	26.693	65.273	110.75	485.67

F. Haber and co-workers found that the conductivity of porcelain is appreciable at 300°, and at higher temp. it conducts electrolytically, and it is therefore decomposed by the current. M. Pirani and W. von Siemens represented the relation between the resistance R and the absolute temp. T by $\log R = a + bT^{-1}$, where a and b are constants dependent on the type of porcelain in use. One sample had a resistance of 1.098 megohms at 613°, and 68,700 ohms at 900°; while another had a resistance of 100,000 ohms at 727°, and 3400 ohms at 1292°. R. G. Allen found the results indicated in Fig. 126 for two samples of electric porcelain. Observations have been reported by W. Dietrich, F. Fleischmann, G. Stadel, G. Benischky, E. Rosenthal, A. V. Bleining and co-workers, B. S. Radcliffe, E. F. Northrup, E. F. Earhart, A. V. Henry, E. Watkin, F. H. Riddle, F. Wernicke, H. F. Haworth, J. Lustgarten, W. D. A. Peaslee, T. M. Feder, L. E. Barringer, E. E. T. Creighton, etc. Good insulators may deteriorate with use, and what appears a non-porous body may acquire a certain porosity. W. D. A. Peaslee attributes this to a piezoelectric effect in the quartz grains which have not been dissolved by the vitreous magma of the body in the firing. The alternating electrostatic field sets up a kind of vibratory movement in the crystals which may rupture them along the cleavage planes, or along the line of contact of the crystal with the surrounding magma. R. M. Friese found the **dielectric constant** of porcelain to be between 4.5 and 5.3. H. F. Haworth gave for the capacity K , of porcelain in microfarads at different temp.:

	0.38°	19.92°	44.04°	60.50°	79.86°	99.00°
K	0.0011170	0.0013803	0.0023020	0.0035531	0.0063010	0.0098226

R. Rieke observed no relation between the dielectric strength and the composition

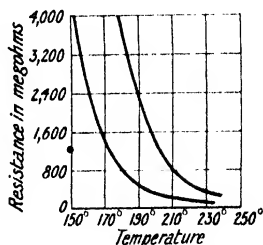

FIG. 126. Effect of Temperature on the Electrical Resistance of Porcelains

of porcelain. A. S. Watts found that the **puncture voltage** of vitreous bodies, the so-called electrical porcelain, varies but little with the composition or maturing temp. of the body. E. Rosenthal studied the influence of composition on the puncture voltage. A. S. Watts found that the resistance to puncture is much less when porcelain is under-fired than when properly vitrified. C. E. Henderson and G. O. Weimer observed that raising the temp. from 24° – 525° lowered the puncture voltage from 60,700–20,000 volts. The properties of porcelain for high-tension insulators have been discussed by M. F. Dahl, etc.¹¹

Porcelain, if not thoroughly vitreous, or well glazed, may be pervious to gases and air. J. Priestley¹² drew some wrong conclusions on the conversion of water into air by not allowing for this fact pointed out to him by J. Wedgwood. C. H. Pfaff discussed the permeability of retorts to gases. The fact that solid carbon diffuses into porcelain crucibles and cups has been established by the work of J. Violle, and S. Marsden. Porcelain is fairly resistant towards chemical reagents; and the glaze of hard porcelain is usually more resistant than glass. Acids other than hydrofluoric acid have but a slight action. The evaporation of hydrochloric acid soln. in glazed porcelain basins day after day causes an appreciable erosion; alkaline soln. attack rather more quickly than acids. A. Emmerling studied the action of water, dil. hydrochloric acid, aq. ammonia, soln. of ammonium chloride, etc., on porcelain glazes—*vide* glass. Fused alkali hydroxides and carbonates and lead oxide attack porcelain quickly producing, in the former case, a mass readily decomposed by acids. Porcelain is attacked by heated phosphoric acid, and more so by hypophosphorous acid. H. von Wartenberg found that many metals in a reducing atm. attack porcelain above 1200° , forming silicon and silicides; hydrogen alone above this temp. also forms silicon; and chlorine attacks the iron silicates in porcelain: $3\text{Fe}_2\text{SiO}_4 + 3\text{Cl}_2 = 2\text{FeCl}_3 + \text{Fe}_4(\text{SiO}_4)_3$. W. Nernst and H. von Wartenberg found that water vapour also attacks the iron in porcelain above 1200° .

§ 37. Glass

The manufacture of glass appears to have originated in Egypt. It is possible that the glass industry developed from the art of glazing pottery. Egyptian pottery was first glazed with the idea of making vessels water-tight and durable; and the glaze was afterwards employed for producing decorative effects. This view of the origin of glass appears to have been taken by H. B. Walters,¹ W. Fröhner, G. Perrot and C. Chipiez, A. C. Kisa, etc. How glasses or glazes came to be discovered is unknown. In the first century of our era, Pliny, in his *Historia naturalis* (36. 65), related the following story:

A ship laden with *nitrum* was moored beside the river Belus, in Phœnicia, and the merchants preparing their food on the sea-shore, used some lumps of nitre from the vessel to support their cooking-pot over the fire. The heat from the fire melted the *nitrum*, which combining with the sand formed transparent streams of an unknown liquid. This was the origin of glass.

Modified versions have been repeated by B. Palissy, A. Neri, etc. J. Beckmann discredited the legend, although there is nothing improbable in some such mode of discovery. According to J. du Halde, the Chinese made glass in the district of Yen-Tsching from very early times.

The ancient writers attributed the discovery of the art of making glass to the Phœnicians, but excavations in Egyptian tombs have shown that the Egyptians must have been adept glass-makers long before the Phœnicians practised the art. This indicates that the Phœnicians were probably distributors of Egyptian glass before their own factories were established at Sidon. In the work cited above, Pliny said that glass was made in Italy, and in the Gallic and Spanish provinces, by fusing sand with three times its weight of nitre; and he added that in India rock-crystal was used in place of sand. Bases other than the alkalies are needed to make the glass resist rapid attack by moisture. These might have been added deliberately, or brought in as impurities with the sand or alkalies. Pliny also mentioned that there were reports of a *vitrum flexibile—malleable glass—vide* 5. 33, 1. This recalls the Delhi flexible sandstone—*vide supra*. Pliny wrote:

It is said that in the time of Tiberius, a combination was devised which furnished malleable or flexible glass; but the workshop of the artist was totally destroyed in order to prevent the value of copper, silver, and gold from being depreciated. This report, however, was for a long time more widely spread than well authenticated.

Representations of the processes of glass-making are depicted on the walls of the tombs of Ben-Hassam near Thebus, 3000–1700 B.C., Fig. 127. These tombs

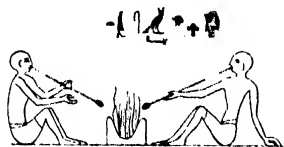

FIG. 127.—Egyptian Glass-makers at Ben-Hassam.

also contain vessels, etc., showing that the artisans were not only acquainted with the making and working of glass, but also with the colouring and cutting of glass in imitation of the precious stones. F. M. de Rozière also found samples of coloured glass in early Egyptian tombs. W. M. F. Petrie collected at Tell-el-Amarna specimens illustrating all stages of the process of glass-making about 1400 B.C. F. Rathgen gave analyses of antique Babylonian glass. Theophrastus, in his *Περὶ λίθων*, about 300 B.C., mentioned the coloration of glass by copper; and in his *Clouds*, Aristophanes referred to a glass-lens used as a burning glass. From Cicero, it would appear that glass from Egypt was greatly prized by the Romans; so much so that when Augustus subdued Egypt, 29 B.C., a portion of the Egyptian tribute was ordered to be paid in glass. At the time of Tiberius, Egyptian workmen were imported to Rome, and Roman glass rivalling that from Egypt was soon obtained. Works were also established in Italy, France, and Spain at an early date. In the

second century, H. Philo, in his *De legatione ad Caicum Caligulum*, alluded to the use of translucent stones as windows in the halls and chambers of the emperor's palace, and in the fourth century, L. C. Lactantius, in his *De opificio Dei*, mentioned the use of glass itself for windows. It is therefore probable that about the third century glass was employed in the construction of windows; but, according to L. Dutens,² the excavations of Pompeii, near Naples, show that at that time *les salles de bain étaient garnies de fenêtres en verre aussi belles que les nôtres*. After the fall of the Roman Empire the manufacture of glass was taken up in Byzantium (1. 1, 12), where it flourished for about five centuries. The fall of the Eastern Empire was attended by the migration of the glass-makers to other parts of Europe. Many were attracted to the Venetian Republic, and the Venetian glass became famous throughout the civilized world.

In the early Middle Ages, glass-making was taken up in Germany; and in his *De re metallica* (Basiliæ, 1546), G. Agricola gave a drawing of a glass-furnace; and shortly afterwards J. Mathesius, in his *Sarepta* (Nürnberg, 1562), described the practice employed in Venice, Germany, and Bohemia. A. Neri³ published a number of recipes in 1612, and some years afterwards this work was elaborated by J. Kunckel.

The factories in different localities acquired fame for some peculiarity in manufacture; the Bohemian manufacturers, for example, excelled in the production of colourless glass rivaling that from Venice. The manufacture of glass in Bohemia suffered a relapse owing to the heavy import duties levied against it, and the inducements held out to Bohemian workmen by foreign countries. Both the Venetian and Bohemian glass industries were revived in more recent years. The manufacture of the better types of glass in France commenced in the eighteenth century in factories erected first at Paris and then at St. Gobain. The latter is now famous for the manufacture of plate-glass. According to H. J. Powell, it is possible that during the Roman occupation a few beads, small cups, and bottles were made in England; but the resemblance of the scattered vessels and fragments of vessels to those found elsewhere makes it probable that there were only a few centres of glass manufacture in the Roman empire, and that the vessels were distributed from these to various parts. Glass was manufactured in England in the thirteenth century, for the industry was in existence at Chiddingfold, Surrey, in 1226. The south-eastern counties—Surrey and Sussex in particular—were favourite spots for the native glass-makers from the thirteenth to the sixteenth centuries. Glass was manufactured in Russia in the seventeenth century; and, in the United States, near the beginning of the nineteenth century.

Theophilus, in the latter half of the eleventh century, related that, in Italy, flint glass was used for imitating gem-stones, and added that the Jews were engaged in the manufacture of these imitations. Towards the end of the eighteenth century, J. Strasser, of Vienna, was famous for his skill in this work. He made a flint glass very rich in lead, and of high refractive power and sp. gr., which was called *strass*, and which was tinted with the necessary colouring oxides—e.g. 0.8 per cent. of chromic oxide to imitate the emerald; a mixture with 0.8 per cent. of manganese oxide, 0.5 cobalt oxide, and 0.2 gold purple, to imitate the amethyst. A. B. Ryley, in his *Old Paste* (London, 1913), has discussed this subject.

Ordinary glass is a fused mixture of silicates of the alkalis and alkaline earths which has congealed without crystallization. The molten mixture on cooling passes through various stages of viscosity, until, when cold, it furnishes a hard and brittle solid. There is no sign of a f.p. on the cooling curve (1. 9, 6). The simple silicate of potassium or sodium, or a mixture of the two, even when a large proportion of silica is present, is attacked by water and acids; so also is calcium silicate glass. A mixture of alkali and calcium silicates is fairly fusible, but under ordinary conditions it furnishes a glass which resists the action of water and acids very well, and this the more the greater the proportion of silica and alumina which may be present. For special purposes, the calcium silicate may be wholly or

partly replaced by other silicates—*e.g.* those of barium, lead, magnesium, zinc, lithium, didymium, arsenic, antimony, etc.—and the silica may be in part replaced by boric oxide, phosphoric oxide, etc. For lead glasses, see pottery glazes, and lead silicates.

The more common types of glass are represented by (i) *soda-lime glass* with 71–78 per cent. SiO_2 ; 0–2, K_2O ; 12–17, Na_2O ; 5–15, CaO ; and 1–4, $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$. It fuses at a comparatively low temp., and can be easily worked. It is used in making glass tubes, laboratory apparatus, window glass, and plate-glass. In the latter case it is called *crown glass*; (ii) *potash-lime glass*, also called *Bohemian glass*, with 72–76 per cent. SiO_2 ; 12–15, K_2O ; 0–3, Na_2O ; 8–10, CaO ; and about one per cent. of $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$. It fuses at a higher temp. than soda-lime glass, and it is used for making chemical apparatus, combustion tubes, etc.

Common *bottle glass* is usually coloured yellow, brown, or green owing to the presence of a relatively high proportion of ferruginous and other impurities. The composition approximates: 60–65 per cent. SiO_2 ; 3–5 per cent. alkali oxides; 18–20, CaO ; and 6–11, $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$. The raw materials used in the manufacture of this glass are not selected with such care as is the case with other types. Common sand; wood-ashes; by-products from the alkali-works, soap-works, and gas-works; common salt; salt-cake; and felspathic rocks represent some of the cheap raw materials which have been used. A. F. Gehlen⁴ discussed the use of Glauber's salt as a source of the alkali.

A third type of glass is represented by the *potash-lead glasses*, and *flint glass*. Such glasses have 40–50 per cent. SiO_2 ; 8–11, K_2O ; 28–53, PbO ; and about one per cent. $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$. These glasses are very fusible and easily worked. Owing to the ready reduction of lead silicate to metallic lead, the heating of these glasses must be done in an oxidizing atm. The sp. gr. and index of refraction of these glasses are greater than is the case with the other types of glass. This glass is not suitable for laboratory apparatus, but it is employed for articles in common use, table glass, etc. In the so-called *crystal*, a higher proportion of lead is introduced. This glass is used for optical purposes. In *strass*, mentioned above, a still higher proportion of lead is added.

The so-called *boro-silicate glasses* have many special applications; such a glass is used for making high-temp. thermometers. The so-called *Jena glass* has zinc and barium oxides as bases; it is specially resistant towards water, and is used for laboratory beakers and flasks. A boro-silicate glass, free from alkali, but with zinc, barium, and aluminium oxides as bases, is used for photographic objectives. A *phosphato-silicate glass*, with alkali, baryta, and alumina as bases, is used for microscopic objectives. L. M. Dennis and A. W. Laubengayer made glasses with *germanium* oxide in place of silica. Glasses are thus made with the idea of enhancing particular properties—*e.g.* refractive index, resistance to attack by particular liquids, transparency or opacity to particular parts of the spectrum, resistance to abrupt temp. changes, high softening temp., etc. Much attention has been devoted to the so-called optical glasses.⁵ An extraordinary number of analyses of ancient and modern glasses has been reported.⁶ The analysis of a glass, plus an elementary knowledge of the available raw materials, soon enables the practitioner to imitate any particular glass; it may, however, take the workmen a longer time to master the idiosyncrasies of the imitation in order to make its manufacture a commercial success. E. Zschimmer, and G. W. Morey discussed the classification and nomenclature of glasses, glazes, and enamels.

The manufacture of ordinary glass is comparatively simple. Glass is made by intimately mixing the raw materials required to give the desired composition. The mixture may or may not be exposed to a low temp. to drive off moisture, etc., likely to cause spitting and frothing, in the subsequent melting of the glass. The mixture is then placed in large crucibles made from fireclay, and called *glass-pots*. These are arranged on ledges in a circular or oblong furnace, and exposed to a steadily rising temp. until the mass is free from bubbles, streaky patches, quartz granules, etc. The scum or glass-gall is skimmed off. A portion of the molten glass is gathered at one end of an iron rod and blown into the required shape. The glass vessels are annealed by slow cooling, or by reheating them in an annealing furnace or lehr. The melting of the glass may be done in a tank-furnace,

which is an adaptation of the reverberatory furnace. The heat is applied by gaseous fuel on the regenerator principle. The automatic blowing machines for shaping glass bottles are a triumph of mechanical skill.

These and related subjects are discussed by H. Benrath, *Die Glasfabrikation* (Braunschweig, 1875); F. Tschuschner, *Handbuch der Glasfabrikation* (Leipzig, 1885); R. Gerner, *Die Glasfabrikation* (Wien, 1897); R. Dralle, *Die Glasfabrikation* (München, 1911); R. Müller, *Chemische Technologie des Glases* (Leipzig, 1911); F. W. Hodkin and A. Cousen, *A Textbook of Glass Technology* (London, 1925).

In spite of the most careful selection of the available raw materials, sufficient iron oxide is usually present to impart a pale yellow tinge to the glass matured in an oxidizing atm., or a pale green tinge in a reducing atm. Pliny, in his *Historia naturalis* (38, 26, c. 77 A.D.), spoke of the use of *magnes lapis* in making glass, and J. Reckmann believes that a manganese ore is here implied; while experimenting on the effects of different oxides on the colour of glass, it must have been noted that when a very small proportion of *magnes lapis* was employed, the yellow colour produced by iron was masked and a colourless glass obtained. Proportions of manganese oxide in excess of those required to mask the yellow tinge of iron give violet-reds and browns. Selenium compounds for the purpose of bleaching the yellow tinge of iron have been used in recent years.

In addition to ordinary, clear, colourless, transparent glass, and glasses with special colours for arresting particular kinds of rays from transmitted light, there are glasses stained with particular colouring oxides for ornamental effects. Thus, cobalt oxide dissolved in glass imparts a fine azure-blue; copper oxide in alkaline glasses gives a turquoise-blue, and in many glasses an emerald-green, both under oxidizing conditions. The ruby-red colour obtained by the use of very small proportions of copper oxide under reducing conditions, and the ruby colour obtained by the use of gold, have been described (3, 23, 11). A green and a red colour is obtained by means of chromic oxide. Manganese oxide furnishes a series of pink and violet colours in alkaline glasses and under oxidizing conditions; and in other varieties, manganese oxide produces a brown colour. A kind of Naples yellow is obtained by the use of antimony oxide, by the use of silver salts, and by iron oxide. Under reducing conditions, iron oxide may give a green colour; while under oxidizing conditions a reddish-brown, blood-red, or yellow colour may be obtained with ferric oxide. J. C. Hostetter and H. S. Roberts discussed the coloration of glass by iron oxide. K. Fuwa studied the yellow colours obtained with ceria. H. le Chatelier and P. Chapuy found that with glazes didymium oxide gave green, blue, or violet colours in a reducing atm.; erbium, violet or blue, in a reducing atm., and green or red, in an oxidizing atm.; lanthanum, violet or blue, in a reducing atm.; neodymium, violet, blue or green, in a reducing atm.; thallium or thorium, blue or green, in a reducing atm.; vanadium, blue, green, or yellow, in an oxidizing atm.; titanium, violet, blue, or green, in a reducing atm., and yellow or red, in an oxidizing atm.; molybdenum, blue or violet, in a reducing atm.; and tungsten, violet, blue, yellow, or red, in a reducing atm. A. Granger obtained a yellow with tungsten oxide, in an oxidizing atm. K. Fuwa has reported on the colours produced by manganese, antimony, molybdenum, chromium, tungsten, and vanadium oxides; S. D. Whitmer, F. K. Pencer, H. Wicks and J. W. Mellor, and T. Perry, by nickel oxide; and K. Fuwa, and T. Cohn, cobalt and copper oxides. Sulphide impurities in the glass were shown by D. C. Splitgerber, E. Grieshammer, and R. Zsigmondy to produce a yellow colour. Thomas Aquinas, in his *De case et essentia mineralium*, described a mode of preparing artificial topaz by using smoke obtained by placing a piece of aloe-wood over the pot in which the glass was melted. Selenium and cadmium oxide may give a red or yellowish-red colour to alkaline glasses, and for marking the coloration due to iron oxide. The selenium-red has been discussed by F. Kraze,⁷ P. Fenaroli, E. Fränkl, and O. Witt; the effect of tellurium, by P. Fenaroli, and of bismuth and stannic oxides, by K. Fuwa. Combination tints may be obtained by using a mixture of oxides in the right proportions. A black glass is obtained by using a mixture of iron, copper, chromium, and manganese oxides in suitable proportions. The so-called opaque-white glass, or milk-glass, is translucent, and the opacity is produced by undissolved particles of calcium phosphate, tin oxide, sodium antimoniate, zirconia, or other suitable opacifying

agents. Matte effects are produced by a sand-blast, or by etching with hydrogen fluoride in aq. soln. or as a gas.

F. Leydolt⁸ found that when the surface of clear, apparently homogeneous glass is etched with conc. hydrofluoric acid, and examined microscopically, evidence of crystalline formations can be detected. W. Jackson and E. M. Rich made similar observations; and H. E. Benrath said:

Remembering that the content of silica in commercial glasses is very variable, and that at a higher temp. more of this acid can be taken up than can be retained by the glass as the temp. falls the further, feldspathic minerals may be taken up and again separated by a molten glass; finally, also sulphates, phosphates, borates, metallic oxides, and metals (gold) may enter into the constitution of glasses, it would appear that these facts allow of no other explanation than that commercial glasses are quickly solidified soln. not only of different silicates in each other, but even soln. of basic oxides or silica and the other salts and metals, in molten silicate. Whether in all glasses some fundamental silicate, a compound—say, $\text{Na}_2\text{O} \cdot \text{CaO} \cdot 6\text{SiO}_2$, or $\text{Na}_2\text{O} \cdot \text{CaO} \cdot 4\text{SiO}_2$ —is to be taken as the solvent or not, must remain a question so long as nothing more is known than at present; yet many of the observations appear to speak for such an assumption.

J. B. A. Dumas regarded glass as an indefinite mixture of definite silicates; W. Jackson and E. M. Rich powdered various commercial glasses, and separated the fractions of different sp. gr. by flotation in methylene iodide, or by elutriation. In both cases the fractions had a different composition. They therefore concluded that glass must be considered to be a mixture of various silicates and oxides more or less homogeneous according to the method of manufacture. In ordinary crown and flint glass the mixture is sufficiently imperfect to allow the constituents to be readily separated by grinding; but the optical glasses show a much greater degree of homogeneity. All this means that the congealed soln. of silicates (L. 9, 6) known as glass is not necessarily homogeneous. This may be largely due to the difficulty in adequately mixing such viscid soln. *L'analogie du verre avec une gelée* was discussed by P. Bary, C. Doelter, M. W. Travers, and A. Silverman; and the colloidal chemistry of glass by R. G. Liesegang. G. Quincke applied his theory of foam cells (L. 11, 4) to the structure of glass. T. T. Smith and co-workers found in optical glass a difference of ± 2 in the fourth decimal between the indices of refraction of the striæ and the rest of the glass. L. N. G. Filon and F. C. Harris' experiments on the elasticity of glass indicated a two-phase system. H. le Chatelier believed that above 800° , glass is in a different "allotropic" state from glass below that temp. N. Seljakoff and co-workers regard glass as an amorphous undercooled liquid.

C. Zulkowsky reported that for a good serviceable glass, the relation of acids to bases should form approximately a trimetasilicate—*e.g.* $\text{KO} \cdot \text{SiO} \cdot \text{O} \cdot \text{SiO} \cdot \text{O} \cdot \text{SiO} \cdot \text{OK}$. C. Dralle could not confirm this. W. L. Baillie recommended a modification of the hypothesis. W. and D. Asch applied their hexite-pentite hypothesis to glasses, assuming that they are all chemical individuals. H. Fritz, F. Cediwoda, and O. Inwald discussed the formation of phosphate glasses without silica.

The various physical properties of glass naturally depend on the composition. Attempts to correlate the physical properties of glass with composition have given only empirical results. The results of much German work on the subject is summarized in H. Hovestadt, *Jenaer Glas und seine Verwendung in Wissenschaften und Technik* (Jena, 1900; London, 1902). Observations were made by J. W. Döbereiner,⁹ W. H. Harcourt, E. Zschimmer, E. W. Tillotson, etc. S. Salpeter examined the properties of different glasses in the light of the periodic law. The **specific gravity** of alkali-lime crown glass is between 2.4 and 2.6; that of alkali baryta glass, 2.4–3.6. M. Faraday prepared flint glass with a sp. gr. 5.44, and the sp. gr. of flint glass may be as low as 2.9; and that of alkali-lead glass between 3.0 and 3.8. A. Lamy, and O. Schott prepared a thallium-lead glass of sp. gr. 4.18. K. Schall found for the sp. gr. of light crown glass, 2.49; phosphate glass, 2.58; crystal glass, 3.10; barium phosphate glass, 3.35; light flint glass, 3.44; heavy flint glass, 3.63; very heavy flint glass, 4.91; and the heaviest flint glass, 6.33. The sp. gr. of glass is primarily dependent on its

composition, and attempts have been made to find a relation between the two. A. Winkelmann and O. Schott found that if a_1, a_2, a_3, \dots represent the percentage amounts of the several oxides present in glass, and z_1, z_2, z_3, \dots the sp. gr. constants, then, the sp. gr. of the glass, S , is $100/S = a_1/z_1 + a_2/z_2 + a_3/z_3 + \dots$. The sp. gr. constants are not the same as the sp. gr. of the individual oxides because, if these are employed, the calculated values of S are smaller than the observed. Consequently, the total vol. is diminished by combination. They showed that the above formula is approximately fulfilled by taking the following values of z :

	SiO ₂	B ₂ O ₃	ZnO	PbO	MgO	Al ₂ O ₃
z	2.3	1.9	5.9	9.6	3.8	4.1
Sp. gr.	2.17	1.46	5.65	9.32	3.40	3.85

	As ₂ O ₃	BaO	Na ₂ O	K ₂ O	CaO	P ₂ O ₅
z	4.1	7.0	2.6	2.8	3.32	2.55
Sp. gr.	4.09	5.0	2.55	2.66	3.15	2.38

C. J. Peddle studied the sp. gr. of the SiO₂-Na₂O-K₂O, binary and ternary glasses, of the SiO₂-CaO-Na₂O or K₂O glasses; SiO₂-BaO-K₂O- or Na₂O; and of the SiO-PbO-Na₂O or K₂O glasses. J. R. Clarke and W. E. S. Turner measured the sp. gr. of the lime-soda series of glasses. E. W. Tillotson found the additive rule for lime-magnesia glasses, lithia-baryta glasses, and lithia-lime glasses works better with the factors SiO₂, 2.3; CaO, 4.1; MgO, 4.0; BaO, 7.0; Li₂O, 3.7; and Al₂O₃, 2.75, than with A. Winkelmann and O. Schott's factors. S. English and W. E. S. Turner investigated the sp. gr. of the soda-lime glasses, soda-magnesia glasses, soda-magnesia-lime glasses, and aluminous and boriferous glasses; and W. L. Bailie examined the subject and proposed another set of factors. These factors are all purely empirical; and they must be dependent on the working conditions because each worker recommends his own set of factors, but in practice uses the observed data.

F. Auerbach¹⁰ has measured the **pressure-hardness** of glass, and obtained numbers in agreement with H. Hertz's formula, $12p\epsilon/d^3E = (1-\sigma)$, where p denotes the mutual press. between a plate and a lens with a radius of curvature, ϵ ; d , the diameter of the surface of contact; σ , the elastic modulus or Poisson's ratio; and E , Young's modulus. If H denotes the absolute hardness of the glass; a_1, a_2, a_3, \dots the percentage amounts of the several oxides in the glass; and y_1, y_2, y_3, \dots the hardness coeff. of the several oxides, then $H = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, when

SiO ₂	B ₂ O ₃	ZnO	PbO	Al ₂ O ₃	BaO	Na ₂ O	K ₂ O	CaO	P ₂ O ₅
$y = 3.32$	0.75	7.1	1.45	10.2	1.95	-2.65	3.9	6.3	1.32

J. R. Rydberg, C. Benedicks, J. Schneider, and O. Schott studied the hardness of glasses; and F. Auerbach also determined the scratching-hardness of glass, but observed no regular relation between the two forms of hardness. A. Lecrenier concluded that soda glasses are usually harder than silica glasses containing an equal vol. of silica; with lime-soda glasses, the hardness increases with increase of lime and decrease of soda; boric oxide imparts great hardness to glass; and the addition of soda and lime to lead glasses increases the hardness.

K. Arndt¹¹ found the **viscosity** of glass at 1050° to be 36.0 (water at 20° = 0.01); at 1100°, 17.0; and 1200°, 12.0. A. L. Field found that the temp.-viscosity curves of blast furnace slags always approximate to a rectangular hyperbola, and that replacing lime by magnesia lowers the viscosity at all temp. Alumina did not decrease the viscosity at high temp. F. Farup and co-workers found that increasing the alumina and silica decreases the viscosity. F. T. Trouton and E. S. Andrews gave 0.01211 for the viscosity coeff. of a soda glass at 575°; 0.0123, at 660°; and 0.045, at 710°. S. English, C. E. Guye and co-workers, investigated the viscosity of various kinds of glass near the annealing temp.; and J. T. Littleton and E. G. Roberts suggested that the annealing temp. of a glass may be determined

by measuring its viscosity at various temp. H. le Chatelier represented the viscosity, η , of a number of glasses at the temp. θ° by $\log \eta = a - b\theta$, where a and b are constants. Observations on the viscosity of glass were made by C. Doelter and H. Sirk, E. Greiner, V. Vesely, C. E. Guye and S. Vassileff, A. Lecrenier and co-workers, H. F. Staley, G. Tammann, J. Masson and co-workers, and E. W. Washburn and co-workers. E. W. Tillotson, and A. Lecrenier and co-workers measured the **surface tension** of molten glasses. E. W. Washburn found the surface tension of the soda-lime-silica glasses between 1200° and 1450° to be of the order 150 dynes per cm.; and A. A. Griffith gave for the surface tension of a glass:

	15°	745°	801°	852°	905°	1110°
σ	(0.0031)	0.00251	0.00257	0.00249	0.00239	0.00230

E. Warburg¹² discussed the **diffusion** of metals in glass; and A. Günther-Schulze, of silver in glass. H. Wessels observed the thermolysis or Soret's effect in glass.

The **elastic properties** of glass have been investigated by R. Reiger,¹³ J. Salpeter, E. Stephan, A. Kundt, G. Quincke, L. Boltzmann, J. Salpeter, C. Brodmann, H. K. Onnes, L. Grenet, B. Halle, E. Warburg, G. Tammann, B. Halle, etc. The **tensile strength** of glass varies from 2.9-8.35 kgms. per sq. mm. This constant has been measured by J. von Kowalsky, etc. J. von Kowalsky found that the greatest linear extension with a simple pull was 0.00131; with bending, 0.00132; with torsion, 0.00183; and with an end-pressure, 0.00129. Hence, glass can bear a much greater extension by torsion than by pull, bending, or end-pressure. A. Winkelmann and O. Schott represented the tensile strength, T , in kgms. per sq. mm., by $T = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where a_1, a_2, a_3, \dots represent the percentage amounts of the component oxides in the glass; and y_1, y_2, y_3, \dots the respective tenacity coeff. which are:

	SiO_2	B_2O_3	ZnO	PbO	MgO	Al_2O_3
y	0.09	0.065	0.15	0.025	0.01	0.05
	As_2O_3	BaO	Na_2O	K_2O	CaO	P_2O_5
y	0.03	0.05	0.02	0.01	0.20	0.075

The term *elastische Nachwirkung*, or *elastic after-effect*, refers to a residual effect which occurs after glass has been deformed. The residual effect subsides only gradually when the body is left to itself. The subject was investigated by G. Weidmann, who found an after-effect after bending, or flexure, after compression, and after torsion. F. Kohlrausch represented the subsidence of the after-effect by $x = Ce^{-atm}$, where x denotes the amount of deformation after the time t reckoned from the instant when the body is free, divided by the original deformation; and C, a , and m are constants. J. Hopkinson studied the elastic after-effect after the release of a torsional strain. A. Pazziani and C. E. Guye studied the torsion modulus, and the effects of annealing on glass fibres. J. W. French, E. Thomson, F. W. Preston, and A. J. Dalladay and F. Twyman discussed the stresses produced in glass by cutting with a diamond, and by grinding. A. A. Griffith found the maximum tensile strength of glass in the corners of a crack may be more than ten times the tensile strength as ordinarily measured. Freshly prepared rods have a great tensile strength which reduces to the normal value in a few hours. This is attributed to the development of numerous ultramicroscopic cracks.

A. Winkelmann and O. Schott¹⁴ measured the **crushing strength** or resistance to crushing and found numbers between 60.6 and 126.4 kgms. per sq. mm. If R denotes the crushing strength, a'_1, a'_2, a'_3, \dots the percentage amounts of the respective oxides in the glass; and y_1, y_2, y_3, \dots the crushing coeff. of the respective oxides, then $R = a'_1y_1 + a'_2y_2 + a'_3y_3 + \dots$, where

	SiO_2	B_2O_3	ZnO	PbO	MgO	Al_2O_3
y	1.23	0.9	0.6	0.48	1.1	1.0
	As_2O_3	BaO	Na_2O	K_2O	CaO	P_2O_5
y	1.0	0.05	0.02	0.05	0.2	0.76

G. Berndt obtained for the mean crushing strength of borosilicate glass with cubes 5 mm. edge, 1200 kgrms. per sq. cm. for 10 mm. cubes, 9000 kgrms. per sq. cm.; and for 15 mm. cubes, 8700 kgrms. per sq. cm. For unannealed cylinders with the press. continually increased 15,000 kgrms. per sq. cm., for annealed glass the numbers are respectively 14,200 and 12,500 kgrms. per sq. cm. P. B. Galitzin found that the **bursting pressure of glass tubes** (i) is independent of the rapidity of compression of the contained water; (ii) varies with the ratio of internal and external diameters; (iii) increases at first with the radius to a maximum value and then slowly decreases; and (iv) is independent of the absolute thickness of the walls—although the thicker the walls the more likely are flaws to be present. Observations were also recorded by D. I. Mendeléeff, and W. P. Bradley and A. W. Browne. A. A. Griffiths found the **breaking stress**, S , of glass fibres, of diameter d inches, to be in lbs. per sq. in.:

d	0.040	0.004	0.002	0.00115	0.00050	0.00026	0.000130
S	24,900	42,300	79,600	88,700	195,000	332,000	491,000

A. Föpl tested the **brittleness** of glass by letting a hammer fall from a definite height on a cube of glass. The ratio of the brittleness to the crushing strength varied with different glasses. P. Gaubert attributed to internal strains the regular system of cracks and regular shape of fragments sometimes found in glass ruptured *par les explosions*. J. Wolf reported on shock-resisting glasses; and E. E. Schumacher, on the cracking tendency of glasses.

The elasticity of glass or **Young's modulus** of glass was investigated by A. Winkelmann and O. Schott,¹⁵ A. E. Williams, etc. They found that the elasticity ranges from 4802–7971 kgrms. per sq. mm.; and if E denotes Young's modulus; a_1, a_2, a_3, \dots the percentage amounts of the respective components; and y_1, y_2, y_3, \dots the elasticity coeff. of these oxides, $E = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where the values of y are different for different types of glass. A. Winkelmann found for the silicate glasses, without boric or phosphoric oxide, baryta or magnesia:

	SiO ₂	ZnO	PbO	Al ₂ O ₃	As ₂ O ₃	Na ₂ O	K ₂ O	CaO
y	70	52	46	180	40	61	40	70

for leadless borosilicates free from phosphoric oxide:

	SiO ₂	B ₂ O ₃	ZnO	MgO	Al ₂ O ₃	As ₂ O ₃	BaO	Na ₂ O	K ₂ O	CaO
y	70	60	100	40	150	40	70	100	70	70

and for the remaining types comprising borates, lead borosilicates, and phosphates:

	SiO ₂	B ₂ O ₃	PbO	MgO	Al ₂ O ₃	As ₂ O ₃	BaO	Na ₂ O	K ₂ O	P ₂ O ₅
y	70	25	55	30	130	40	30	70	30	70

A. Winkelmann found that if E denotes Young's modulus at θ° up to nearly 482° and E_{20} , the value at 20° , $E = E_{20}\{1 - \alpha(\theta - 20)^\beta\}$, where α and β are constants for a given type of glass. It was found that if a glass be first tested at ordinary temp. and then at the higher temp., on its return to ordinary temp. it exhibits a greater resistance to bending than before. If it undergoes only one such heating, the enlarged elasticity decreases with time. Several heatings and coolings are needed before the elasticity becomes constant. Corrections are needed for the thermal expansion of glass. A. Winkelmann found that the simultaneous presence of large amounts of soda and potash favour* the change of elasticity with temp.; but if boric oxide be simultaneously present, the change is in the opposite direction. E. Wandersleb found that Young's modulus is smaller in the normal condition than in the *accommodation condition* observed by A. Winkelmann; and Hooke's law is fulfilled in the normal condition of glass up to the breaking point, but in the accommodation condition the ratio of the bending to the stress is increased. The effect of temp. on Young's modulus is $E = E_{15}\{1 - \alpha(\theta - 15) + \beta(\theta - 15)^2\}$ in the

accommodation condition, and $E = E_{15}\{1 - \alpha(\theta - 15)^2\}$ in the normal condition. A. E. Williams measured for the modulus of rupture and Young's modulus of 5000 samples of various types of glass, and found for window glass 7000 lbs. per sq. in. and 11,000,000 lbs. per sq. in. respectively; and for plate glass, respectively 6500 and 10,000,000 lbs. per sq. in. L. N. G. Filon and F. C. Harris studied the effect of temp. on the elastic constants of glass.

The ratio of the lateral contraction to the longitudinal extension with a longitudinal pull or thrust furnishes the so-called **Poisson's ratio**, σ —*vide* 1. 13, 17. Measurements were made by F. Twyman and J. W. Perry,¹⁶ G. Wertheim and E. Chevandier, W. Pscheidl, J. Kieweit, A. Winkelmann and O. Schott, A. Winkelmann, W. Ludwig, J. D. Everett, A. Cornu, H. T. Jessop, W. Voigt, M. Cantone, J. von Kowalsky, and H. H. Anagat. R. Straubel found that the observed values range from 0.197–0.239; and if a_1, a_2, a_3, \dots denote the percentage amounts of the respective oxides, and y_1, y_2, y_3, \dots the Poisson coeff., then $\sigma = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where

	SiO ₂	B ₂ O ₃	ZnO	PbO	Al ₂ O ₃	BaO	Na ₂ O
y	0.001533	0.002840	0.003460	0.002760	0.001750	0.003560	0.004310
	K ₂ O	CaO	P ₂ O ₅	Sb ₂ O ₃	MgO	As ₂ O ₅	Mn ₂ O ₃
y	0.003969	0.004163	0.002147	0.002772	0.002500	0.002500	0.002500

F. Auerbach calculated indirect values for Poisson's ratio and obtained a relation between the hardness and Poisson's ratio. R. Straubel showed that the supposed relation is invalid.

R. Straubel¹⁷ used the formulæ indicated 1. 13, 17, and calculated values for the **rigidity or resistance** to shearing and the **compressibility**, vol. elasticity, or resistance to compression from Young's modulus, and Poisson's ratio. He obtained values for the rigidity ranging from 1840–3140 kgrms. per sq. mm., and for the compressibility 3470–7520 kgrms. per sq. mm. J. E. P. Wagstaff found for the coeff. of rigidity of a glass plate 2.576×10^{11} to 2.59×10^{11} dynes per sq. cm. per unit shear. P. W. Bridgman represented the compressibility of pyrex glass at a press. p , by $dv/v_0 = 0.0_93027p - 0.0_{12}99p^2$. L. H. Adams and E. D. Williamson found the compressibility of plate glass to be $\beta = 2.27 \times 10^{-6}$ at atm. press., 2.23×10^{-6} at 2000 atm. press., and 2.05×10^{-6} at 10,000 atm.; or $\beta = 0.0_62226 - 0.0_6220(p - p_0)$. J. Y. Buchanan gave for the linear compressibility of flint glass, 0.072, and for ordinary glass tubing, 0.0846. Observations were made by E. Madelung and R. Fuchs. G. Ercolini found that a tension, compression, and a shearing force in an electric field produced no variation in the elastic constants.

J. Cardanus,¹⁸ in 1557, noted that when glass is kept for some time near the temp. of liquefaction, it loses its transparency and becomes opaque. Glass when cooled has all the characteristics of a congealed soln., but some glasses are very liable to crystallize or devitrify during the cooling; all depends on the nature and proportions of the different components, and on the time occupied in the cooling. Other glasses must be kept in the temperature zone of crystallization for hours in order to obtain crystals. J. B. A. Dumas found by analysis of a piece of devitrified glass:

	Na ₂ O	CaO	Al ₂ O ₃	SiO ₂
Crystallized portion	14.9	12.0	4.0	68.2 per cent.
Vitreous portion	19.8	12.0	3.5	64.7 „

Analyses and observations on devitrification were made by B. G. Sage, F. Hundeshagen, E. Péligot, H. Schwarz, M. Gröger, and A. Terreil. Some of the alkali-lime glasses furnish crystals of wollastonite. H. le Chatelier observed the formation of tridymite. As previously indicated, a small proportion of alumina is inimical to the process of devitrification. The subject has also been discussed in connection with Reaumur's porcelain. The first signs of devitrification are a faint turbidity and the appearance of a bluish tinge by reflected light. Observations were made by W. Lewis, A. Dartigues, D. C. Splitgerber, N. L. Bowen, L. B. G. de Morveau,

J. Fournet, J. B. A. Dumas, J. Pelouze, S. F. Cox, L. Appert, M. Bontemps, H. Knoblauch, J. W. Mellor, J. Fowler, N. Heaton, D. Herman and F. Rutley, N. L. Bowen, H. Insley, C. N. Fenner and J. B. Ferguson, Lord Rayleigh, F. Gelstarp, H. le Chatelier, C. J. Brockbank, Y. Amanomiya, R. Wietzel, A. F. O. Germann, etc. The alleged devitrification of old glass has not been clearly established, for it is probably due to a kind of surface weathering—*vide infra*. A. F. O. Germann removed the surface film by washing with hydrofluoric acid, and found the underlying glass to be quite normal.

E. Kochs and F. Seyfert¹⁹ obtained an empirical formula to calculate the **melting point** of a silicate. Let $[\text{SiO}_2]$ denote the percentage amount of silica; $[\text{Al}_2\text{O}_3]$, the percentage amount of alumina; K , their ratio; A, B, C, \dots , the percentage amounts of various fluxes; and M_a, M_b, M_c, \dots , the mol. wts. of the various fluxes. If F represents the sum $A/M_a + B/M_b + C/M_c + \dots$, what they call the fusibility quotient, Q , then $Q = 0.005767T^2/KF$. The fusibility quotient, Q , of potash-felspar is 0.153, of potash-lime glass 0.00004, etc. It will be observed that the assumption made is that the fusibility is solely determined by the mol. wts. of the constituent oxides. A. Granger used this formula. As shown by E. Zschimmer, etc., glasses have no definite m.p.; and F. Weidert and G. Berndt refer to the deformation temp. as the upper limit at which a piece of glass loses its form. F. Singer, R. L. Frink, R. Schaller, and F. Springer have discussed the effect of small additions of alumina in making soda-lime glasses more friable. A. Q. Tool and co-workers observed a small heat absorption shown on the heating curve of powdered glass just above the annealing temp. Observations were also made by J. W. Mellor and co-workers, L. Grenet, A. A. Lebedeff, K. Beck, H. and F. le Chatelier, etc. The thermal effect which occurs on heating glass was observed by A. Q. Tool and C. G. Eichlin, and it corresponds to the effect produced by a change of state, but is thought to be due to the formation of some molecular aggregate producing homogeneity, and relieving strains as in annealing.

P. S. Laplace and A. L. Lavoisier²⁰ measured the coeff. of **thermal expansion** of flint glass and found 0.03812–0.03872; lead-free glass, 0.03875–0.03898; and mirror glass, 0.03891. P. L. Dulong and A. T. Petit found the coeff. of cubical expansion up to 300° to be 0.0000251 + 0.04251 + 0.0166°. H. V. Regnault measured the coeff. for a number of glasses of different composition, and obtained for crystal-glass values ranging from 0.042144–0.042442; and for ordinary white glass, values ranging from 0.042324–0.042758. H. le Chatelier gave between 0° and 40°, 0.04186, and between 0° and 700°, 0.04225. O. Schott obtained values ranging from 0.04110–0.04337; and A. Winkelmann and O. Schott found that if a_1, a_2, a_3, \dots denote the percentage amount of the respective oxides, and y_1, y_2, y_3, \dots their expansion coeff., the coeff. of cubic expansion will be $\alpha \times 10^7 = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where

	SiO_2	B_2O_3	ZnO	PbO	MgO	Al_2O_3	As_2O_3
y	0.8	0.1	1.8	3.0	0.1	5.0	2.0
	BaO	Na_2O	K_2O	CaO	Sb_2O_3	Li_2O	
y	3.0	10.0	8.5	5.0	2.0	2.0	

The additive character of the thermal expansion coeff. was confirmed by J. Mori, J. Salpeter, and S. English and W. E. S. Turner for soda-lime glasses, such that if the symbols of the constituents represent the percentage amounts, the coeff. of cubical expansion of these glasses is $0.078[\text{SiO}_2] + 0.061[\text{Na}_2\text{O}] + 0.065[\text{CaO}]$. Similarly, for the magnesia-soda glasses, the results are given by the factors $\text{SiO}_2, 0.15; \text{Na}_2\text{O}, 12.96; \text{CaO}, 4.89; \text{and MgO}, 1.35$. With the soda-lime glasses the coeff. of linear expansion ranged from 0.041138–0.04801; and for the soda-magnesia glasses from 0.041138–0.04594. W. E. S. Turner and co-workers also determined the effects of silica, boric oxide, soda, titania, and alumina on the thermal expansion of glasses. J. Salpeter found a relation between the at. vols. of the elements and the coeff. of thermal expansion. H. Schönborn observed that different varieties

of glass have a critical zone of temp. in which there is a discontinuity in the curve representing the rate of expansion with temp. This zone corresponds approximately with a variation in the electrical resistance of the glass (*q.v.*). W. B. Pietsenpol found the thermal expansion of glasses increased linearly with temp., up to 450° or 550°, during the next 60° or 100° increased 4–6 times more rapidly, and therefrom increased linearly to the softening point. With unannealed glass the rate of expansion decreased as the internal strain disappeared, and this indicates a method of finding the proper annealing temp. O. Schott showed that a sample of glass in a state of strain produced by rapid cooling, had a coeff. of cubical expansion 0.042895, while the unstrained glass had a coeff. 0.042748; and the result was confirmed by J. Wolf. C. Pulfrich found a rise in the value of the coeff. from 0.04258 between 4.85° and 18.7°, to 0.04265 between 18.7° and 90.5°. Measurements at different temp. were made by M. Thiessen and co-workers, who gave for the linear coeff., $(7797 + 364\theta)10^{-9}$; and for the cubical coeff., $(23391 + 10.92\theta)10^{-9}$. For normal Jena glass, A. W. Warrington gave for the vol. at θ° , $v = v_0[1 + (23714 + 10.62\theta)10^{-9}\theta]$, when v_0 represents the initial vol. The subject has been discussed by E. Reimerdes, F. C. H. Wiebe, F. C. H. Wiebe and G. Möller, E. Zschimmer, R. Rieke and W. Steger, H. Auffenberg, G. W. C. Kaye, W. B. Pietsenpol, C. G. Peters and C. H. Cragoe, M. Meyer and B. Havas, F. E. Wright, etc. K. E. Guthe found the linear coeff. of a glass to be 0.045; J. T. Bottomley and W. J. Evans gave 0.00181 for the cubical expansion of Jena glass between 0° and 100°. C. Holborn and E. Grüneisen gave for the expansion of Jena borosilicate glass between 0° and 500°, $(5184\theta + 0.804\theta^2)10^{-9}$ and $(5852\theta + 0.959\theta^2)10^{-9}$. F. Henning found a rod of this glass, a metre long, contracted 0.877 mm. when cooled to -191°. C. G. Peters and C. H. Cragoe found for intervals approximately 19°–500°, $\alpha = 0.0462 - 0.04120$; and between 500° and 600°, $\alpha = 0.04205 - 0.04649$. P. Lafon studied the irregularities which occur in the dilation of glass with rise of temp. O. Schott found a zinc borate glass with the small coeff. 0.04110, and an alumina-glass with the coeff. 0.04337, which is nearly that of iron or nickel, and a glass with the coeff. 0.045 is used for making lamp chimneys. A. Arnulf devised a machine for automatically recording the expansion of glass.

The glass of a newly-made glass thermometer only gradually resumes its original volume, so that the mercurial column gives continually higher indications for one and the same temp. A thermometer which has been allowed to season before calibration does not show this *rise of zero*, but if it be heated to a high temp. there is a *depression of zero* which gradually resumes its normal value as the original volume is restored. R. Weber stated the phenomena are due to what he called the *Nachwirkung*, or the *after-effect*, or the *thermal after-effect*. The phenomenon has been studied in its application to thermometry by W. Schlösser, F. C. H. Wiebe, O. Schott, B. Eckardt, F. Grützner, A. Böttcher, J. Pernet, C. E. Guillaume, M. Thiessen and co-workers, K. Scheel, F. Allihn, W. Pomplun, H. Lemke, A. Mahlke, P. Chappuis, M. Tonnelot, etc. O. Schott devised a kind of compensation for the after-effect by enclosing within the thermometer bulb a small rod of another kind of glass with the same coeff. of expansion, but with a much larger thermal after-effect, so as to correct the depression of the zero when the thermometer is heated. The subject was investigated by W. Hoffmann, and G. Müller. No exact relation was observed by G. Weidmann between the thermal and elastic after-effects. As indicated above, A. Winkelmann observed that the coeff. of elasticity was increased after heating and cooling; and the effect became stationary after a repetition of the treatment a number of times. The phenomenon was called the *thermo-elastic after-effect*, and it has also been observed with platinum. L. Marchis made observations on the subject.

If liquid glass is abruptly cooled, say, by falling drop by drop into cold water, the congealed droplets are called *Rupert's drops*, *lacrymæ vitæ*, *Knallgläser*, or *guttis vitæis* (glass tears). When the thin tip is broken, the whole is converted into a fine powder with a feeble detonation. These drops were first brought to England

by Prince Rupert, but, according to J. Beckmann,²¹ they were not invented by him; they appear to have been made prior to 1661, because they were mentioned by B. de Monconys in that year. Theses on glass drops by J. C. Schulenburg appeared in 1695, by J. G. Baier in 1708, and by S. Reyher in 1714. According to P. D. Huet, the first glass drops came from Germany; according to A. le Grand, they came from Prussia; and according to G. Montanari, and H. Regius, they came from Sweden. On the authority of B. de Monconys, J. Beckmann argued that the drops first came from Holland. A tumbler of the unannealed glass may shatter to fragments when slightly scratched, say, by dropping a small piece of flint into the glass. F. B. A. R. de la Bastie found that if glass articles are heated to redness, suddenly immersed in oil at 300°, and then allowed to cool very slowly, the product is the so-called *toughened glass*. It resists abrupt changes of temp. better than untoughened glass, and it is not readily broken when dropped; but if it once does break, it shatters into fine fragments. A crack may occur in toughened glass without shattering the whole; but it cannot be cut with a diamond. Glass is annealed in order to relieve the strains introduced during the cooling. This subject was investigated by L. H. Adams and E. D. Williamson, G. Guadet, H. Schuz, etc. A. Q. Tool and C. C. Eichlin examined the effect of annealing on the heating curves of glass.

Glass is a bad conductor of heat. The **thermal conductivity** of glass was measured by O. Paalhorn,²² and he obtained numbers ranging from $k = 0.001082-0.002267$ cal. per cm. per sec.; and H. Hecht obtained 0.0025. A. Winkelmann showed that the absolute conductivity can be calculated from $k = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where a_1, a_2, a_3, \dots denotes the percentage amounts of the constituent oxides; and y_1, y_2, y_3, \dots represents the conductivity coeff., viz.

	SiO ₂	Ba ₂ O ₃	ZnO	PbO	MgO	Al ₂ O ₃
y	0.0,220	0.0,150	0.0,100	0.0,80	0.0,84	0.0,200
z	0.34	0.66	15.0	16.0	5.0	2.5
	As ₂ O ₃	BaO	Na ₂ O	K ₂ O	CaO	P ₂ O ₅
y	0.0,20	0.0,100	0.0,160	0.0,10	0.0,320	0.0,160
z	3.0	13.0	10.5	13.3	6.0	6.7

A. Winkelmann obtained better results by using b_1, b_2, b_3, \dots as the vol. percentages instead of a_1, a_2, a_3, \dots percentages by weight; and using the corresponding coeff. z_1, z_2, z_3, \dots . In that case the reciprocal of the conductivity $k^{-1} = b_1z_1 + b_2z_2 + b_3z_3 + \dots$. Measurements were also made by T. M. Focke, A. Eucken, J. Thoulet, C. H. Lees, H. Mayer, and O. Venske. J. Krüger studied the influence of temp. on the thermal conductivity of glass, and represented the value of k at θ° , when the conductivity at θ° is k_0 , by $k = k_0(1 + a\theta)$, where a is a constant dependent on the type of glass. W. M. Thornton observed a relation between the thermal conductivity, k_1 , the elasticity, E , and the sp. gr., D , such that $k = ED = V^2D^2$, where V is the velocity of sound in the glass. J. R. Clarke could not confirm this relation. E. D. Williamson and L. H. Adams studied the distribution of temp. in glass during heating or cooling. P. W. Bridgman represented the thermal conductivity of pyrex glass at a press. p by $0.0261 + 0.071p$ at 30°–75°.

A. Winkelmann²³ determined the **specific heat** of various glasses and obtained numbers ranging from 0.08174–0.2318. If c denotes the sp. ht. of a glass; a_1, a_2, a_3, \dots the percentage amounts of the constitutional oxides, and y_1, y_2, y_3, \dots the sp. ht. of the component oxides, then $c = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where

	ZnO	B ₂ O ₃	Al ₂ O ₃	SiO ₂	As ₂ O ₃	PbO	MgO
y	0.1248	0.2272	0.2074	0.1913	0.1276	0.05118	0.2439
	BaO	Mn ₂ O ₃	Na ₂ O	K ₂ O	Na ₂ O	CaO	P ₂ O ₅
y	0.06728	0.1661	0.2674	0.1860	0.5497	0.1903	0.1902

The sp. ht. of glass rises with temp., and the sp. ht. in the amorphous or glassy

state is slightly higher than in the devitrified or crystalline condition; the difference is more marked with glasses with a high proportion of alkali. I. Iitaka found the sp. ht. of ordinary glass to be 0.212 at 133.3°; 0.221 at 213°; 0.231 at 318°; and 0.236 at 405°. G. E. Gibson and W. F. Giauque showed that in the case of glycerol, the entropy of a glass exceeds that of a crystal of the same composition at absolute zero.

Thermal shock tests are made by heating the glass vessel containing a suitable liquid to progressively higher and higher temp. until the glass fractures. A. Winkelmann²⁴ and O. Schott introduce a number of assumptions into an argument which reduces to an empirical expression for what they call the *thermischer Widerstandskoeffizient*—coeff. of thermal endurance, representing the power of glass to withstand the inequalities of temp.:

$$\text{Thermal endurance} = \frac{P}{\alpha E \sqrt{\frac{K}{cD}}}$$

where K denotes the thermal conductivity; c , the sp. ht.; D , the sp. gr.; E , Young's modulus; α , the coeff. of linear expansion; and P , the tensile strength of the glass. The values of the thermal endurance so calculated range from 3.51 to 13.52. The results often agree with observation, although some irregularities were noted. Glasses usually resist compressive forces better than tensile forces, and hence they will withstand rapid uniform heating better than quick uniform cooling. Glasses rich in alkali have a high coeff. of expansion, and therefore are more liable to break with abrupt temp. changes than glasses with a smaller expansion coeff.

The refractive index of glass ranges from 1.50 to 1.9626 for the densest flint glass. A. Baudrimont and J. Pelouze²⁵ said that the refractive index increases with the mol. wt. of the contained bases, thus lead glass has the highest index of refraction, next comes baryta glass, then potash glass, and least of all, soda glass. J. von Fraunhofer found for crown glass and for medium and dense flint glasses:

	A-line.	C-line.	D-line.	E-line.	F-line.	G-line.	H-line.
Flint (3.723)	1.628	1.630	1.635	1.642	1.648	1.660	1.671
Flint (3.512)	1.602	1.604	1.609	1.615	1.620	1.631	1.640
Crown (2.535)	1.526	1.527	1.530	1.533	1.536	1.542	1.547

Hundreds of other observations have been made—e.g. by M. Dutirou, H. Starke, H. du Bois, J. W. Gifford, F. E. Wright, T. Smith, F. Eckert, C. J. Peddle, P. J. van Kerkhoff, V. S. M. van der Willigen, R. J. Montgomery, etc. O. Schott gave for the index of refraction, μ for the D -line, the mean dispersion μ_c , μ_F and the ratio, γ , of the mean dispersion divided by $\mu - 1$:

	Sp. gr.	μ	$\mu_c - \mu_F$	γ
Light phosphate crown glass	2.58	1.5159	0.00737	70.0
Crown glass	—	1.4650	—	65.7
Borosilicate crown glass	2.47	1.5100	0.00797	64.0
Heavy baryta crown glass	3.55	1.6112	0.01068	57.2
Soft silicate crown glass	2.55	1.5151	0.00910	56.6
Extra light flint glass	2.87	1.5398	0.01142	47.3
Ordinary silicate flint glass	3.63	1.6202	0.01709	36.2
Heavy silicate flint glass	3.87	1.6489	0.01919	33.8
Heaviest silicate flint	6.33	1.9626	0.04882	19.7

C. J. Peddle studied the refractive indices of the binary and ternary systems, $\text{SiO}_2\text{-K}_2\text{O-Na}_2\text{O}$; $\text{SiO}_2\text{-CaO-Na}_2\text{O}$ or K_2O ; $\text{SiO}_2\text{-BaO-K}_2\text{O}$ or Na_2O ; and $\text{SiO}_2\text{-PbO-Na}_2\text{O}$ or K_2O ; and F. E. Wright, the refractive indices and dispersion of a variety of glasses. E. S. Larsen found that for all the albite-anorthite series of glasses the formulæ of Gladstone and Dale and of Lorentz and Lorenz give results which are sensibly additive; E. W. Tillotson found the sp. refractivities calculated by either of the above-mentioned formulæ give results with the soda-lime glasses which are additive, so that if a_1, a_2, a_3, \dots denote the percentage amounts of the constituent oxides, and y_1, y_2, y_3, \dots the sp. refractivities of the oxides, $100K = a_1y_1 + a_2y_2 + a_3y_3 + \dots$, where y_1 for SiO_2 is 0.1220; y_2 for CaO is 0.1210; and y_3 for Na_2O is 0.1302. Similar results were obtained for soda-baryta glasses, and for

the albite-anorthite series of glasses. J. R. Clarke and W. E. S. Turner found the replacement of soda by lime in the glasses of the type $2\text{Na}_2\text{O} \cdot 6\text{SiO}_2$ produces a linear change in the refractive index. R. J. Montgomery studied the refractive indices of the lead glasses. A. R. von Schrötter gave for the thallium lead glass of sp. gr. 4.18, $\mu = 1.661$ for the *B*-line, 1.673 for the *D*-line, and 1.710 for the *H*-line. G. Muller also made observations on the refractive indices of thallium glasses. T. J. Pelouze, and W. E. S. Turner and co-workers studied the refractive indices of aluminous and boriferous glasses. E. Zschimmer found that the refractive indices of glassy boric oxide, 1.4620, and of fused silica, 1.4585, are raised by the dissolution of metallic oxides, but not proportionally with the mol. wt. For instance, Li_2O , ZnO , PbO , and BaO , each eq. to 40 per cent. BaO , in 100 parts of boric oxide raised the refractive index in the 3rd decimal respectively 77, 93, 114, and 248 units. The effect did not increase with conc., for the optical effect decreased with Li_2O in B_2O_3 , Na_2O in SiO_2 , and ZnO in B_2O_3 or alkali silicate glass, but it increased with PbO and BaO . In potassium-silicate glass—15 per cent. K_2O —the addition of boric oxide increased the refractive index to a maximum with 15 parts of B_2O_3 to 100 of glass, and therefrom decreased the refractive index. E. S. Larsen investigated the relation between the sp. gr. and refractive index of glass. H. Rubens measured the dispersion for the ultra-red rays; and H. T. Simon for the ultra-violet rays. The subject was also investigated by J. Hartmann, L. Mouton, S. P. Langley, H. Trommsdorff, H. Rubens, E. L. Nichols, O. Reinkober, C. Schäfer and M. Schubert, and K. Löwe. C. Pulfrich measured the effect of temp. up to about 100° on the index of refraction, and J. O. Reed worked at temp. up to 500° . F. Pockels studied the effect of elastic deformation on the optical properties of glass. The reflexion and elliptical polarization were examined by J. Jamin, P. Drude, Lord Rayleigh, G. C. Schmidt, O. Lummer and K. Sörgo, M. Volke, H. Schulz, R. Kynast, and O. Hebecker. L. N. G. Filon, and F. C. Harris studied the effect of time and temp. on the photo-elastic constants of glass.

Glass which has been rapidly cooled is not optically homogeneous nor optically isotropic; the outer layers are cooled faster and shrink more than the interior. Hence, the interior is in a state of strain. In 1814, T. J. Seebeck, and D. Brewster showed that a piece of glass when irregularly heated exhibits double refraction like many uniaxial crystals, and that under press. the glass shows interference colours in polarized light. The colour patterns were called by T. J. Seebeck *die entoptischen Farbenfiguren*; and they have been called *Seebeck's colours*. According to E. G. Coker, when a strip of glass between crossed nicols is subjected to an increasing strain, it first shows a greyish-white colour which passes successively through the colour changes, lemon-yellow, reddish-purple, to blue; and if the strain increases, the scale of colours is repeated for approximately double the intensity of the stress. There is thus a well-defined colour scale corresponding to the torsional stress. For simple compression and tension, the relative retardation of the rays producing the colour effects is proportional to the intensity of the stress, and to the thickness of the material. E. Zschimmer found the strains could be introduced in large articles from their own weight.

The birefringence of strained glass was studied by J. Kerr, A. Q. Tool and C. G. Eichlin, H. du Bois, O. D. Tavern, O. Reeb, H. Ambronn, W. Köhler, A. Winkelmann, H. Boissier, F. Eckert, Lord Rayleigh, L. H. G. Filon, L. H. G. Filon and H. T. Jessop, F. Pockels, W. König, F. Twyman and co-workers, E. and M. Henriot, H. Schulz, G. Berndt, F. E. Neumann, F. Taffin, T. T. Smith and co-workers, P. S. Nutting, E. E. Wright, A. L. Kimball, S. Czapsky, etc. O. Schott found that the double refraction disappeared from strained ordinary and borosilicate crown glasses between 400° and 410° , and from flint glass between 350° and 360° . Glass is annealed in order to relieve these strains. E. Hagenbach examined samples of glass which had cracked without any apparent cause and found Seebeck's colours were present. He suggested testing glass for soundness by its appearance in polarized light, rejecting that which exhibits the strain-colours.

F. Vogel measured the **absorption of light rays in the visible spectrum** by different glasses and found for the coeff. of absorption, k , for two flint glasses and two crown glasses :

λ	0.677	0.580	0.535	0.503	0.477	0.455	0.436 μ
Flint (light)	0.0059	0.0102	0.0129	0.0138	0.0106	0.0214	0.337
Flint (heavy)	0.0231	0.0188	0.0213	0.0246	0.0357	0.0411	0.0569
Crown	0.0102	0.0137	0.0108	0.0137	0.0151	0.0196	0.0216
Crown	0.0151	0.0201	0.0233	0.0254	0.0260	0.0261	0.0227

This shows that at the red end of the spectrum the light flint glasses are less absorbent than the crown glasses, but at the other end this condition is reversed. The absorption by the heavy flint glass exceeds that of other glasses as the wave-length diminishes ; and its absorption for the longer waves is not surpassed by the crown-glasses. The effect of temp. on the absorption of light by glasses was discussed by J. Königsberger and co-workers, W. Rieder, H. du Bois and G. J. Elias, G. B. Rizzo, R. A. Houston, A. Silvermann, J. Becquerel and F. Eckert, H. Rubens, G. Rosengarten, J. M. Eder and E. Valenta, F. Vogel, G. E. Grantham, F. Eckert, W. W. Coblentz and W. B. Emerson, C. Schäfer, M. Schubert, F. Eckert, and A. W. Smith and C. Sheard investigated the transparency of various glasses for the ultra-red or heat rays ; according to W. W. Coblentz, the transparency for the ultra-red rays is very great up to 2μ ; and as with most silicon compounds, there are bands at 5.6μ and 6.25μ . He also studied the ultra-red reflexion spectrum. The absorption of light in coloured glasses has been studied by R. Zsigmondy and C. Grebe, R. Zsigmondy, P. P. Fedotieff, J. Königsberger, P. P. Fedotieff and A. Lebedeff, J. W. Mellor, W. W. Coblentz and co-workers, K. S. Gibson, R. A. Houstoun, S. B. Nicholson and E. Pettit, R. C. Gibbs, E. P. Hyde and co-workers, M. Luckiesh, etc. F. Weidert studied the absorption spectra of glasses containing didymia. In general, the absorption increases as the temp. rises, though in some parts of the spectrum there may be a decrease. In some cases the absorption bands remain stationary ; in others, there is a shift towards the red. There is usually a complete recovery when the original temp. is restored. The absorption of ultra-violet light by glass has been investigated by E. Zschimmer, F. F. Martens, C. Fritsch, E. de Chardonnet, N. Schjerning, H. A. Krüss, G. Krüss, H. Pflüger, W. Rieder, J. Duclaux and P. Jeantet, F. Eckert, R. C. Williamson, F. Pflüger, and A. W. Smith and C. Sheard. The ultra-violet transmission spectrum of glasses has been investigated by W. R. Ham and co-workers, J. R. Clarke and W. E. S. Turner, L. Bell, H. P. Gage and W. C. Taylor, K. S. Gibson, E. Zschimmer, and H. T. McNicholas. W. Crookes studied the effect of the oxides of cerium, chromium, cobalt, nickel, copper, iron, manganese, neodymium, praseodymium, and uranium on the absorption of heat rays and ultra-violet rays, and on the transmission of luminous rays. H. J. Möller found dark brown, dark green, or red glass bottles protect best the contents from the chemical action of light. Obviously glasses which cut off the heat rays would be useful for railway carriage windows, etc., in sunny climes ; and goggles, and spectacle-lenses which cut off all but the luminous rays would prevent irritation. This subject has been discussed by W. W. Coblentz and co-workers, G. Alleman, W. P. Graham, M. Luckiesh, F. Eckert, C. Grebe, R. Zsigmondy, F. Schanz, F. E. Lamplough, E. L. Hettinger, K. W. Hausser and W. Vahle, J. van der Hoeve, A. L. Forster, etc. K. Köhler studied the transmission of light through frosted glass. E. P. Lewis and A. C. Hardy found that the **reflective power** of ordinary glass for radiation below $\lambda=1860$ was from 10–13 ; and for dense glass, 10 (rock salt, 8–9). M. Kahanowicz and A. Estrafalaces studied this subject. P. Zeeman and co-workers discussed the **Fizeau effect** in flint glass.

W. C. Röntgen observed that lead glasses absorb **X-rays** more than do the leadless glasses. A. Winkelman and R. Straubel studied the subject and found that baryta glasses behaved like lead glasses, and that the presence of antimony oxide or zinc oxide diminishes the transparency. Of the glass-making compounds in

powder form, they found the most transparent were alumina, boric acid, and sodium nitrate and carbonate; the least transparent were lead oxide, red lead, antimony oxide, and barium nitrate; while zinc oxide, sand, and potassium carbonate and nitrate were of intermediate transparency. The order of transparency from greatest to least with glasses containing the rare earths, etc., were cerium, didymium, zirconium, and thorium. Glasses with zirconia behave like fluorite in transmitting the X-rays; the effect was weaker with glasses containing didymia and erbia. No effect was observed with glasses containing beryllium, uranium, cerium, or thorium. O. Schott found that transparency of glasses to X-rays follows the inverse order of at. wt. of the elements in the oxides; and found a glass containing 39.6 per cent. SiO_2 ; 30 of B_2O_3 ; 20 of Al_2O_3 ; 0.4 of As_2O_5 ; and 10 of Na_2O , to be very transparent to these rays. The absorption of X-rays by glass was investigated by R. Glocker, and C. and F. Lindemann; the reflection of X-rays by A. P. Compton; and the coloration of glass by X-rays, by A. Dauvillier.

The **fluorescence** of glass was discussed by E. Lommel, W. Spring, H. Geiger, J. B. Burke, E. L. Nichols and E. Merritt, G. M. Sägmüller, P. Lenard, P. Pringsheim, E. Wiedemann and G. C. Schmidt, R. C. Gibbs; the discoloration of glass by exposure to radiations of various kinds by M. Berthelot, B. Delachanel, J. C. M. Garnett, R. W. Lawson, L. Michel, H. Greinacher, G. T. Beilby, E. Rutherford, and P. Villard and F. Erkert; and the luminescence in **cathode rays** by E. Gehrke and O. Reichenheim, A. Schmauss, E. Wiedemann and G. C. Schmidt, E. Goldstein, and O. Reichenheim. The phosphorescence of potash glass when exposed to **radium radiations** was observed by G. T. Beilby; and when exposed to the rays from radio-tellurium, by H. Greinacher. E. Rutherford observed that radium emanation, decaying in a capillary tube of soda glass, formed a red-coloured area, probably due to the X-rays. C. Doelter and H. Sirk, A. Miethe, W. A. D. Rudge, S. C. Lind, F. Eckert, M. Berthelot, W. Crookes, S. Avery, and G. T. Beilby studied the coloration of glass by radium rays. Soda glass is coloured violet by a prolonged action, and when the glass is heated, like purple fluor spar, there is a pale violet thermoluminescence and the colour is discharged. E. Newberry and H. Lupton found that lead glass acquires a brown colour under the action of radium, and the colour is discharged by heat. Borosilicate glasses acquire a purple-brown colour under similar conditions. C. Doelter also examined the effect of radium rays on different kinds of glass. J. R. Clarke found that all the glasses he tried fluoresced in radium rays, but a fatigue effect was noted at about the same time as the maximum coloration was reached. He thought the α -rays were the active agents. None of the glasses fluoresced with the γ -rays; but soda-lime glass and a selenium glass fluoresced slightly in **ultra-violet light**. All the glasses exposed to radium radiations exhibited thermoluminescence with the disappearance of the coloration between 100° and 235° ; and R. E. Nyswander investigated the thermophosphorescence produced by radium rays. H. Jackson considered the green phosphorescence of X-ray tubes depended on the presence of traces of manganese oxide; without this agent, the glow is faint blue. The coloration of glass by exposure to **sunlight** was observed by S. Avery, B. Delachanel, M. Faraday, R. A. Gortner, and W. Crookes; and by exposure to ultra-violet light, by F. Fischer, and J. B. Nathanson. J. R. Clarke found glasses containing selenium or cobalt oxide as bleaching agents were coloured brown by β -rays. A soda-lime glass was feebly affected only by the α -rays. J. R. Clarke thought that the colorations are due to the formation of colloidal particles in the glass. The **triboluminescence** of glass was observed by F. Haukebee²⁶ in 1705; G. de Razoumowsky in 1787, and T. Wedgwood in 1792. P. Heinrich said that Rupert's drops almost always emit light when they are ruptured.

H. F. Richards²⁷ studied the contact electricity of glass, quartz, fluorite, and steel when taken in pairs. F. Kohlrausch said that glasses easily attacked by water have bad **insulating properties** owing to the formation of a film of water on the surface acting in conjunction with alkali dissolved from the glass. Assuming that

the glasses at the outset all insulate well, and that they have been for some time in contact with water, rinsed with distilled water, and dried in the sun or in the oven, then decidedly bad glassés will be recognizable by their discharging a gold-leaf electroscope almost instantly when the percentage of saturation in the air is between 50 and 60, and in a short time (1 sec. or 2 secs.) when it is between 40 and 50. With glasses of medium quality, as well as with lead crystal and Jena thermometer glass, the corresponding percentages of saturation will be about 20 higher. The Thuringian glass made at Gehlberg insulates perfectly up to 40 per cent. of saturation, fairly well at 60 per cent., and discharges in a few seconds at 80 per cent. With Bohemian potash glass, which at least as regards quantity of alkali dissolved must be reckoned among good glasses, no traces of conduction appeared till the percentage was above 50 per cent.; and the insulation was still fairly good at 75 per cent. At the head of all stood the alkali-free Jena glass, which insulated perfectly at above 60 per cent., and well even at 80 per cent. of saturation. P. Woog examined the effect of the surface weathering of glass on its insulating qualities for high voltage currents.

H. Buff, and E. Warburg and F. Tegetmeier found that the **electric conductivity** of glass becomes appreciable at 200°. If sodium amalgam be separated from mercury by a glass partition in a containing vessel heated to 200°, and if an electric current be passed from the amalgam through the glass to the mercury, the glass is electrolyzed, sodium passes into the mercury, and a corresponding amount is lost by the amalgam without the glass losing its clearness. If the sodium amalgam be replaced by lithium amalgam, the glass becomes opaque on the lithium side, and the opacity travels through the glass, as lithium takes the place of the displaced sodium. The glass in which lithium has taken the place of sodium becomes very brittle. It is assumed that lithium—at. vol. 15.98—can pass along the tracks or mol. galleries left by the sodium atoms—at. vol. 16.04—but the potassium atoms—at. vol. 24—are too large to pass along the spaces left by the sodium. W. J. Sutton and A. Silvermann, K. Horovitz, M. von Pirani, H. Schönborn, H. Freundlich and P. Rona, G. Borelius, and C. A. Kraus and E. H. Darby also replaced sodium in glass by silver. The phenomena were confirmed by W. C. Roberts-Austen, who found that if copper or gold amalgam be used the glass is coloured by the copper or gold. The electrolysis of glass was also studied by A. Heydweiller and H. Kopfermann, H. Schiller, H. Schönborn, M. le Blanc and F. P. Kerschbaum, A. Günther-Schulze, J. Königsberger, E. Rasch and F. W. Hinrichsen, J. W. Rebbek and J. B. Ferguson, and R. Lorenz. H. H. Poole showed that the electrical conductivity of glass is not entirely electrolytic; and K. Horovitz, and R. Ambronn found that not only does glass conduct electrolytically, but it also becomes polarized. The results obtained at different temp., $T^\circ \text{K.}$, show that if L_0 and β are constants depending on the composition of the glass, the conductivity, L , at T° , is $L = L_0 e^{-\beta/T}$. L_0 is a linear function of the percentages of soda and lime in the glass. Observations on the electrical conductivity of glass were made by J. R. Clarke, A. Denizot, R. Ambronn, W. Dietrich, G. Fousereau, W. Thomson, J. Perry, A. A. Somerville, N. Rood, C. E. Philips, C. Barus, F. Haber and Z. Klemensiewicz, F. Baumeister, E. Bollé, A. Speransky, H. H. Poole, A. Günther-Schulze, etc. F. Farup and co-workers found that increasing the alumina and silica decreased the conductivity. T. and A. Gray and J. J. Dobbie found the sp. **electric resistance**, R , of glass increased with the percentage of lead oxide, and with the sp. gr.; and further, that the conductivity is doubled for every 9° rise of temp. It was further found that for soda-lime glass,

	55°	72°	93°	116°	149°
$R \times 10^{10}$	531.05	89.15	11.901	1.874	0.202

for potash-lead glass at 142°, $R \times 10^{10} = 1328.6$; and for soda-lead glass,

	73°	83°	104°	120°	140°
$R \times 10^{10}$	215.13	144.64	20.82	4.93	1.89

L. L. Holladay represented the electrical resistance, R , of various glasses between

20° and 500° by $\log R = a \log T - bT^{-1} - c$, where a , b , and c are constants dependent on the nature of the glass; and the temp. T is represented in °K. F. W. Hinrichsen and E. Rasch, and E. Schönborn found the conductivity of glass followed the same rule. Different varieties of glass also showed a transition point ranging between 384° and 560°, analogous with those obtained with the thermal expansion. The effect of absorbed gases on the conductivity was measured by V. Bush and L. H. Connell. F. F. S. Bryson found pitting occurred in the glass in the vicinity of the sealed platinum electrode of an interrupter connected with an induction coil. This was attributed to the electrolysis of the glass lying between the wire and the surrounding liquid—sulphuric acid. F. Haber and Z. Klemensiewicz, H. Schiller, and W. S. Hughes measured the **potential difference** between glass and soln. in contact therewith. The variation is approximately the same as for the variation in the hydrogen electrode potential, and is approximately a linear function of the latter. K. von der Grinten studied the **cataphoresis** of powdered glass. A. V. Bleiningner noted a **thermoelectric current** by sealing platinum wires in small blocks of different glasses ground flat, and heating a pair of blocks in contact with one another while the wires are connected with a millivoltmeter.

The permittivity, sp. inductive capacity, or **dielectric constant**, K , of glass was found by M. Romich and J. Nowak to be 7.5; N. N. Schiller gave 3.3–6.34; J. Hopkinson, 6.6–9.1; J. E. H. Gordon, 3.0–3.24; G. Quincke, 3.6–25.3; K. F. Löwe, 5.48–9.13; W. Donle, 6.88–7.76; and A. Winkelmann, 6.46–7.57. The last-named gave for leadless glass 7.11, and 7.44 for a glass with 45 per cent. of lead. H. Starke gave 5.48–9.13. The ratio K/S , where S denotes the sp. gr., is 2.17–3.38. J. J. Thomson, E. Lecher, R. Blondlot, and K. F. Löwe found that the dielectric constant increases as the frequency diminishes. A. Gray and J. J. Dobbie found for the sp. inductive capacity of soda-lime glass at 11°, 6.26, and at 129°, 6.79; for soda-lead glass, 7.36 at 19°, and 8.44 at 130°; and for potash-lead glass, 6.76 at 19°. M. von Pirani, W. M. Thornton, H. F. Richards, E. Schott, C. F. Hill, A. Coehn and A. Curs, and F. L. Ekman made observations on the dielectric constants of glass. The former represented the relation between the dielectric constant, K , and the sp. gr. S of flint glasses by $K = 6.61 + 1.2965(S - 2.89)^2$; and the relation between the dielectric constant and the refractive index, μ , for the F -line, by $K = 6.61 + 95.6(\mu - 1.549)^2$. C. L. Addenbroke found these relations did not hold for flint glasses with $S = 4.85$, and $K = 11.2$; and $S = 6.01$, and $K = 13.0$. The ratio of K to μ^2 increased continually as the sp. gr. increased. The heaviest flint glass known has a sp. gr. 6.33 and has a composition very nearly PbSiO_3 ; it was therefore suggested that the heavy flint glasses may be solid soln. of silica in lead metasilicate. F. M. Jäger measured the dielectric constant for different wavelengths. G. Quincke discussed the **puncture voltage** of glass; and the cleavage cracks of punctured glass. Different phases of the subject were examined by N. Hessehus, A. Günther-Schulze, K. W. Wagner, J. L. R. Hayden and C. P. Steinmetz, J. Mosciaki, B. Walter, J. Almy, F. Kohlrausch, J. Hopkinson, J. Currie, T. J. Baker. E. E. Schumacher examined the relation between the composition of a glass and its tendency to crack while conducting electricity. A. Willner and W. Wien found the increase in the internal vol. of spherical and cylindrical condensers produced by electrostriction is in general less than the value obtained from Young's modulus. They also examined the effect of press. on the dielectric constant. K. R. Brain studied the **piezoelectric effects** with glass. P. Drude, and K. F. Lowe measured the **absorption of electromagnetic radiation**. H. du Bois found **Verdet's constant**, W_D , ranged from 0.0161–0.0888 when the value for fluorite was 0.0091; and O. Junghaus, 0.0197–0.0856. The latter also measured the **electromagnetic rotation** of the plane of polarization and found for Na-light, 1.827°–0.0421° for different glasses. H. du Bois, and O. D. Tavern studied **Kerr's effect**—i.e. the double refraction developed in an electric field—with various glasses; and J. Königsberger, the **magnetic susceptibility**.

F. Degen,²⁸ and M. Faraday noted that glass adsorbs water, and, according to

the latter, glass acquires a certain surface conductivity which renders it unsuited for electrostatic experiments. A. Fusinieri and A. Bellani, and M. Faraday also referred to the film of air which is adsorbed tenaciously on glass surfaces. P. Chappius found that 1.6752 sq. m. of glass surface between 0°–180° adsorbed 0.45 c.c. of hydrogen; 0.58 c.c. of air; 1.03 c.c. of sulphur dioxide; and 1.41 c.c. of ammonia—between 0° and 100°, 0.63 c.c. of ammonia was adsorbed. The amount of carbon dioxide was between that of air and of sulphur dioxide. H. Zwaardemaker found that pyridine is scarcely adsorbed by glass surfaces, though valerianic acid is retained by the glass. Observations on the adsorption of gases on glass surfaces were made by L. Chiozza, H. Kayser, F. Kohlrausch, F. Mylius, S. Dushman, D. H. Bangham and F. P. Burt, I. Langmuir, R. G. Sherwood, G. von Elissafoff, W. Falta, K. Horovitz and F. Paneth, G. Quincke, P. Volkmann, J. E. Shrader, L. Joulin, A. Smith, F. Weber, E. W. R. Pfeiffer, N. R. Campbell, H. Krause, J. B. Hannay, W. Voigt, J. F. Bottomley, J. Gaspar, F. Melhorn, G. Melander, and D. Ulrey. R. Bunsen found that the amounts of water retained by 2.11 sq. m. at different temp. were:

	23°	107°	215°	320°	415°	468°	503°
Water . .	22.3	14.2	11.6	7.6	2.8	0.9	0.0 mgrm.

Hence, it requires a temp. approaching 500° to remove the adsorbed water from glass surfaces. R. Whytlaw-Gray found glass adsorbs and dissolves hydrogen chloride; and that it adsorbs niton. J. K. Carver, and R. E. Wilson and T. Fuwa studied the adsorption of toluene by glass surfaces; and M. H. Evans and H. J. George, the adsorption of sulphur dioxide, ammonia, nitrous oxide, and acetylene by powdered glass, and found no evidence that the surface layer of adsorbed gas is just one mol. thick—*vide* adsorption by carbon. I. Langmuir discussed the general problem of the adsorption of gases on glass surfaces. J. J. Manley investigated the films of gas on glass. G. C. Schmidt and F. Durau measured the adsorption of aniline dyes from soln. by glass powder. E. Warburg and T. Ihnori, and H. Krause showed that glass dried at 500° does not adsorb carbon dioxide appreciably, while in the presence of moisture much is adsorbed. P. Mulfart could not confirm this; but moist and dry carbon dioxide are adsorbed by glass. D. H. Bangham and F. P. Burt studied the adsorption of ammonia and carbon dioxide by glass. The Pouillet effect with glass (I. 9, 9) was examined by C. S. M. Pouillet,²⁹ H. L. F. Melsens, P. Chappius, C. Cantoni, T. Martini, and F. Meissner. P. Schützenberger said that a high-tension discharge will drive water vapour through glass, but neither F. Meyer nor M. Berthelot could confirm this. M. Pirani examined the behaviour of films of moisture on glass under the influence of streams of electrons. F. G. Keyes studied the errors in gas measurements due to the adsorption of the gas, say carbon dioxide, by glass.

Glasses, glazes, fused silicates, and slags can absorb gas and reject it with or without spitting during cooling. The phenomenon was noticed by H. St. C. Deville and L. Troost,³⁰ and J. B. Hannay. Again, I. L. Bell said that the slag from a blast furnace afforded evidence of being impregnated with gas, which during the cooling of the slag escapes in the form of miniature volcanoes on its surface, or bursts out into small jets of flame. If the glass of a vacuum tube used with hydrogen, argon, helium, and other gases be fused, it becomes clouded, and, under the microscope, is seen to be permeated to some depth from the inside surface by a multitude of minute spherical bubbles. Sometimes the melted glass appears to boil, and the bubbles can be seen and heard bursting. Observations were also made by R. S. Willows; and the Staff of the General Electric Co., J. E. Shrader, S. Brodetsky and B. Hodgson, and F. H. Newman studied the disappearance of gas in the electric discharge tube. Four explanations have been given. R. Pohl assumed that the bubbles are produced by a chemical action between the glass and the aluminium disintegrated from the electrodes; F. Soddy and T. D. Mackenzie said that the gas is evolved from the glass by chemical decomposition; and

A. A. C. Swinton said that the gas is driven mechanically into the glass by the cathode rays. When the glass is heated, the gas penetrates further and forms bubbles on cooling much in the same way that air bubbles are formed in ice. J. J. Thomson said that the gas passes into the glass by ordinary diffusion. G. A. Williams and J. B. Ferguson found that glass is impermeable to hydrogen, but some glasses are permeable to helium, and some are blackened when heated in hydrogen; and A. Piutti and co-workers, A. Lo Surdo, E. Cardoso, and C. C. van Voorhis examined the diffusion of hydrogen, helium, and neon through heated glass. G. A. Williams and J. B. Ferguson found one c.c. of pyrex glass, sp. gr. 2.25, dissolved 0.00835 c.c. of helium (at n.p. θ) at 515° and press. 752–755 mm. B. Moore and J. W. Mellor also observed the dissolution of hydrocarbon gases in lead-silicate glass—about 14 c.c. of gas per 100 grms. of glass; and E. W. Washburn found that all varieties of glass dissolve gases, and the gas is thus liable to effervesce violently from the liquid glass if the press. be reduced. J. E. Harris and E. E. Schumacher studied the gases from glasses of different composition; the contained gases are principally carbon and sulphur dioxides, water, oxygen, and nitrogen. J. W. Ryde and R. Huddart analyzed the gases in the bubbles in glass. In agreement with these observations, M. Berthelot found that hot glasses are somewhat pervious to hydrogen, carbon monoxide, and oxygen gases, and C. Zenghelis reported that glasses are similarly permeable to iodine vap., but A. Stock and H. Heyemann were unable to confirm this observation. The subject was discussed by G. Quincke, H. H. Landolt, and B. Tollens. J. B. Firth observed no diffusion of bromine through a thin partition of glass in 9½ years but with iodine if the glass has been previously heated to 360° a small diffusion occurred. D. Ulrey observed no diffusion of atm. air through glass at temp. up to the softening point. M. Pirani found that the distillation of mercury in vacuo removed the film of air adsorbed by glass surfaces. K. von der Grinten showed that powdered glass adsorbs alkali from aq. soln., and the amount per sq. cm. of surface varies with the conc. of the soln., but reaches a maximum with 1.6×10^{14} mols. per sq. cm.

F. Kohlrausch³¹ measured the hygroscopicity of powdered glass and found the percentage gain in wt. by different glasses varied from 2 to 18 per cent. The durability of glass exposed to moist air depends largely on its power of resisting attack by water. Dry glass, said R. Bunsen, resists attack by dry carbon dioxide. F. Mylius and F. Förster showed that the weathering of glass begins by the adsorption of water, then the water is absorbed, and hydrates are formed. The alkaline components are liberated, and the corresponding carbonates are produced. Lead glass is blackened when heated in an atm. of hydrogen sulphide, or hydrogen owing to the formation of lead sulphide. M. Faraday observed the blackening of flint glass in dwelling-houses owing to this cause; and a bottle of such glass was found by G. Bischof to be eroded and blackened by ammonium hydrosulphide. Ammonia vap. acting on the exposed surface of glass windows in the vicinity of stables and manure heaps is markedly corrosive. D. H. Bangham and F. P. Burt investigated the adsorption and desorption of carbon dioxide, sulphur dioxide, acetylene, and ammonia by glass. E. Mellor discussed the accelerating influence of lichen growths on the deterioration of glass.

E. Zschimmer studied the action of air and dry dust on glass kept in a room for a number of years. Silicates and borosilicates with up to 20 per cent. of B_2O_3 free from lead and alkali showed under the microscope ($\times 80$ –120) a uniformly spread alteration of the whole surface, consisting either of minute drops or of a network of crystals, due to the slow separation of potash or soda from the silicate, and the subsequent formation of deliquescent potassium carbonate or crystalline sodium carbonate. Borate glasses absorb moisture without becoming damp, and simply swell on the surface, which is not visibly altered till the expansion becomes so great as to tear away the surface from the layers beneath when the whole surface becomes cracked and fissured. This cracking can be produced at an earlier stage

if the glass be heated to 170°. Similar borosilicates free from lead but containing alkali showed surface alterations only in the vicinity of specks of dust. The alterations consist in the deposition of minute drops of water, in the formation of crystals radiating from the speck, in a combination of both of these appearances, or, in the case of lead glasses, in a blackening near the speck, due to metallic lead or its sulphide. The nature of the dust (whether a hygroscopic body or an organic or sulphur-containing substance) is, of course, operative, as well as the composition of the glass, in determining the nature of the alteration of the surface. In lead-free silicates, the decomposition depends on the amount of alkali in the glass. With 10 per cent., dust-decomposition readily sets in, and with 20 per cent. or over, the separation of alkali sets up air-decomposition. In lead-containing silicates, the proportion of lead, as well as that of alkali, determines the ease with which decomposition occurs; but dust-decomposition will occur in silicates containing 20 per cent. or more of lead, even though free from alkali. The decomposition of borate glasses containing over 20 per cent. B_2O_3 , and over 20 per cent. PbO occurs with the separation of the lead oxide not only on the outer surface, but in some of the layers below, producing an iridescence similar to that observed in labradorite and similar minerals. This iridescence is not removed by rubbing or polishing the surface, and is increased in intensity by heating the glass. The borosilicates are, on the whole, the least easily decomposable glasses; the alkalis seem to separate out less easily than from the silicates, and with a given alkali-content there is much less tendency to the appearance of hygroscopic moisture or of crystals on the surface than in the case of silicates. The phosphate glasses are all hygroscopic. The microscopic appearance is similar to that of the hygroscopic alkali silicates, though the crystals of phosphoric acid or of phosphate are easily recognizable. The dimming of optical glass owing to the formation of a film or deposit on the surface may give trouble. In order to enhance the desired optical qualities, the product may have a small margin of safety, and would not retain its polish and transparency under ordinary conditions of use. Optical glasses which are markedly unstable in the atm. are used only for combinations in which they can be cemented between two lenses or more durable glass. The method of testing optical glass for durability on exposure has been described by F. Mylius, W. Morey, J. W. French, F. Förster, A. V. Elsdon, O. Roberts and H. S. Jones, E. Zschimmer, W. H. Withey, and F. R. von Bichowsky. W. D. Bancroft thought that mercury would wet glass if the adsorbed air were removed, and E. E. Schumacher found that this was true with some glasses, and with quartz.

A. L. Lavoisier, and C. W. Scheele were familiar with the fact that the glass vessels employed by the chemist are attacked by water (1. 2, 4), forming a soln. of alkali silicate, and flecks of silica or calcium silicate. The early chemists thought water could be transmuted into an earth by boiling it in glass vessels. H. Davy also proved that the alkali produced during the electrolysis of water is derived from the glass of the containing vessel (1. 2, 6). R. Weber, and F. Mylius observed that glass vessels containing moist ether acquire an opaque coating on the inside owing to the action of water on the glass. The subject is of importance in certain analytical processes, as discussed by B. Reinitzer, G. Kreisler and O. Henzold, E. Bohlig, E. Hoyer, J. Kjeldhal, E. Jalowetz, K. Barclt and H. Schönwald, C. Liebermann, etc.; and mal-observations may occur if the fact be overlooked. Thus, the trace of alkali dissolved from glass was shown by M. Berthelot, and D. M. Kooij to act as a catalytic agent modifying the course of some chemical reactions. H. Moissan and F. Siemens found that silicon is slowly attacked by water at 100° in glass vessels through the traces of alkali dissolved from glass. J. S. Stas, and T. W. Richards emphasized the error introduced in at. wt. determinations by the use of glass vessels. R. Weber showed that microscopic objects preserved between glass plates might undergo change owing to the instability of the glass. C. Nicolardot, G. W. Morey, J. W. French, G. Bischof, J. N. von Fuchs, M. Faraday, J. B. A. Dumas, T. Griffiths, and D. Colladon cited experiments

confirming these observations. F. Mylius showed that much alkali but relatively little silica is extracted, and G. Bischof noted that moist glass powder reddens turmeric paper; red litmus is likewise coloured blue; phenolphthalein and hæmatoxyline are coloured red or purple; F. Mylius showed that a soln. of iodine and starch is coloured blue, and that the orange-yellow soln. of iodeosin in aq. ether is changed red—this reaction has been made quantitative—and similar remarks apply to R. F. von Walther's observation that a yellow soln. of alizarine becomes reddish-violet. Tests—quantitative and otherwise—were devised by R. Weber, F. Mylius, F. Mylius and F. Förster, F. Mylius and E. Groschuff, F. Haber and H. Schwencke, E. Baroni, E. W. Hagmaier, W. L. Baillie and F. E. Wilson, L. Kröber, W. L. Baillie, T. Kato, W. H. Withey, E. Zschimmer, W. E. S. Turner, A. E. Williams, etc. The Institute of Chemistry has prepared a specification for testing glass. G. W. Morey has discussed in a general way the effect of the composition of glass on its corrodibility; and E. Turner and C. Barus, the action of steam on glass.

F. Mylius found that potash water-glass is more susceptible to attack than soda water-glass. F. Mylius and F. Förster found that the solubilities of potash and soda glasses diminish rapidly as the proportion of lime increases. F. Kohlrausch analyzed the material removed from glass by the solvent action of water. Numerous comparisons of the solvent action of water, etc., on glasses of different countries and different firms have been made. The general (of course erroneous) impression one gets is that each country, and indeed each firm, can produce a more resistant glass than any other country or firm. Observations on the solvent action of water on different glasses were made by R. Weber, F. Kohlrausch, F. Mylius and F. Förster, J. Pelouze, A. Daubrée, A. Vogel and C. Reischauer, H. C. Sorby, B. Tollens, A. E. Williams and S. E. Fox, O. Lecher, J. Wolf, J. Körner, L. Appert and L. Henrivaux, P. Nicolardot, H. von Schwarz, R. von Rieth, L. A. Palmer, D. E. Spligerber, P. H. Walker, E. C. Sullivan, W. E. S. Turner and co-workers, R. Warrington, R. Cowper, F. Cedivoda, and P. Nicolardot. C. J. Peddle studied the solubility of the binary and ternary glasses, $\text{SiO}_2\text{-Na}_2\text{O-K}_2\text{O}$, $\text{SiO}_2\text{-CaO-Na}_2\text{O}$ or K_2O ; $\text{SiO}_2\text{-BaO-Na}_2\text{O}$ or K_2O ; and $\text{SiO}_2\text{-PbO-Na}_2\text{O}$ or K_2O ; G. Keppeler, baryta and strontia glasses; and G. Blumenthal, and W. E. S. Turner, the solubility of boric oxide frits. The above discussion may give a wrong idea of the relative solvent action of water on glass. With good glasses only minute portions of alkalis are removed after a prolonged action. If it were otherwise, the use of glass for domestic purposes would affect the composition and flavour of food-stuffs, and liquids with which it is brought in contact. Similarly, if window-glass under normal conditions were appreciably attacked by rain-water, or gases of the atmosphere, its use would be less satisfactory than it is to-day. P. Volkmann could detect no difference in the capillary rise of water in glass tubes made of different materials.

E. Pfeiffer showed that glass is attacked by water more vigorously when the temp. is raised, and F. Kohlrausch found that the solvent actions at 10.8° , 17.2° , and 23.6° are related as 1:2.7:7.4. Superheated water is an active corrosive agent as shown by the short life of the gauge glass tubes of steam-boilers working under high press. It is probably not steam, but liquid, which is the potent agent. This is shown by the corrosion above the water-line being in special tracks cut in the glass as the water condensed on the glass tube and trickled down. C. Barus found that liquid water attacks glass so rapidly at 185° , as to choke up the glass tubes in which it was confined by separation of hydrated silica. F. Förster made a number of observations on the resistance offered by different types of glass to water under a press. of steam at 183° in closed vessels. O. Schott and M. Herschkowitsch, and F. Krull investigated the effect with different kinds of glass when used in contact with hot water and steam up to 40 atm. press. F. W. Hodkin and W. E. S. Turner found soda-lime glasses are quickly attacked by steam and water at 2-25 atm. press. The action decreases as the proportion of lime is increased.

E. Turner studied the action of high press. steam on glass and silicates; and O. Schott and G. Linck showed that at 250° and 35 atm. press., a borosilicate glass absorbed 7 per cent. of water in 3 weeks. It is inferred that the absorption of water is not due to chemical combination, but rather imbibition by a gel. O. Schott and G. Linck found that powdered glasses adsorbed up to nearly 16 per cent. of water when heated with water in an autoclave for 30 days. The dehydration was not completed below 1000°.

When old soda-glass tubing, which has stood in the laboratory for some time, is heated, the outer surface may become exceedingly rough owing to the exfoliation and splintering, or to the development of innumerable spits—presumably by the evolution of absorbed water. Observations on this subject have been made by F. Mehlhorn, E. Priwoznik, and A. R. von Schrötter. O. Schott observed similar results with the thermometer tubes which had been immersed in boiling water for some days; he also found soda glasses are less affected than potash glasses. F. Förster found that water is always taken up when glass is acted on by liquid or steam, and hydrated products are formed—*vide* alkali silicates, hydrated water-glasses.

All kinds of glass are quickly corroded by hydrofluoric acid, forming silicon tetrafluoride, and fluosilicates of the alkalies, alkaline earths, etc. H. Moissan found that thoroughly dried hydrogen fluoride attacks glass, but dried fluorine attacks it only slowly, and no action was observed at -187°. The etching of glass—H. F. Smith—and pottery glazes is effected by means of this acid. In the case of aluminous and plumbiferous glazes and glasses, the acid is mixed with some ammonium acetate to prevent the formation of a protective deposit of sparingly soluble fluorides on the parts to be attacked. According to J. B. A. Dumas, glass which has a low proportion of silica is attacked by boiling sulphuric acid; and glass which is easily devitrified is attacked by boiling hydrochloric or nitric acid, and by aqua regia. The acids dissolve out the alkalies, alkaline earths, and bases, while silica separates out. The acids attack powdered glass much more quickly than they do a plane or curved surface. C. Nicolardot, R. Warrington, W. Tepohl, and A. Emmerling studied the action of dil. hydrochloric acid on glass. T. Griffiths found that boiling hydrochloric acid extracts potash only, not lead oxide, from glass. This statement is very doubtful in view of the action of that acid on lead silicate glasses, discussed by T. E. Thorpe and C. Simmonds, W. Jackson and E. M. Rich, and W. Thomason—*vide* lead-silicate glasses. H. Hess said that in distilling hydrochloric acid from a green glass retort, potassium chloride, ferric chloride, and silica were dissolved, and a crystalline sublimate was formed. K. Beck investigated the solubility of plumbiferous glasses in acetic acid—*vide* lead silicates. Glasses which resist attack by acetic acid were found by J. B. A. Dumas to be sometimes quickly attacked by sulphuric acid. R. Warrington studied the action of tartaric acid on glass. F. Förster, M. Berthelot and L. P. St. Giles, E. P. Poste, E. Egger, P. H. Walker and F. W. Smither, F. Cedivoda, W. Tepohl, W. E. S. Turner and co-workers, etc., investigated the action of acids on glass. They found that for one and the same glass, the loss of weight at 100° was the same whether sulphuric, or nitric acid of normal, decinormal, or millinormal conc. be used. Conc. acids are less active than dil. acids; and all the dil. acids were less active than water. Hence, F. Förster concluded that the acid does not act directly on the glass, but merely modifies the action of water. The effects with superheated acids—at 160°–190°—were somewhat similar. F. Förster explains the action of acids on glass somewhat as follows: The first action involves the dissolution of alkali by the water. Under ordinary conditions the alkaline soln. so formed is more active than water—*vide infra*. The acid neutralizes the alkali and prevents it accelerating the attack, and the neutralization is effected more quickly with conc. than with dil. acids. The influence of the conc. is greatest when the alkali is being most quickly extracted, namely, at a high temp. The character of the action of water on glass is not altered by acids; the difference is merely due to the fact that the acid prevents

the accumulation of free alkali in the soln. The alkali is more completely washed out of the glass by acid soln. than it is by water alone. A few silicates—e.g. wollastonite, labradorite, and sodium metasilicate glass—are directly attacked by acids, and more quickly by conc. acids than by dil. acids; and dil. acids more quickly than by water. The glass $\text{Na}_2\text{O} \cdot 0.3\text{SiO}_2$ behaves towards acid soln. like ordinary glasses. The mechanism of the action of water on glass was discussed by F. R. von Bichowsky. The resistance of lead glasses to acids was found to be increased by long exposure to the acid. E. Siegwart found that flue gases containing sulphurous gases produce a white film of alkali sulphate on glass; and E. Priwoznik observed a similar effect produced on the cylinders about the flame of coal gas. R. Cowper examined the action of aq. soln. of hydrogen sulphide. E. Frémy and L. Clémandot produced iridescent films on glass by the action of 10–12 per cent. of hydrochloric acid at 120° – 150° . P. Jannasch decomposed various silicates by hydrochloric acid at high temp. and press. The effect of aq. soln. of carbon dioxide has been discussed in connection with the weathering of glass. C. Matignon and G. Marchal examined the corrosion of glass by water in the presence of carbon dioxide under 10 atm. press. during 10 years; L. Pfaundler, the action of liquid and compressed vap. of carbon dioxide. J. S. Stas found that glass containing lead or aluminium is more readily attacked by acids than is the case with potash-lime glasses which withstood the action best. J. W. Mellor found that a high content of boric oxide in lead glasses increases the solubility of the contained lead oxide in 0.25 per cent. hydrochloric acid, and conversely with alumina. Alumina helps to counteract the unfavourable effects produced by the boric oxide. F. Förster, and G. T. Beilby found that the vap. of sulphuric acid attacks glass, and this the more the higher the temp. The sulphuric acid contained in the products of combustion of coal and coal-gas attacks glass, giving it a white coating of alkali sulphates easily removed by washing with water. J. B. A. Dumas found that all kinds of glass are decomposed by hot conc. soln. of phosphoric acid; and the action of this acid was also investigated by K. Hüttner. Hypophosphorus attacks glass even more rapidly than phosphoric acid.

Glass is attacked by soln. of sodium or potassium hydroxide, and silica passes into soln. The attack is facilitated by raising the temp., or increasing the conc. At ordinary temp., the alkali-lye in glass bottles dissolves the glass and causes it to crack. F. Förster investigated the action of the alkali-lye on different kinds of glass. He found that no sharp line can be drawn between the attack by water and by dil. soln. of the alkalies. The alkali extracted by water from glass, so long as it remains near to the glass and is therefore only moderately diluted, strengthens the attack in two ways: (i) by swelling up the surface, and (ii) by dissolving silica—particularly at high temp. Very dil. soln., say millinormal, attack glass no more quickly than does water, but if the alkali soln. be more conc. the attack is quickened, and this the more with increasing conc. With lime-alkali glasses, the alkali silicate is dissolved, and the calcium silicate is left undissolved, so that the surface appears to be dulled. If the alkali-lye be more conc., the calcium silicate is also attacked, so that a 2N-NaOH soln. dissolves calcium silicate as a whole. No materially increased attack occurs by raising the conc. of the soln. The attack by conc. soln. of alkali hydroxides decreases by lowering the temp. The order of attack is soda-lye (most vigorous), potash-lye, ammonia soln., and baryta-water. Glasses do not usually differ so much in susceptibility to attack by alkali soln. as by water. W. E. S. Turner and co-workers found that after 3 hrs.' action of 2N-NaOH, the losses in mgrms. per sq. decm., at different temp. were:

	20°	40°	60°	80°	100°
Loss . . .	0.0	1.7	4.1	18.9	31.7
					74.2

The results vary with different glasses; F. Mylius and F. Förster found that with one glass the rate of attack was 1900 times faster at 80° than at 0° . They also examined the effect of magnesia on the resistance of glass to attack by alkaline soln. The action of alkalies on glass has been also studied by G. C. Schmidt and

F. Durau, W. E. S. Turner and co-workers, and P. H. Walker and F. W. Smithers : of soln. of barium, strontium, and calcium hydroxides, by F. Jones ; and of baryta-water, by C. Bunge.

T. Griffiths, P. H. Walker and F. W. Smithers, P. Nicolardot, and A. Emmerling, found that aq. ammonia attacks many kinds of glass, and a flint-glass bottle containing a soln. of ammonium carbonate became so fragile that on shaking it pieces of glass were detached. B. Silliman found that a dry mixture of ammonium chloride and nitrate attacks glass when heated in contact therewith ; and R. F. Marchand observed a similar effect with dry ammonium sulphate or hydrosulphate. P. Nicolardot, and F. Förster investigated the action of soln. of alkali carbonates on various glasses, and found that the attack is greater than with soln. of the alkali hydroxides. Sodium carbonate exerted a greater action than potassium carbonate. Alumina increases the resistance of glass to alkali carbonates. H. D. Richmond found a specimen of potassium carbonate containing less than 5 parts per million contained 120 parts of lead after being kept in a lead-glass bottle for 9 weeks. E. A. Coad-Pryor made some observations on this subject. A soln. of sodium sulphate did not have any marked effect ; but soln. of sodium phosphate have a marked action ; and aluminiferous glasses have a greater resistance than alumina-free glasses. W. E. S. Turner and T. E. Wilson examined the action of soln. of sodium phosphate. P. Nicolardot, and A. Emmerling studied the action of aq. soln. of ammonium chloride, etc., on glass. R. Cowper examined the action of ammonium sulphide soln. on glass ; A. Lachaud and C. Lepierre, the action of ammonium hydrosulphate ; and J. H. Smith, the action of sodium phosphate. E. C. Sullivan found coarsely powdered window glass became blue by contact with a soln. of cupric sulphate owing to the exchange of bases.

M. Berthelot studied the action of aq. soln. of alcohol, glycerol, and organic acids on glass ; R. Weber, and F. Mylius, the action of aq. ether ; and R. Weber, the action of aq. alcohol. In 1757, T. Tronchin, in his *De colica pictonum* (Genevæ, 1757), showed that many wines are able to dissolve lead from the glaze of earthenware vessels in which the wines were stored—vide lead. R. Warrington, and A. Frank examined the effect of wines on glass ; R. L. Frink, the effect of beer ; A. Lesure, A. Dian, L. Kröber, the effect of pharmaceutical preparations ; and M. Guerbet, and A. W. Bitting, that of milk. K. Scheringa observed the adsorption of metal salts from drinking water by glass, and he found that lead is precipitated chemically on the glass. G. T. Beilby found that halos are formed about pieces of metal foil on glass when heated to a sufficiently high temp., in the presence of the products of combustion of coal gas and air. The halos are produced by the decomposition products of the glass itself.

F. Gelstharp studied the solubility of sodium sulphate, sodium chloride, and calcium and sodium sulphides in glasses ; A. D. Holdercroft, the solubility of zinc oxide in glazes ; and E. Greishammer, and R. Zsigmondy, the solubility of metal sulphides in glass. G. J. Knox found glass is reduced when heated with many metals.

§ 38. Cement

The use of lime for making mortar has been traced back to very ancient times. There is a reference to mortar in *Deuteronomy* (27, 2), and the analyses of the mortar employed in the construction of the pyramid of Cheops, show that the early Egyptians must have possessed great skill in the arts of compounding lime-mortar. The Assyrians and Babylonians employed clay, or bitumen, or a kind of burnt gypsum as a mortar in building with bricks; and the early Greeks used lime as a kind of plaster to cover the walls of buildings constructed with unburnt bricks. About a century and a half before our era, Cato the Elder in his *De re rustica* has

several references to the preparation and use of lime-mortar; and Pliny, in his *Historia naturalis* (36. 55), in the first century of our era, referred to a number of public buildings in which lime-mortar was used in their construction. Vitruvius also, in his *De architectura* (2. 5), written near the beginning of our era, described the manufacture of lime-mortar for building purposes. A. F. Gori reported in his *Museum Etruscum exhibens insignia veterum Etruscorum monuments* (Florentiæ, 1743) that tombs and cisterns found near the ancient cities of Iguvium, Clusium, and Volterra were built or lined with a calcareous mortar. The writers in the Middle Ages seem to have done little more than follow Vitruvius' description of lime-mortar, but they also mentioned the use of volcanic tufa—santorine, pozzolane, and trass—in the production of mortars, and in some cases, the products had the property of setting hard, while immersed in water.

The modern cement industry started in 1756, when J. Smeaton¹ was employed by Parliament to build a lighthouse on the partially submerged rocks at Eddystone in the English Channel. He required for the foundations a cement which would harden under water. The ordinary lime-mortars then in use completely failed to satisfy this condition. J. Smeaton obtained an argillaceous limestone which when calcined and mixed with the pumice-like pozzolana, of volcanic origin, produced a satisfactory mortar. The pozzolana was found in a few volcanic districts, notably in Italy, where it was used in making the famous old Roman cement, and further attempts were made to manufacture artificial Roman cements without using pozzolana. Most of these were made by burning argillaceous limestone. J. Parker, for example, in 1791 made a cement by calcining "certain stones or argillaceous productions," and it was later called by the misleading term *Roman cement*, but, later still, it was called *Parker's cement*. In 1818, M. St. Leger, and in 1822, J. Frost, also patented the manufacture of cement by burning siliceous limestones or marls. In M. St. Leger's case, the burning temp. was not very high, and the products were only hydraulic limes. J. Frost called his product *British cement*. In 1824, J. Aspdin patented an improved cement by heating together an intimate mixture of limestone and clay to a temp. sufficient to drive the carbon dioxide from the limestone. He called the product *Portland cement* from its resemblance to the building-stone of Portland. Although the temp. of burning in J. Aspdin's first process does not produce a cement like that now known as portland cement, this defect was very soon overcome, and the value of heating the raw materials to incipient fusion was discovered in 1825. Consequently, portland cement may be regarded as the finely pulverized product which results from the partial fusion of an intimate mixture of argillaceous and calcareous materials in certain proportions; and, when mixed with water, it sets to a hard stone-like mass. It is used largely in constructional work—sidewalks, houses, bridges, tunnels, etc.—as a substitute for stone. The strength and permanence of the cement depends largely upon the constituents formed in the cement during its preparation. Numerous patents for improvements in the methods of manufacture, etc., have been taken—e.g. by W. H. Hurry, T. R. Crampton, F. Ransome, F. W. S. Stokes, etc.

Portland cement is usually prepared by heating together limestone and clay; or blast-furnace slag and limestone; or any other combination of raw materials containing the right proportions of lime, alumina, and silica. The raw materials are crushed, mixed in the required proportions to give the necessary ratio $\text{CaO} : \text{Al}_2\text{O}_3 : \text{SiO}_2$, and ground to a fine powder. The mixture is burned in a rotary kiln 60–100 ft. long, and 5–8 ft. diameter, built of steel plates lined with firebrick; the cylinders are supported in a slightly inclined position on friction rollers, and slowly rotated. The raw materials are fed into the cylinder at one end, and discharged at the other as a partially fused mass in the form of granules varying in size from a pea to a large marble and called *cement clinker*. The fuel used is powdered bituminous coal blown by compressed air at the lower end of the cylinder so that the raw material passing down encounters a progressively increasing temp. The time of transit through the cylinder is about 1½ hrs. and the final temp. 1425°. In passing through the rotary kiln, the material is first dried, then the organic matter is destroyed and the carbon dioxide expelled, and finally there is a chemical reaction between

the lime, alumina, and silica to form the clinker. The clinker is ground to a fine powder to furnish the portland cement of commerce, and during the grinding a small proportion of gypsum may be added in order to regulate the time of setting of the cement when it is mixed with water.

R. K. Meade gave for the average composition of good grades of portland cement:

CaO	Al ₂ O ₃	SiO ₂	Fe ₂ O ₃	MgO	SO ₃
62.0	7.3	22.0	2.5	2.5	1.5

showing that more than 90 per cent. consists of the three oxides CaO, Al₂O₃, and SiO₂. The other oxides exert only a secondary influence, and a good portland cement has been made from these three oxides alone. G. A. Rankin and F. E. Wright have investigated the possible compounds of lime, alumina, and silica at high temperatures, and the results are summarized in the ternary diagram, Fig. 161; but since the relative proportions of the three oxides in good cements vary between comparatively narrow limits—60 to 64 per cent. CaO; 5 to 9 per cent. Al₂O₃; and 19 to 25 per cent. SiO₂—the practical problem is concerned with only a very restricted portion of the ternary field.

G. A. Rankin and F. E. Wright have shown microscopically that commercial portland cement clinker contains over 90 per cent. of a mixture of the three compounds, 2CaO.SiO₂, 3CaO.SiO₂, and 3CaO.Al₂O₃, and it is therefore inferred that the cementing value of portland cement is largely due to one or more of these compounds. When a mixture of 64 per cent. of CaO as carbonate, 8 per cent. of alumina, and 23.6 per cent. of silica is slowly heated, the principal changes which occur in different intervals of temperature during the formation of clinker are summarized by G. A. Rankin in Table XVIII. While the lime is present at 1450°,

TABLE XVIII.—THE TEMPERATURES OF FORMATION OF THE CONSTITUENTS OF PORTLAND CEMENT.

Raw mix.	1000°.	1000°-1335°.	1335°-1450°.	1450°-1650°.
CaCO ₃	CaO	CaO	CaO, Flux	2CaO.SiO ₂
Al ₂ O ₃	Al ₂ O ₃	5CaO.3Al ₂ O ₃	3CaO.Al ₂ O ₃	3CaO.SiO ₂
SiO ₂	SiO ₂	2CaO.Al ₂ O ₃	2CaO.SiO ₂	3CaO.Al ₂ O ₃
		3CaO.Al ₂ O ₃	3CaO.SiO ₂	

it is entirely combined when the temperature reaches 1650°, and the cooled clinker has the composition indicated in the last column of the table. The small amounts of ferric oxide, magnesia, and alkalis always present under manufacturing conditions lead to the formation of a flux at a lower temperature than with pure materials, and this promotes the combination of lime with alumina and silica. Thus, G. A. Rankin has shown that the impurities were mainly MgO, Fe₂O₃, and alkalis. The second sample examined was commercial white portland cement; the third, a common grey variety. The three types of clinker are made up largely of the same constituents: tricalcium silicate, dicalcium silicate, and tricalcium aluminate, all compounds of the three major components of cement. If the clinker of the grey cement of Table XIX were perfectly burned it would contain about 36 per cent. of 3CaO.SiO₂; 33 per cent. of 2CaO.SiO₂; 21 per cent. of 3CaO.Al₂O₃; and 10 per cent. of the minor constituents. If the raw materials be imperfectly ground, or inadequately fired, the chemical reactions will not be completed. The compound 3CaO.SiO₂ is the last to form by the combination of lime with dicalcium silicate: CaO+2CaO.SiO₂=3CaO.SiO₂, and therefore if imperfectly burned the cement will contain free lime and more 2CaO.SiO₂—according to the particular stage at which the reaction was arrested. The presence of free lime is detrimental, leading to the early disintegration of the cement, but increasing the proportion of combined lime increases the percentage of 3CaO.SiO₂, and also

TABLE XIX.—THE COMPOSITION AND BURNING TEMPERATURE OF PORTLAND CEMENT.

Percentage composition.				Burning temp.	Constituents of cement clinker.
CaO.	Al ₂ O ₃ .	SiO ₂ .	Impurities.		
68.4	8.0	23.6	0	1650°	2CaO.SiO ₂ ; 3CaO.SiO ₂ ; 3CaO.Al ₂ O ₃ .
66.2	6.4	25.0	2.4	1525°	2CaO.SiO ₂ ; 3CaO.SiO ₂ ; 3CaO.Al ₂ O ₃ , with a small amount of lime.
63.2	7.7	22.4	6.7	1425°	2CaO.SiO ₂ ; 3CaO.SiO ₂ ; 3CaO.Al ₂ O ₃ , with small amounts of lime, 5CaO.3Al ₂ O ₃ , and ferrites.

the strength of the cement. This is the most important constituent of portland cement, and it is formed with the greatest difficulty; this constituent is the one which hardens and develops the greatest strength within a reasonable time.

In 1818, L. J. Vicat² also experimented on the cements made by calcining mixtures of lime and clay, and his *Recherches expérimentales sur les chaux de construction, les betons, et les mortiers ordinaires* (Paris, 1818), started in 1812, was an attempt (i) to find the relation between the quality of hydraulic lime and cement, and the chemical composition of the raw materials; (ii) to find the nature of the compounds formed during burning; and (iii) to find the changes which occur when cement is mixed with water and hardens. This work may be regarded as among the earliest of the attempts to found a "chemistry of cements." Other observations were reported by J. F. John, C. L. Treussart, B. Quist, S. Rinmann, R. A. Vogel, J. Ziegler, J. A. C. de la Faye, B. Faujas de la St. Fond, J. A. C. Chaptal, H. V. Collet-Descotils, C. F. Wiebekeing, E. Candlot, B. F. Bélior, P. Berthier, J. N. von Fuchs, H. Meyer and C. M. Kersten, F. Kuhlmann, J. Kreating, etc. E. Jordis and E. H. Kanter have compiled a bibliography dealing with work on the nature and properties of portland cement from the time of L. J. Vicat.

H. le Chatelier, and A. E. Törnebohm noted microscopically four different constituents in cement clinker. The two kinds which predominate have been called alite and celite. The former is the predominating constituent, the latter appears as a filling material or matrix between the grains of alite. This suggests that **alite** is the main product of the clinkering of cement, and that celite is the more fusible portion or flux which has solidified after the crystallization of the alite. In well-burnt cements the crystals of alite have sharp outlines, in poorly burnt cements the outlines are rounded and indefinite. O. Schmidt has prepared crystals of pure alite. The **celite** is usually a deeper colour than the alite, probably because the ferric oxide tends to accumulate in the flux. According to H. le Chatelier, celite acts on polarized light, and he gave it the imaginary formula: $3\text{CaO} \cdot 2(\text{Al}, \text{Fe})_2\text{O}_3$. C. Richardson believed celite to be a solid soln. of dicalcium aluminate in dicalcium silicate. The crystals of alite belong to the rhombic system, and H. le Chatelier believed this constituent to be a calcareous *peridot*, or lime-olivine, $3\text{CaO} \cdot \text{SiO}_2$, which on calcination crystallizes in the matrix of celite. C. Richardson claimed that alite is a solid soln. of tricalcium aluminate, $3\text{CaO} \cdot \text{Al}_2\text{O}_3$, and tricalcium silicate, $3\text{CaO} \cdot \text{SiO}_2$, because the analytical ratio Bases : Silica = 3 : 1. The third constituent is called **belite**, and it resembles alite in some respects. It is usually dirty green in colour and striated. It has not been isolated. It is a secondary constituent and is found principally in cements poor in lime. This circumstance, and the fact that the crystals sometimes occur partially disintegrated, has led to its being considered to be calcium silicate, $2\text{CaO} \cdot \text{SiO}_2$, i.e. calcium orthosilicate, Ca_2SiO_4 . H. le Chatelier supposed it to crystallize in the cubic system, because he found it to have no action on polarized light. He regarded it as tricalcium aluminate, $3\text{CaO} \cdot \text{Al}_2\text{O}_3$, or a solid soln. of this compound with dicalcium aluminate. The fourth constituent, **felite**, is also found in colourless rhombic crystals in blast

furnace slags which have partially disintegrated. H. le Chatelier found it to have a very energetic action on polarized light. This constituent has not been isolated, and it is considered by H. Kappen to be a solid soln. of dicalcium aluminate with the non-hydraulic form of dicalcium silicate, while belite contains the hydraulic form of this latter compound. Some magnesium silicate, $2\text{MgO} \cdot \text{SiO}_2$, is probably also present in solid soln. in the dicalcium silicate.

When portland cement is mixed with water, a hard mass is formed by chemical reactions between the constituents of the cement and the water. In the first stage of setting, the cement mortar sets by passing from a plastic to a solid state—this requires a few hours; the cement then *hardens* by gradually increasing in strength—this may occupy years. G. A. Rankin added:

Taking the three constituents separately, tricalcium dioxycaluminate, $3\text{CaO} \cdot \text{Al}_2\text{O}_3$, or $\text{Ca}_3\text{O}_2(\text{AlO}_2)_2$, when mixed with water sets and hardens very rapidly; the setting and hardening are due to the formation of an amorphous hydrate on the individual grains which are thus cemented together. The amorphous material sometimes crystallizes. Slabs made of this compound remain sound under water, but they develop little strength, they are rather soft and are appreciably soluble in water. Calcium orthosilicate, $2\text{CaO} \cdot \text{SiO}_2$, or Ca_2SiO_4 , slowly reacts with water, and only after many months does a moulded slab develop any marked strength; it is not appreciably soluble in water. The cementing material is a coating of an amorphous hydrate on the individual grains. Calcium hydroxide can be leached out from the hydrate until amorphous silica alone remains. Any crystals which develop are hydrated calcium hydroxide. The dicalcium silicate is more rapidly hydrated by water saturated with calcium aluminate, so that in portland cement the rate of hydration of the dicalcium silicate is faster than when alone. Tricalcium silicate, $3\text{CaO} \cdot \text{SiO}_2$, or Ca_3SiO_6 , sets and hardens rapidly. Slabs of this compound remain sound, and in a relatively short time develop a strength comparable with that of portland cement. The hydrated product behaves towards water just like hydrated dicalcium silicate. According to H. le Chatelier, *la réaction fondamentale*, which brings about the hardening, is the splitting up of a basic calcium silicate into hydrated calcium metasilicate and calcium hydroxide: $3(\text{CaO} \cdot \text{SiO}_2 + \text{Aq.}) = 2\text{Ca}(\text{OH})_2 + \text{CaO} \cdot \text{SiO}_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$. The beginning of the hydration and the formation of elongated crystals of the hydrated silicate, $\text{CaSiO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, is illustrated by Fig. 128, where the dimensions of the acicular crystals have been exaggerated by doubling their proportionate size. The rate of formation of the hydrated product is not affected by the presence of the other constituents of portland cement. The minor constituent, pentacalcium dioxycitraluminate, $5\text{CaO} \cdot 3\text{Al}_2\text{O}_3$, $\text{Ca}_5\text{Al}_6\text{O}_{14}$, or $\text{Ca}_5\text{O}_2(\text{AlO}_2)_3$, sets and hardens rapidly. Slabs of this cement when placed in water disintegrate rapidly partly owing to dissociation and partly owing to solubility. The compound in setting forms an amorphous material on the surface of individual grains, and this partially crystallizes. The crystals are probably hydrated tricalcium aluminate.

FIG. 128.—Formation of Acicular Crystals of Hydrated Calcium Metasilicate in the Hydration of Portland Cement.

G. A. Rankin describes the setting and hardening of portland cement as involving the formation of an amorphous hydrated material which subsequently partially crystallizes. "The initial setting is probably due to the hydration of $3\text{CaO} \cdot \text{Al}_2\text{O}_3$; the hardness and cohesive strength at first are due to the cementing action of the amorphous material produced by the hydration of this aluminate and of the $3\text{CaO} \cdot \text{SiO}_2$; and the gradual increase in strength is due to the further hydration of these two compounds together with the hydration of the $2\text{CaO} \cdot \text{SiO}_2$. Of the three compounds which thus take part in the setting and hardening of portland cement, $3\text{CaO} \cdot \text{SiO}_2$ appears the best cementing material; that is, this

compound is the only one of the three which when mixed with water will set and harden in a reasonable time to form a mass which in hardness and strength is comparable with portland cement. The compound $2\text{CaO} \cdot \text{SiO}_2$ requires too long a time to set and harden in order to be in itself a valuable cementing material. The compound $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ while it sets and hardens rapidly, is rather soluble in water and is not particularly strong or durable. From this it would appear that tricalcium silicate is the essential constituent of portland cement; consequently, the higher its percentage the better, and that gelatinous silica is the most essential constituent of a cement mortar." The release of gelatinous silica in the action of water on tricalcium silicate is probably the reason why this compound is such a valuable cementing material; indeed, certain of the toughest sandstones are made up of grains of sand bonded together with gelatinous silica which was gradually deposited from soln. on to the grains of sand, and subsequently hardened.

P. H. Bates and A. A. Klein thus describe their observations of the different constituents during the setting of portland cement:

At early periods the constituents of portland cement of normal composition and manufacture, in order of their strength-conferring properties, are: Tricalcium silicate, tricalcium aluminate, and dicalcium silicate. At periods beyond 28 days the dicalcium silicate gains sufficient strength to place it almost on an equality with the tricalcium silicate. Tricalcium aluminate containing 10 per cent. plaster gains practically no strength after the first period at which it was tested; that is, 24 hours. Tricalcium silicate of the purity used in this investigation (90 per cent. $3\text{CaO} \cdot \text{SiO}_2$ in one case and 95 per cent. in the other) has all the important properties of portland cement, especially those of the "rate of setting" and strength developed. Dicalcium silicate, such as used in this investigation, sets too slowly and attains strength too slowly to be of any commercial value when used alone. Tricalcium aluminate alone, as used in this investigation, sets too rapidly and attains too little strength to be of any commercial value as a hydraulic cementing material. Tricalcium aluminate, when used to replace about 19 per cent. of the dicalcium silicate (which is approximately the amount of aluminate present in portland cement) adds somewhat to the strength of the latter at the later periods. Tricalcium aluminate, when used to replace about 19 per cent. of tricalcium silicate, did not add to the strength of the latter, showing rather a slight tendency to decrease it. The addition of 3 per cent. of plaster gave higher early strengths but lower later ones. Tricalcium aluminate, when used to replace about 19 per cent. of a mixture of equal parts dicalcium and tricalcium silicate, increased the strength at 24 hours and 7 days, but decreased it at the later periods. It appears, therefore, that the composition of portland cement should be along lines which would not produce a great preponderance of either silicate. The ideal cement should possibly have an excess of the dicalcium silicate, which would give a not too dense hydrated material, gaining strength at later periods. A lesser amount of the tricalcium silicate would furnish the desired early strength and also overcome the excessive porosity of the dicalcium silicate. It is possible to make a cement that will have the properties of portland cement by grinding together the previously separately burned constituents in approximately the amounts in which they exist in portland cement. The function of tricalcium aluminate in the finished cement is somewhat problematical. A cement with less than one per cent. of alumina has all the properties of portland cement. Such a cement is, however, not a commercial possibility from the manufacturing standpoint, on account of the temperatures and amount of burning involved. To state, however, that the aluminate in the finished cement is of the nature of a diluent or inert material would be drawing a conclusion which while justified by the present investigation, requires further confirmatory work. The actual products of the hydration are those noted by A. A. Klein and A. J. Phillips, excepting as noted before the case of the dicalcium silicate, when apparently during the hydration of this compound lime hydrate is formed.

The observations of A. A. Klein and A. J. Phillips are thus summarized by them:

The hydration of cements is thus brought about by the formation of amorphous hydrated tricalcium aluminate with or without amorphous alumina, the aluminate later crystallizing. At the same time sulphoaluminate crystals are formed, and low-burned or finely ground lime is hydrated. The formation of the above compounds begins within a short time after the cement is gauged. The next compound to react is tricalcium silicate. Its hydration may begin within 24 hours, and it is generally completed within 7 days. Between 7 and 28 days the amorphous aluminate commences to crystallize and beta-orthosilicate begins to hydrate. Although the latter is the chief constituent of the American portland cements, it is the least reactive compound. The early strength

(24 hours) of cements is probably due to the hydration of free lime and the aluminates. The increase in strength between 24 hours and 7 days depends upon the hydration of tricalcium silicate, although the further hydration of aluminates may contribute somewhat. The increase between 7 and 28 days is due to the hydration of beta-calcium orthosilicate, but here are encountered opposing forces, in the hydration of any high-burned free lime present and in the crystallization of the aluminate. It is to this hydration that the falling off in strength between 7 and 28 days of very high-burned high-limed cements is due, whereas the decrease shown by the high alumina cements is due to the crystallization of the aluminate. Finally, the iron in the cement is resistive to hydration and does not form any definite crystalline hydration products, but occurs as a rust-like material.

These theories of the setting involve the crystallization of one or more constituents. A. Michaelis advocated a colloidal theory of setting in which the formation of a colloidal substance is the essential feature; and W. Rosenhain argued in favour of the colloidal theory in another form by assuming that the solid grains are initially surrounded by a liquid soln. of certain constituents which solidifies owing to the removal of water—by percolation or chemical action. This solidification may take place by crystallization, but if very thin it may congeal in an amorphous condition. These amorphous films or layers impart to the whole mass its great hardness and strength.

According to E. Martin,² if a mixture of a mol of silica and two mols of calcium carbonate be heated at 1200°, and the free lime removed with a soln. of sugar, the resulting silicate, $10\text{CaO} \cdot 5\text{SiO}_2$, or $(\text{Ca}_2\text{SiO}_4)_2$, is inactive as a cement. It is completely soluble in acetic acid; sodium carbonate removes 3 mols. of the silica from it. Cement silicate is obtained by heating a mixture of a mol of silica with 3 mols of calcium oxide at 1400°; it is never free from the inactive silicate, $5\text{SiO}_2 \cdot 10\text{CaO}$, but its composition is deduced to be $5\text{SiO}_2 \cdot 13\text{CaO}$. It is completely soluble in acetic acid, but is unaffected when boiled for a short time with sodium carbonate soln.; prolonged treatment with the cold soln. removes 2 mols. of the silica. When it sets there is liberated $3\text{Ca}(\text{OH})_2$ with the formation at first of $5\text{SiO}_2 \cdot 10\text{CaO} \cdot 2\text{H}_2\text{O}$, which gradually undergoes further hydrolysis. When setting takes place in presence of carbon dioxide a protective coating of calcium carbonate is formed. Prolonged heating of silicate cement at 1000° causes it to dissociate into $5\text{SiO}_2 \cdot 10\text{CaO}$ and 3CaO . The silicate thus formed is not identical with the inactive silicate of the same composition, but is of a little value as a cement. A hydraulic cement of the composition $5\text{SiO}_2 \cdot 8\text{CaO}$ was obtained by heating a mixture of hydrated silica (obtained from the acetate) with 2 mols. of CaCO_3 at 1200°.

The physical and chemical properties of portland cement, and the effect of various salts on the setting and endurance of the cement are described in special books on the subject.

The so-called *ciment fondu*, *ciment noir*, or *ciment électrique* is made by fusing the raw materials in an electric furnace. Its composition approximates SiO_2 , 10; Al_2O_3 , 42; CaO , 42; Fe_2O_3 , 46. The fused material is ground extremely fine, and magnetized. It is used in place of portland cement when quick-setting is specially desired.

§ 39. Topaz

The *τοπάζος* of Theophrastus' *Ἐπεὶ λίθων*, and the *topazius* of Pliny's *Historia naturalis* (37. 42), referred to what is now called chrysolite, and their chrysolite refers to what is now called topaz; or, as A. B. de Boodt¹ expressed it, *topazius vulgaris erat chrysolithos veterum*. According to Pliny, the name topaz was adopted from that of an island in the Red Sea. The topaz was mentioned by J. de Laet, J. F. Henckel, J. G. Wallerjus, A. Cronstedt, C. Linnæus, etc. The crystals were described by J. B. L. Romé de l'Isle, R. J. Haiiy, J. A. Monteiro, A. Russell, and A. Lévy.

W. Hisinger and J. J. Berzelius applied the term *pyrophyllite*—from *πῦρ*, fire; and *φυλλαίς*, a bubble—to a coarse, opaque, yellowish-white, compact mass of topaz from Finbo, in allusion to its intumescence when heated before the blowpipe flame. C. A. S. Hofmann considered the first syllable to be redundant and called it *physalite*. A. G. Werner, A. Cronstedt, B. G. Sage, and J. B. L. Romé de l'Isle referred to a white schorl, or a schorl-like beryl which J. C. Delaméthérie called *leucolite*; D. L. G. Karsten, *Stangenstein*; M. H. Klaproth, *schorlite*; R. Kirwan, *schorlite*; and R. J. Haiiy, *pycnite*—from *πυκνός*, dense, compact. The compact mineral with a columnar structure was

considered to be a distinct species because G. Forchhammer said that the mineral is monoclinic, while topaz is rhombic. G. Rose, and A. des Cloizeaux showed that the properties of the crystals are the same as those of topaz; and C. F. Rammelsberg showed that the two minerals have the same chemical composition.

Early attempts were made to find the chemical nature of topaz. J. H. Pott² reported that by calcination the crystals became matte, and brittle. A. S. Marggraf's analysis indicated that the dominant constituents were alumina and lime; but this was made ten years before the discovery of hydrofluoric acid. M. H. Klaproth, L. N. Vauquelin, J. C. Wiegand, and J. T. Lowitz found that the chief constituents of topaz are silica and alumina; but M. H. Klaproth's analysis was about 7 per cent. low; he then showed that the missing component was fluorine, and L. N. Vauquelin found that the actual amount of fluorine in the mineral approaches 20 per cent. J. J. Berzelius, G. Forchhammer, H. St. C. Deville, and C. F. Rammelsberg approached the problem with improved methods, and since then many analyses have been made. C. F. Rammelsberg³ assumed that topaz is an anhydrous silicate, and that the small amount of water indicated in many analyses is due to decomposition. He gave the formula $n\text{Al}_2\text{SiO}_5 \cdot \text{AlSiF}_{10}$. G. Städelé gave $\text{Al}_2\text{SiO}_4\text{F}_2$, and he regarded it as a compound of aluminium silicate, $\text{SiO} : \text{O}_2 : (\text{AlO})_2$, and aluminyl fluosilicate, $\text{SiF}_2(\text{AlO})_2$. H. Klemm used a mixture formula like that of C. F. Rammelsberg. P. Groth represented topaz as an isomorphous mixture of andalusite, $\text{Al}(\text{AlO})\text{SiO}_4$, and the fluoride $\text{Al}(\text{AlF}_2)\text{SiO}_4$. F. W. Clarke and J. S. Diller represent the composition by $\text{Al}_3(\text{SiO}_4)_3(\text{AlF}_2)_3$ analogous with $\text{Al}_3(\text{SiO}_4)_3(\text{AlO})_3$ for andalusite—both derivatives of aluminium orthosilicate $\text{Al}_2(\text{SiO}_4)_3$. S. L. Penfield and J. C. Minor assume the formula of topaz to be $\text{SiO}_4(\text{AlF})_2$, or $\text{Al}=\text{SiO}_4--\text{AlF}_2$; like P. Jannasch and J. Locke, they consider that the hydroxyl can replace the fluorine isomorphously, and they write $\text{SiO}_4[\text{Al}(\text{F},\text{OH})]_2$. Topazes corresponding with the end-member, $\text{SiO}_4(\text{AlF})_2$, are known, and Brazil furnishes a topaz with $\text{F}:\text{OH}=3:1$ which is the highest hydroxyl derivative known. P. Erculisse regarded the topazes as salts of fluo-aluminosilicic acids. K. Daniel represented topaz as **dialuminyl difluosilicate**:

W. and D. Asch, postulating their hexites and pentites, assume a series with one terminal member, $(\text{OH})_{12}\text{Al}_{12}\text{Si}_6\text{O}_{24}$, and by the successive replacement of hydroxyl by fluorine arrive at the other terminal member, $\text{F}_{12}\text{Al}_{12}\text{Si}_6\text{O}_{24}$. C. F. Rammelsberg observed that when topaz is heated to redness part of the fluorine escapes as silicon fluoride and part as aluminium fluoride; and W. and D. Asch affirm that twice as many fluorine atoms are united to the aluminium as are united to the silicon atoms, and added:

Weitere Untersuchungen müsssen ergeben, dass das Verhältnis des als Fluorsilicium fortgehenden Fluors zu dem als Fluoraluminium sich absaltenden = 1 : 2 ist.

Even if the premise be correct, so many secondary changes might obscure the issue that the "must" is too dogmatic. They also stated that only the fluorine atoms united to silicon, but not to aluminium, are easily replaced by hydroxyl radicles.

Topaz usually occurs along with tourmaline, mica, beryl, apatite, fluorite, and cassiterite in granite or gneiss, and especially in stanniferous pegmatites;⁴ Brazilian topazes occur in decomposed material, which, according to O. A. Derby, was probably a mica schist. W. Cross also found it in cavities in rhyolite and other volcanic rocks. C. G. C. Bischof discussed the formation of topaz from kaolinite, and feldspar by the action of alkali or aluminium fluorides. It is probable that gaseous emanations containing fluorine have played an important part in the genesis of topaz. A. Daubrée reported the synthesis of a substance allied to topaz

by heating alumina in a stream of silicon tetrafluoride, but H. St. C. Deville was unable to get a fluoriferous compound by this means. C. Friedel and E. Sarasin also said that they prepared a substance like topaz by heating a mixture of alumina, silica, water, and hydrofluosilicic acid at 500°. The only satisfactory synthesis is that by A. Reich, who heated a mixture of silica and aluminium fluoride at a bright red heat, and afterwards ignited the product in a stream of silicon tetrafluoride. The composition and crystallographic properties of the product agreed with those of topaz.

Topaz occurs usually in colourless, prismatic crystals; it also occurs in columnar masses, and coarse- or fine-grained masses. The colour may be white, straw-yellow, wine-yellow, grey, green, pale blue, or pale pink. The cause of the coloration is not known. L. Wöhler and K. von Kraatz-Koschlan assumed that the topaz from Villa Rica is coloured by chromium; W. Hermann found topaz coloured with iron oxide, but the results were indecisive with respect to chromic oxide; and C. F. Rammelsberg said that the topaz from Schnckenstein is coloured by a hydrocarbon. G. O. Wild and R. E. Liesegang also investigated the colour of the topaz. The crystals of topaz are sometimes red with enclosed microscopic crystals of rutile, ilmenite, or hæmatite. As shown by D. Brewster,⁵ topaz contains liquid inclusions, e.g. water, liquid carbon dioxide, and possibly another kind of liquid. One liquid had a refractive index of 1.311 and a high coeff. of thermal expansion; it was called *brewsterlin*, *brewsterlin*, and *brewsterlinite* by J. D. Dana. Another liquid had a refractive index 1.2946 and a coeff. of thermal expansion nearly like that of water; it was called *cryptolin* by J. D. Dana. These two liquids are immiscible. T. Erhard and A. Stelzner found the critical temp. of brewsterlinite to be near that of carbon dioxide. A. E. von Nordenskjöld observed in a Russian topaz a liquid which appeared to be a hydrocarbon like naphtha. There are besides crystals of several kinds of soluble salts within the fluid. This subject has been discussed by W. N. Hartley, A. A. Julien, H. Vogelsang, and H. Rosenbusch. No carbon dioxide is liberated in many of the reactions in which topaz has been formed in nature; and the presence of liquid carbon dioxide inclusions in the crystals shows that the liquid happened to be present when the crystals were formed. That a high temp. prevailed at the time of crystallization is evidenced by the fact that many of the cavities are only half filled with water. Both the water and the carbon dioxide are due to the condensation from enormously compressed vap. which, as W. N. Hartley expressed it, formed a kind of emulsion in the silicate soln. before crystallization occurred.

Topazes for use as gem-stones come from Russia, Brazil, Australia, etc. Colourless topaz, known also as *pingos d'agua*—drops of water—are cut in the form of brilliants; the sp. gr. is near that of the diamond, but their birefringence and index of refraction are smaller than those of the diamond. The lustre and brilliancy of the topaz are much less than is the case with the diamond. Yellow corundum is also sold as a gem-stone, under the name *oriental topaz*. Many yellow stones sold as topaz—*golden topaz*, and *Spanish topaz*—are really quartz; and they are often heated to convert them into the more valuable pink topaz. Pink topaz is distinguished from pink tourmaline by the sp. gr. and dichroism. The violet-red topaz of Sanarka River is very rare. Bluish green and blue topaz are sold in the trade as beryl or aquamarine. The two minerals can be distinguished by their sp. gr.

According to N. von Kokscharoff,⁶ the crystals of topaz belong to the rhombic system and have the axial ratios $a:b:c=0.528542:1:0.476976$. Observations were made by A. des Cloizeaux, G. vom Rath, L. Grünhut, G. Rose, V. Goldschmidt, V. Rosicky, M. Hoshina, H. Bücking, D. Brewster, H. Laspeyres, P. Groth, A. Corsi, A. Breithaupt, P. von Jeremejeff, W. E. Hidden and H. S. Washington, etc. V. Goldschmidt and R. Schröder, and L. Cahn described some growths of topaz needles on garnet. The cleavage of the crystals parallel to (001) is perfect, but imperfect parallel to (101) and to (011). These directions, according to O. Mügge, correspond with the percussion figure. H. Baumhauer, M. Eichler, V. Rosicky, S. Ichikawa, and A. Pelikan studied the corrosion figures.

A. N. Alling, C. Hintze, A. des Cloizeaux, P. Groth, E. Bertrand, and W. Ramsay measured the **optic axial angles**. A. Mulheims found :

	a-	B-	C-	D-	E-	b-	F-line
2V	65° 59'	65° 58½'	65° 58'	65° 41'	65° 12½'	65° 12'	64° 54½'

and F. Rudberg gave :

	E-	F-	G-	H-line
2V	56° 59'	56° 43'	55° 51'	55° 11'
2E	100° 55'	100° 32'	99° 0'	97° 50'

A. des Cloizeaux found that at 20°, $2E=119^\circ$ and at 250°, $2E=123^\circ$. P. Groth also found a small increase in the axial angles when the temp. is raised. S. L. Penfield and J. C. Minor measured the effect of the relative proportions of fluorine and combined water on the sp. gr. and on the optic axial angle. The results for Na-light are indicated in Table XX. The faces in the prismatic zone are often vertically

TABLE XX.—EFFECT OF COMPOSITION ON THE OPTIC AXIAL ANGLE OF TOPAZ.

	2E	Sp. gr.	Per cent. F	Per cent. H ² O
Thomas Range	125° 53'	3.565	20.37	0.19
Nathrop, Colorado	125° 51'	3.567	20.42	0.29
Tenagari, Japan	120° 59'	3.565	19.50	0.57
Aduntschilon, Siberia	118° 46'	3.562	19.24	0.58
San Luis, Mexico	118° 17'	3.575	19.53	0.80
Schneekstein, Saxony	114° 28'	3.555	18.50	0.93
Stoneham, Maine	113° 50'	3.560	18.56	0.98
Minas Geraes, Brazil	84° 28'	3.532	15.48	2.45

striated; they often show vicinal planes; and sometimes appear hemimorphic. F. Scharff made some general observations on the structure of the crystals of topaz. The **optical anomalies** were observed by D. Brewster, A. des Cloizeaux, and A. Mack; and to explain them E. Mallard supposed the crystals of topaz to be pseudo-rhombic, really monoclinic. The optical anomalies are probably due to variations in the composition of different parts of a crystal resulting in variations in the density; and producing molecular strains. H. Haga and F. M. Jäger, and J. Leonhardt examined the **X-radiograms** of topaz; the last-named found that for the elementary parallelepiped, $a=4.6$ A., $b=8.78$ A., and $c=8.37$ A., in agreement with the axial ratios 0.5285 : 1 : 9546. There are four mols. in each elementary parallelepiped; and it is assumed that there are no SiO_4 -groups, but that SiO_2 -groups are present. Each of the four molecules corresponds with $\text{Al}_2\text{F}_2\text{O}_2\cdot\text{SiO}_2$. The **corrosion figures** were studied by H. Baumhauer, E. S. von Fedoroff, V. Goldschmidt, V. Rosicky, and A. P. Honess.

The observed **specific gravity** of topaz ranges from 3.40–3.65. A. H. Church found for white, flawless, Brazilian crystals, 3.571–3.597; for sky-blue crystals, 3.541; and for wine-yellow crystals, 3.539 before ignition, and 3.533 after ignition. I. I. Saslavsky studied the mol. vol. of topaz. The **hardness** of topaz is between that of quartz and that of corundum, and is 8 on Mohs' scale. A. Rosiwal measured the hardness of topaz; and P. J. Holmquist, the abrasive hardness (quartz 1000), using carborundum of different grain-sizes as the abrasive. He gave for the (110)-face, and for the (001)-face, 813; and for the (001)-face, 633. W. Voigt found for the **modulus of elasticity**, $E_1=23,040$, $E_2=28,900$, $E_3=26,520$, $E_4=26,700$, $E_5=28,920$, and $E_6=31,860$ kgms. per sq. mm.; for the **torsion modulus**, he found $T_{23}=11,040$, $T_{31}=13,530$, and $T_{12}=13,360$ kgms. per sq. mm.; and for the **compressibility** $\beta=0.60\times 10^{-6}$. F. Auerbach gave for the elasticity modulus perpendicular to the base, 28,100–30,200 kgms. per sq. mm. E. Riecke has made some observations on this subject. H. Fizeau found the coeff. of **thermal expansion** to be $\alpha=0.08325$

in the direction of the *a*-axis, 0.058362 in the direction of the *b*-axis, and 0.054723 in the direction of the *c*-axis. F. Pfaff gave $\alpha=0.058325$ for the *a*-axis, $\alpha=0.054723$ for the *b*-axis, and $\alpha=0.058362$ for the *c*-axis; this makes the coeff. of cubical expansion 0.00002137. A. Offret made some observations on this subject. F. E. Naumann found the **specific heat** of topaz 0.2000–0.2037; J. Jolly, 0.1997–0.2004 between 10° and 100°; and G. Lindner found

Sp. ht.	50°	100°	150°	200°	250°
	0.2097	0.2151	0.2270	0.2357	0.2508

According to G. Forchhammer, and H. St. C. Deville, topaz, at a white-heat, loses the whole of its fluorine as silicon tetrafluoride; and, according to C. F. Rammelsberg, both silicon and aluminium fluorides are given off—*vide supra*. According to W. Vernadsky, topaz is transformed into sillimanite at a white heat. At a high temp., topaz melts and furnishes a glassy mass in which are crystals of sillimanite; these crystals are developed at a lower temp. if heated with a fluoride as a flux. The **indices of refraction** have been measured by A. des Cloizeaux, V. Rosicky, J. C. Heusser, A. Mülheims, P. Groth, F. Rudberg, A. N. Alling, etc. A. Mülheims gave for light of different wave-length:

	<i>a</i> -	<i>B</i> -	<i>C</i> -	<i>D</i> -	<i>E</i> -	<i>b</i> -	<i>F</i> -line
α	1.60916	1.61000	1.61091	1.61327	1.61615	1.61680	1.61870
β	1.61187	1.61273	1.61365	1.61597	1.61882	1.61947	1.62134
γ	1.61838	1.61926	1.62019	1.62252	1.62542	1.62608	1.62792

S. L. Penfield and J. C. Minor studied the effect of fluorine and combined water on the index of refraction, for Na-light, and found for the Thomas Range topaz with 0.19 per cent. of water and 20.37 per cent. of fluorine, and the Minas Geraes topaz with 15.48 per cent. of fluorine and 2.45 per cent. of water (*vide* Table XX):

	α	β	γ	$\gamma-\alpha$
Thomas Range	1.6072	1.6104	1.6176	0.0104
Minas Geraes	1.6294	1.6308	1.6375	0.0081

A. Offret measured the effect of temp. on the indices of refraction and found that raising the temp. from 0°–100° increased α by 0.00081, β by 0.00090, and γ by 0.00080 per 100°. The birefringence is low and, as just indicated $\gamma-\alpha$ decreases with increasing proportions of hydroxyl. A. Offret found for Na-light at 0°, $\gamma-\alpha=0.00777$ per degree rise of temp. between 0° and 300°; similarly $\beta-\alpha=0.00131$ per degree; and $\gamma-\beta=0.00050$ per degree. Some crystals of topaz are markedly **pleochroic**; J. Grailich and V. von Lang, A. Kenngott, and L. Grünhut have made observations on this subject.

E. Engelhardt found that ultra-violet light induces a feeble **luminescence**. J. Schingaglia showed that yellow topaz gives red fluorescent light which is not always completely polarized. E. Newbery and H. Lupton found that colourless and yellow topaz did not exhibit any thermoluminescence either before or after exposure to radium rays. A yellow topaz became pink when heated, and regained its original colour, perhaps even a deeper yellow, by exposure to radium radiations; when reheated there was a slight thermoluminescence. C. Doelter found that **radium rays** coloured white topaz, orange, and wine-yellow topaz, a dark orange. He also found that topaz is less transparent than andalusite or cyanite to **X-rays**, and the introduction of fluorine is assumed to give increased opacity. The colour of topaz is intensified by X-rays; and a colourless topaz became yellow after 24 hrs. exposure. Topaz is not affected by **cathode rays**, and it does not phosphoresce. Exposure to ultra-violet rays undoes the effects produced by radium rays. N. von Kokscharoff showed that a dark yellow Siberian topaz was almost completely bleached by exposure to light. W. Hermann found that Brazilian yellow topaz became pink when heated in oxygen; lilac, in nitrogen; and green, in sulphur vapour. A specimen heated in oxygen after treatment with radium was found by C. Doelter to be almost colourless, and lilac if heated in nitrogen. S. C. Lind and D. C. Bardwell also studied the action of radium rays on topaz.

The **pyroelectricity** of crystals of topaz was examined by R. J. Haüy, A. Erman, J. D. Forbes, W. G. Hankel, P. Riess and G. Rose, C. Friedel and P. and J. Curie, A. Mack, and J. Beckenkamp. Most crystals are pyroelectric in the direction of their vertical axes; and doubly terminated crystals become electrified at the two ends, and may therefore be twins. R. J. Haüy noted the extreme sensitiveness of topaz to develop electricity by friction. C. Friedel and P. and J. Curie observed that Brazilian topaz exhibits **piezoelectricity**, since it becomes electrified by pressure. C. Doelter found that the **electric conductivity** increases, or the **electric resistance** decreases, with rise of temp., and he assumed that the high temp. conductivity is electrolytic:

Resistance . . .	800°	980°	1180°	1280°	1350°
	190,000	116,000	10,060	3100	2000 ohms.

W. Schmidt found the **dielectric constants** to be $\epsilon_a=6.65$, $\epsilon_b=6.70$, and $\epsilon_c=6.30$. W. Voigt and S. Kinoshuto found the **magnetic susceptibility**, parallel to the a -axis, to be -410×10^{-7} ; to the b -axis, -4.20×10^{-7} ; and to the c -axis, -4.20×10^{-7} . B. Bavink studied the magnetic properties of the crystals.

Topaz is only partially attacked by sulphuric acid. J. Lemberg⁷ found that when topaz is heated with a soln. of sodium silicate for 174 hrs. between 200° and 210°, an alkali aluminosilicate of a zeolitic character is formed. According to F. W. Clarke and J. S. Diller, topaz readily alters by hydration and by the action of percolating soln., and is transformed into muscovite. They add that the reported changes to steatite and lithomarge or kaolinite are probably mal-inferences. The alteration of topaz has been also discussed by A. Atterberg, K. J. V. Steenstrup, etc.

§ 40. The Alkali Aluminium Silicates

A number of alkali aluminium silicates have been prepared; but with most cases the only evidence of chemical combination is chemical analysis, and in some, the formation of crystals which may or may not be isomorphous mixtures. Some of the processes have been discussed in connection with the synthesis of minerals. There is often a difficulty in the study of these ternary systems by the usual thermal methods because the vitreous products do not crystallize readily. R. Riecke,¹ and G. Flach studied the fusibility of mixtures of sodium and potassium oxides and clay. J. J. Berzelius, F. Fouqué and A. Michel-Lévy, S. J. Thugutt, G. Stein, J. Morozewicz, W. C. Brögger and H. Bäckström, W. Vernadsky, and P. G. Silber described products obtained by fusing together mixtures of silica, alumina, and sodium carbonate; and crystals corresponding with $\text{Na}_2\text{O}:\text{Al}_2\text{O}_3:\text{SiO}_2=2:1:2$; $1:1:2$; and $3:3:6$; have been reported. T. J. Pelouze, and W. F. S. Turner and co-workers made a series of alkali-alumina glasses. J. J. Berzelius, and G. Stein obtained the $1:1:2$ potassium compound in a similar manner. P. Berthier, in his study of the fusibility of slags, worked with mixtures corresponding with the two alkali feldspars $1:1:6$, and also with $3:5:33$. The $1:1:2$ compounds are discussed in connection with the nephelite family. A. Gorgeu claimed to have made the $1:1:1$ compound by fusing at a red heat an intimate mixture of kaolinite and potassium carbonate in a current of moist air. After drying in vacuo, the composition of the washed products corresponded with **potassium dialuminyll orthosilicate**, $\text{K}_2\text{Al}_2\text{SiO}_6$, or $\text{K}_2(\text{AlO})_2\text{SiO}_4$. If the $2:1:2$ compound be not a mixture, then the product with the composition $\text{Na}_4\text{Al}_2\text{Si}_2\text{O}_9$ is presumably **sodium dialuminyll orthosilicate**, $\text{Na}_4(\text{AlO})_2\text{Si}_2\text{O}_7$. This product was made by P. G. Silber by heating an intimate mixture of kaolinite and sodium carbonate for a long time, and leaching the soluble sodium carbonate and silicate from the mass. The product is decomposed by hydrochloric acid with the separation of gelatinous silicic acid; gaseous hydrogen chloride at 150° converts one-third of the sodium into soluble chloride; and digestion with conc. aq. soln. of silver nitrate at 130° rapidly converts it into canary-yellow **silver dialuminyll orthosilicate**, $\text{Ag}_4\text{Al}_2\text{Si}_2\text{O}_9$, or $\text{Ag}_4(\text{AlO})_2\text{Si}_2\text{O}_7$.

Quite a number of alkali aluminium silicates have been prepared by hydrothermal processes. G. Friedel, for instance, obtained monoclinic, pseudocubic, doubly-refracting crystals with the composition $6\text{Na}_2\text{O} \cdot 3\text{Al}_2\text{O}_3 \cdot 8\text{SiO}_2$, accompanying the hydronephelinite formed by the action of a 9 per cent. soln. of sodium hydroxide on potash-mica at 500° . The sp. gr. was 2.660 at 12.5° ; and the product was easily

decomposed by cold hydrochloric acid. H. St. C. Déville obtained a product with the composition $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$ by the action of a very conc. soln. of sodium hydroxide on kaolinite, orthoclase, or bauxite; and F. Singer reported a similar product in small scaly crystals, but with the composition $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 4\text{H}_2\text{O}$. H. St. C. Déville similarly obtained $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$; and S. J. Thugutt, $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, by the action of an aq. soln. of potassium carbonate on nephelite, scapolite, kaolinite, and other silicates. J. Lemberg obtained $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 3\text{H}_2\text{O}$ by digesting zeolites, phillipsite, labradorite, analcite, or leucite with an aq. soln. of potassium carbonate,* or by digesting aluminium hydroxide in a 10 per cent. soln. of potassium disilicate at $195^\circ\text{--}200^\circ$. J. J. Berzelius mixed an aq. soln. of potassium aluminate with silicic acid, and H. St. C. Déville heated potassium aluminate and silicate at 200° , and obtained a crystalline powder of $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. B. von Ammon reported $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, to be formed when a hot soln. of alum is allowed to stand in contact with crystallized sodium silicate—*vide infra*, leucite. F. Singer also obtained a product with the composition $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 4\text{H}_2\text{O}$; and another with the composition $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. J. Lemberg obtained $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 6\text{H}_2\text{O}$ by the action of a soln. of sodium silicate and potassium chloride on albite; and F. Singer obtained $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 4\text{H}_2\text{O}$. The latter also reported the silicates $\text{Na}_2\text{O} : \text{Al}_2\text{O}_3 : \text{SiO}_2 : \text{H}_2\text{O}$, 1 : 1 : 7 : 5; 1 : 1 : 10 : 7; 1 : 1 : 12 : 6; 1 : 1 : 15 : 5; and 1 : 1 : 20 : 8—*vide infra*, permutites.

K. von Haushofer treated a soln. of water-glass with potash-alum and obtained a precipitate approximately 1 : 1 : 12 : 40, but much free silicic acid was present. W. Heldt said that the precipitate after washing is free from alkali and approximates 0 : 2 : 15 : 10. B. von Ammon also said that if crystalline water-glass be added to an aq. soln. of aluminium sulphate a clear soln. is obtained until finally a precipitate begins to form. If a soln. of water-glass be treated with an excess of aluminium sulphate, the resulting precipitate contains $\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$, which after washing still retains about one per cent. of the alkali silicate. By digesting aluminium hydroxide with an aq. soln. of water-glass for 6 days at 100° , J. Lemberg obtained a precipitate approximating 1 : 1 : 5 : 0 after thorough drying. W. Heldt said that moist aluminium hydroxide removes no silica from a conc. soln. of water-glass. J. Lemberg digested aluminium hydroxide with a soln. of sodium silicate and sodium sulphide and obtained a precipitate with some of the sulphide; similarly also with soln. of sodium sulphate, carbonate, and chloride. There is nothing to show that these products were chemical individuals—*vide infra*, the sodalites.

U. Pratolongo studied the variation in the composition of the precipitates produced by mixing soln. of sodium aluminate and silicate of different conc. Working with a soln. containing 19.360 grms. of sodium silicate per litre, he found that when mixed with :

Sodium aluminate (grms. per litre.)	Percentage composition of precipitate.			
	H_2O .	SiO_2 .	Al_2O_3 .	Na_2O .
42.318	79.25	41.63	26.56	31.81
21.309	84.25	43.30	25.71	30.99
8.524	93.30	45.52	24.06	30.42
4.261	94.05	51.80	20.14	28.06
2.131	Gelatinization "without precipitation"			

He also measured the variation in the solubility of one of the components according to the amount of solid present; and he found the variations in the amounts of potassium or ammonium chloride adsorbed by the solid with the relative proportion of solid phase present.

The three minerals eucryptite, nephelite, and kaliophilite form a group which can be called the **nephelite family**. The mineral **eucryptite**—from *εὖ*, well, and *κρυπτός*, hidden—forms with albite an apparently homogeneous substance which was once called *β-spodumene*. This latter term, by the way, is now applied to a variety of spodumene proper. G. J. Brush and E. S. Dana² showed that, under the microscope, *β-spodumene* is made up of two minerals, and, when treated with hydrochloric acid, it gives a residue of albite, and eucryptite passes into soln. with the gelatinization of the silicic acid. Eucryptite has a composition corresponding with **lithium aluminium orthosilicate**, LiAlSiO_4 , or *lithium aluminosilicate*. F. W. Clarke and J. S. Diller represent the constitution by the tripled formula $(\text{AlSiO}_4)_2 : \text{AlSiO}_4\text{Li}_3$ —*vide* nephelite. P. Hautefeuille and A. Perrey synthesized this compound by fusing a mixture of kaolinite and lithium vanadate; and Z. Weyberg, by fusing a mixture of lithium sulphate and kaolinite. Hence, he regarded eucryptite as the lithium salt of what he called *kaolinic acid*, HAlSiO_4 . The compound was also made by A. S. Ginsberg, F. M. Jäger and A. Simek, and R. Ballo and E. Dittler, by fusing the right proportions of the constituent silicates, Fig. 129, in a closed crucible at 1500° . This f.p. curve by R. Ballo and E. Dittler has two eutectics with an intervening maximum corresponding with the compound $\text{Li}_4\text{SiO}_4\cdot\text{Al}_4(\text{SiO}_4)_3$, or LiAlSiO_4 , melting at 1330° , which resembles eucryptite although the crystals were not sufficiently well-developed completely to establish the identity. A second compound, $3\text{Li}_4\text{SiO}_4\cdot\text{Al}_4(\text{SiO}_4)_3$, or $\text{Li}_6\text{Al}_2(\text{SiO}_4)_3$, **lithium dialuminium orthosilicate**, decomposes at 1079° , i.e. below its m.p.—*cf.* A, Fig. 129. Only a portion of the ternary system $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ was studied. R. Rieke studied the action of lithia on clay (*q.v.*).

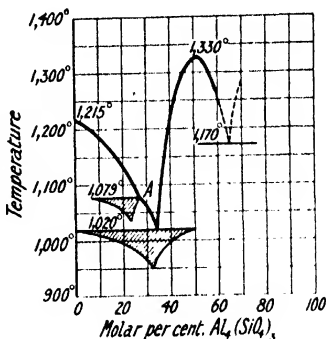

FIG. 129.—Freezing-point Curves of the Binary System: $\text{Li}_4\text{SiO}_4-\text{Al}_4(\text{SiO}_4)_3$.

In 1773, J. J. Ferber,³ and in 1775, I. S. R. I. Eques a Born described some crystals of a mineral from Monte Somma, Vesuvius, which was called *sommite* by J. C. Delam  therie in 1797. R. J. Ha  y applied to the same mineral the name *nepheline*—from *νεφ  λη*, a cloud—in allusion to the cloudy appearance it assumes when placed in nitric acid. The name is sometimes altered to **nephelita**.

F. de Bellevue applied the term *pseudosommite* to some crystals from Capo di Bove which closely resembled those from Monte Somma, as shown by F. Zambonini; the term *pseudonepheline* was used for the same mineral. P. Carpi made a wrong analysis of this mineral. R. J. Ha  y showed that all these substances belong to the same mineral species. According to A. Scacchi, pseudonepheline is represented by distorted crystals of sodalite. T. Monticelli and N. Covelli's *nephelina*, *davina* or *davyn*—named after H. Davy—and their *cavolinite*—named after F. Cavolini—were considered to be possibly *una sotto specie*, but A. Scacchi, H. Rauff, and E. Bertrand showed that they are different—*vide infra*. M. H. Klaproth applied the term *elaeolite*—from *  λαιον*, oil—to a nephelite from Norway in allusion to its greasy lustre; A. G. Werner previously called this mineral *F  ttelein*, and R. J. Ha  y, *Pierre de grasse*. C. Hartmann, and A. des Cloizeaux considered the mineral *phonite*, from Norway, to be a nephelite; W. C. Br  gger showed that the *gabronite* or *gabronite* of C. F. Schumacher is probably elaeolite.

The first analyses of nephelite were made by L. N. Vauquelin,⁴ A. Arfvedson, J. N. von Fuchs, C. G. Gmelin, M. H. Klaproth, and T. Scheerer. Numerous other analyses have since been made.⁵ T. Scheerer⁶ based a formula of the type $(\text{Na},\text{K})_8\text{Al}_8\text{Si}_9\text{O}_{34}$ on his analyses, while C. Bromeis advocated the simpler formula NaAlSiO_4 . The latter formula may be regarded as representing that of an

idealized mineral. H. W. Foote and W. M. Bradley pointed out that the mol. ratio $\text{Al}_2\text{O}_3 : \text{Na}_2\text{O}$ is nearly 1 : 1, and the ratio $\text{SiO}_2 : \text{Al}_2\text{O}_3$ varies from about 2 to 2.21 : 1. There is often therefore an excess of silica above that required by the formula NaAlSiO_4 . Synthetic nephelite is **sodium aluminium orthosilicate**, NaAlSiO_4 , or *sodium aluminosilicate*, which appears to have the same type of mol. as eucryptite, and kaliophilite; but the average of the best analyses corresponds more nearly with T. Scheerer's formula, which was also recommended by H. Rauff. C. F. Rammelsberg assumed that natural nephelite is a mixed mineral containing both the metasilicate, KAlSi_2O_6 , and the orthosilicate, NaAlSiO_4 . C. Doelter made nephelite by fusing together these two silicates. S. J. Thugutt, J. Morozewicz, S. Hillebrand, F. S. Starrabba, P. G. Tschermak, and W. Karandejeff also assumed that nephelite is a kind of additive compound or a solid soln. of two or more silicates. In order to account for the excess silica in the analyses indicated above, H. W. Foote and W. M. Bradley suggested that nephelite is a solid soln. of RAlSiO_4 and silica; while F. W. Clarke supposed the presence of potassium is due to admixed kaliophilite, and that the excess of silica in the natural mineral is due to the isomorphic replacement of SiO_4 by Si_3O_8 so as to form a salt isomeric with albite, $[\text{NaAlSi}_3\text{O}_8]_3$, which is admixed with the nephelite and kaliophilite. This view is favoured by W. T. Schaller, and N. L. Bowen. The *pseudonephelite* or *pseudosommitite* of F. Zambonini, obtained from Cape di Bove, is an isomorphous mixture of nephelite and kaliophilite. J. Lemberg's transformation of nephelite into kaliophilite by heating it and a soln. of potassium silicate for 100 hrs. at 200° , shows the equivalency of nephelite and kaliophilite. Since (i) eucryptite and nephelite both readily alter into muscovite or paragonite, and conversely (ii), since C. and G. Friedel found that muscovite can be changed into nephelite by heating it in a soln. of alkali at 500° , F. W. Clarke argued that the constitutional formula of muscovite, paragonite, and nephelite must be of the same type; and "the formula of muscovite is the key to all the other formulæ in this group of silicates." He therefore writes:

or graphically: nephelite, $(\text{Al}\equiv\text{SiO}_4)_2=\text{Al}-\text{SiO}_4\equiv\text{Na}_3$; and muscovite, $(\text{Al}\equiv\text{SiO}_4)_2=\text{Al}-\text{SiO}_4\equiv\text{KH}_2$. The tripled formulæ were supported by an experiment of P. G. Silber in which one-third the sodium of nephelite is replaced by silver when the nephelite is heated with a soln. of silver nitrate in a sealed tube. The resulting *silver nephelite* is interpreted to mean that only one of three sodium atoms in the mol. is replaced by silver; it may also mean that this represents the halting stage of a balanced reaction.

P. Hautefeuille⁷ made hexagonal prisms of nephelite by fusing a mixture of sodium aluminate, silica, and an excess of sodium vanadate. J. J. Berzelius, and F. Fouqué and A. Michel-Lévy made hexagonal prisms of nephelite by fusing a mixture of silica, alumina, and sodium carbonate. They say that it is one of the minerals which very easily crystallize from fused magma. C. Doelter obtained the crystals in a similar way, and he also imitated the natural product by fusing a mixture of leucite, KAlSi_2O_6 , and soda-nephelite, NaAlSiO_4 . S. Meunier made it by fusing a mixture of silica, alumina, soda, and cryolite. A. Duboin obtained rhombic crystals by melting silica or potassium fluosilicate and alumina with an excess of potassium fluoride. R. Hoffmann made an amorphous silicate of the composition of nephelite by heating together a mixture of kaolinite and sodium carbonate at a temp. below the sintering point. A. Gorgeu, and P. G. Silber used a similar method. R. C. Wallace, and A. S. Ginsberg obtained nephelite by the direct fusion of the constituents. N. L. Bowen showed that there is a transition point at 1352° ; above this temp. *carnegieite* is formed, and below, nephelite appears: *Carnegeite* \rightleftharpoons *nephelite* \rightleftharpoons *anorthite*. E. T. Wherry applied the at. vol. theory to the isomorphism of nephelite and kaliophilite; and he assumed

that K and $(\text{Na} + x\text{SiO}_2)$ are replaceable vol. for vol. Soda-lime-nephelites were made by C. Doelter and E. Hussak, N. L. Bowen, etc. Z. Weyberg made *baryta-nephelite*, and *strontia-nephelite* by fusing nephelite with baryta or strontia; and by fusing barium or strontium chloride with kaolinite. P. Eskola in his work on baryta-felspar observed no signs of the formation of a hexagonal baryta-nephelite, $\text{BaAl}_2\text{Si}_2\text{O}_8$. C. and G. Friedel converted muscovite into nephelite by heating a mixture of that mineral and a soln. of sodium hydroxide in a steel bomb at 500° . R. C. Wallace made a partial study of the ternary system $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$. W. Eitel heated mixtures of nephelite and calcium carbonate under press. of 100–115 kgrms. per sq. cm., so that no decomposition of the carbonate occurred. There is an eutectic at 1190° , Fig. 130, and there is formed cancrinite $3\text{Ne} \cdot \text{CaCO}_3$, where Ne represents a mol. of nephelite. The compound melts at 1253° , and it has the refractive indices $\omega = 1.550$, and $\epsilon = 1.519$, which are higher than the values for cancrinite. For spurrite, *vide supra*.

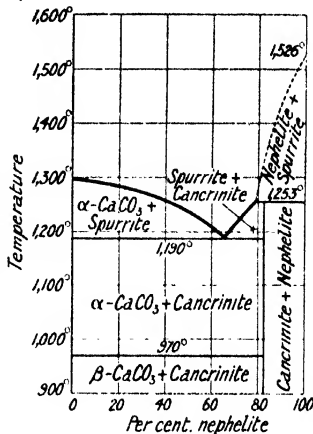

FIG. 130.—Binary System: Nephelite-Calcite.

B. Mierisch⁸ described the mineral **kaliophilite**—from *kali*um, and *philos*, a friend—in allusion to the contained potassium. The mineral was obtained in bundles of slender, acicular, colourless, hexagonal crystals in the ejecta from Monte Somma, Vesuvius. E. Scacchi called it *facellite*—from *φάκελος* or *φάκελλος*, a bundle—hence it is sometimes called *phenacellite* or *phenacelite*. B. Mierisch, E. Scacchi, and N. Covelli analyzed the mineral. The composition corresponds with **potassium aluminium orthosilicate**, KAlSiO_4 , or **potassium aluminosilicate**, and in the opinion of F. W. Clarke and J. S. Diller, this formula should be tripled $\text{Al}_3(\text{SiO}_4)_3\text{K}_3$ —*vide nephelite*. J. J. Berzelius, G. Stein, and C. Doelter synthesized the mineral by fusing together the constituent oxides or silicates; if an excess of potassium silicate be used, a glass is formed. S. J. Thugutt treated kaolinite with a 47 per cent. soln. of potassium hydroxide for 77 hrs. at 190° – 210° and obtained kaliophilite; A. Gorgeu fused the kaolinite with potassium chloride, and Z. Weyberg found the reaction progresses quickly in the presence of a chromate, tungstate, vanadate, or sulphate. A. S. Ginsberg, A. Duboin, and G. Stein proceeded in a similar way. A. Duboin fused together potassium fluoride or fluosilicate, alumina, and silica. A. S. Ginsberg, G. Stein, and E. Bauer obtained kaliophilite by fusing the constituents. M. Schläpfer and P. Niggli heated alumina, potassium hydroxide, silica, and water in a bomb at 470° . C. and G. Friedel converted muscovite into kaliophilite by heating it with a soln. of potassium hydroxide in a steel bomb to 500° . J. Lemberg converted nephelite into amorphous kaliophilite by heating a mixture of nephelite and a soln. of potassium silicate for 100 hrs. at 200° .

The three minerals eucriptite, nephelite, and kaliophilite thus form a family of alkali aluminosilicates which, said F. Zambonini,⁹ are probably isomorphous. A. Sauer's *cryptolite* has the same empirical composition, but hydrogen takes the place of the alkali metal. The crystals may be colourless, or the colour may be white, with a yellowish-, greenish-, or bluish-grey tinge. Brown and red nephelites occur in nature. Eucriptite occurs in symmetrically-arranged, white, hexagonal **crystals** embedded in albite. The artificial crystals of P. Hautefeuille and A. Perrey were said to be rhombohedral; those of Z. Weyberg, rhombic or rhombohedral.

Z. Weyberg, indeed, said that this silicate is trimorphous. Nephelite furnishes stout hexagonal prisms or thick plates. P. Groth gave for the axial ratio of the hexagonal pyramidal crystals of nephelite $a : c = 1 : 0.8383$; and N. von Kokscharoff, $1 : 0.83893$. The crystals of nephelite were also examined by A. Breithaupt, A. and E. Scacchi, C. F. Rammelsberg, H. Baumhauer, G. Strüver, W. C. Brögger, N. B. Möller, P. T. Weibye, J. F. L. Hausmann, C. Klein, etc. For kaliophilite, N. Covelli gave the axial ratio $a : c = 1 : 0.8388$. C. Doelter found the velocity of crystallization to be relatively high. The corrosion figures of nephelite with hydrofluoric and hydrochloric acids were studied by H. Baumhauer. F. Rinne found that the X-radiograms of nephelite agree with the corrosion figures in placing the mineral in the hexagonal pyramidal class. The cleavage of the crystals of the members of this group is distinct and parallel to the $(10\bar{1}0)$ -face; and in nephelite, it is also imperfect parallel to the (0001) -face. F. Rinne, and H. Haga and F. M. Jäger studied the X-radiogram of nephelite. G. J. Brush and E. S. Dana gave for the specific gravity of crystals of eucryptite, 2.644-2.649. The crystals of nephelite prepared by F. Fouqué and A. Michel-Lévy had a sp. gr. 2.555; and those by N. L. Bowen, 2.619. A. Breithaupt gave 2.631-2.637 for the sp. gr. of nephelite; N. L. Bowen, 2.55-2.65; C. F. Rammelsberg, 2.600-2.6087; T. Scheerer, 2.60. For kaliophilite, B. Mierisch gave 2.602, but the observed numbers range from E. Scacchi's 2.4926-2.67; F. Zambonini found a pure transparent crystal had a sp. gr. 2.628; A. Breithaupt gave 2.631, and G. Stein, 2.6. The hardness of eucryptite, nephelite and kaliophilite is 5-6. G. Tammann gave 0.184 for the specific heat of eleolite crystals, and 0.192 for the glass. The heat of solution in a mixture of hydrofluoric and hydrochloric acids for the amorphous glass is 649 cal. per gram, and for the crystals 575 cal. per gram; or the heat of crystallization is 73 cal. per gram. A. S. Ginsberg gave 1307° for the melting point of eucryptite; R. Ballo and E. Dittler, 1330° . A. Brun gave 1120° for the m.p. of nephelite; R. Cusack, 1059° - 1070° ; A. L. Fletcher, 1109° - 1120° ; C. Doelter, 1110° - 1195° for different samples; N. V. Kultaschew gave for artificial nephelite, 1007° ; W. Guertler, 1055° ; and R. C. Wallace, 1018° . F. M. Jäger and A. Simek gave 1388° for the m.p. of pseudo-eucryptite. R. Lorenz studied the relation between the m.p. and the transition temp. of eucryptite, kaliophilite, and nephelite. N. L. Bowen, and A. S. Ginsberg studied the fusion curve of mixtures of anorthite and nephelite. As indicated in connection with Fig. 130, the former showed that nephelite passes into carnegite at 1352° . J. H. L. Vogt gave 73 cal. for the estimated latent heat of fusion. A. S. Ginsberg's, and R. Ballo and E. Dittler's preparations of eucryptite, and F. Fouqué and A. Michel-Lévy's crystals of artificial nephelite, were uniaxial and optically negative; so also was the kaliophilite of B. Mierisch. The indices of refraction of nephelite, according to A. des Cloiseaux, are $\omega = 1.539$ - 1.542 , and $\epsilon = 1.534$ - 1.537 ; H. Rosenbusch, $\omega = 1.5416$ - 1.5427 , and $\epsilon = 1.5376$ - 1.5378 ; S. L. Penfield, $\omega = 1.5469$, $\epsilon = 1.5422$; C. Hlawatsch, $\omega = 1.539$, $\epsilon = 1.536$; B. Jezek gave for D-light, $\omega = 1.54886$ - 1.54912 , and $\epsilon = 1.54327$ - 1.54382 ; and F. S. Starrabba made some measurements. N. L. Bowen gave for artificial nephelite $\omega = 1.537$ (1.541), $\epsilon = 1.533$ (1.537), where the bracketed numbers refer to the natural mineral. The corresponding birefringences, $\omega - \epsilon$, range from 0.0040-0.0050 for the mineral, and 0.003 for the synthetic product. According to F. M. Jäger and A. Simek, when the artificial product is slowly cooled from a fused state, small, irregularly shaped crystals are obtained, for which measurements of the mean refractive index and the density gave $\mu_D = 1.531$ and sp. gr. = 2.362 at 25° . These data indicate that the artificial silicate is not identical with the mineral eucryptite, and the synthetic product has been named *pseudo-eucryptite*. If the fusion is rapidly cooled by quenching, a pseudo-eucryptite glass is obtained, for which $\mu_D = 1.541$. This glass is metastable with regard to the birefringent crystalline modification, and is rapidly converted into this on heating at 900° .

W. C. Brögger¹⁰ emphasized the fact that nephelite is peculiarly subject to

change under natural influences, and C. R. van Hise and S. J. Thugutt have discussed its alteration into analcite, hydronephelite, kaolinite, muscovite, natrolite, sodalite, thomsonite, etc. G. J. Brush and E. S. Dana also noted that eucryptite readily changes into muscovite. The three nephelite minerals are decomposed by acids with the separation of gelatinous silica. J. W. Mellor found that 98.63 per cent. of coarsely ground nephelite and 99.62 per cent. of fine-grained nephelite were decomposed by an hour's treatment with hot sulphuric acid. Nephelite was shown by S. J. Thugutt to be decomposed by water after heating for about 100 hrs. in the vicinity of 200° , whereby natrolite, sodium aluminate, and a micaceous substance were formed; kaliophilite behaves in an analogous manner. He also studied the action of water on kaliophilite at 196° – 233° . J. Lemberg, and S. J. Thugutt examined the effect of a prolonged digestion of nephelite with a soln. of potassium carbonate, sodium carbonate, magnesium sulphate, or calcium chloride. J. Lemberg obtained a substance resembling cancrinite, but with SiO_3 in place of CO_3 , by digesting nephelite with a soln. of sodium silicate. F. Zambonini observed pseudomorphs of leucite after nephelite and of nephelite after leucite, and attributed the latter to the action of soln. of alkali silicate on the leucite at a high temp. S. J. Thugutt examined the action of potassium silicate soln.; and he found that the vapour of sodium chloride transformed nephelite into sodalite; and G. Strüver found that an aq. soln. of sodium chloride behaves similarly. S. J. Thugutt found that kaliophilite is partially changed into nephelite by digesting with a soln. of sodium chloride. Z. Weyburg found eucryptite to be stable in an alkaline soln. of lithium sulphate. F. W. Clarke and G. Steiger studied the action of ammonium chloride, and H. Schneiderhölm, the action of various salt soln. on nephelite. P. G. Silber examined the action of soln. of silver nitrate, and of hydrogen chloride, and concluded that one-third of the sodium behaved differently from the remainder. H. Lötze studied the action of air charged with sulphur dioxide on nephelite. Z. Weyberg found that when kaolinite is melted with lithium bromide, a product with the composition $7\text{LiAlSiO}_4 \cdot \text{LiBr}$, *lithium aluminium heptabromo-orthosilicate*, is formed. S. J. Thugutt heated a mixture of kaliophilite, lithium chloride and carbonate, and water for 120 hrs. at 105° – 200° , and obtained a *hydro-eucryptite*, or *hydrated lithium aluminium orthosilicate*, $\text{LiAlSiO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. G. Tammann and C. F. Grevenmeyer found that magnesite did not react with nephelite at 100° ; lime reacted slowly at 500° ; and baryta, strongly at 275° – 300° .

The white or dark grey mineral, *hydronephelite*, found by F. W. Clarke and J. S. Diller¹¹ at Litchfield, Maine, is an alteration product of sodalite. The analysis corresponds with $\text{HN}_2\text{Al}_3(\text{SiO}_4)_3 \cdot 3\text{H}_2\text{O}$. It is apparently related with the mineral *ranite* (not *rauite*) from several islands in the Langsund fiord, Norway, described by S. R. Pajkull, and named after the old Norse sea-god Ran. According to W. C. Brögger, it includes part of what previously had been called *Spreustein*, by A. G. Werner; and K. Sonden's mineral *brevicite* should also be regarded as hydronephelite. C. F. Schumacher called a similar mineral *bergmannite*—named after T. Bergman; and A. Estner, *crocalite* or *krokalite*. S. J. Thugutt regarded hydronephelite as a mixture of natrolite and hydrargillite, and not as a *selbständiges* mineral species. The composition and nature of hydronephelite has been discussed by F. W. Clarke and J. S. Diller, S. J. Thugutt, A. Brun, J. E. Hibsich, J. Lemberg, C. von Eckenbrecher, F. Hundeshagen, R. A. A. Johnston, etc. Hydronephelite probably belongs to the hexagonal system, for it is uniaxial. The optical character is positive. The sp. gr. is 2.63, and the hardness 4–5; the sp. gr. of ranite is 2.48, and the hardness 5. W. W. Coblentz found the ultra-red transmission spectrum does not show that water of crystallization is present.

B. von Ammon¹² said that *hydrated sodium aluminium orthosilicate*, $\text{NaAlSiO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, separates as a white powder from a soln. of freshly precipitated aluminium hydroxide in a boiling conc. soln. of sodium hydroxide and silicate. J. Lemberg made it by heating aluminium hydroxide with sodium metasilicate;

and also by digesting alkali aluminium silicates, rich in silica, in conc. alkali-lye. Silica is removed and the residue has the composition indicated above. S. J. Thugutt heated kaolinite, sodium hydroxide, and water for about 100 hrs. at about 194° , and the treatment was repeated. The product was regarded as *nephelite-hydrate*, $5\text{NaAlSiO}_4 \cdot 2\text{H}_2\text{O}$; and, according to S. J. Thugutt, the product has little in common with hydronephelite. C. Friedel obtained rhombic crystals of $\text{NaAlSiO}_4 \cdot \text{H}_2\text{O}$ by the action of soda-lye on muscovite at 500° . A. E. Lagorio called the hydrate *lebergite*, and found the crystals are rhombic, but pseudo-hexagonal. C. Friedel gave 2.378 for the sp. gr. A. E. Lagorio said that the mean index of refraction of the rhombic crystals is 1.57; the optic axial angle $66^{\circ} 45'$; the double refraction is 0.003; and the optical character is positive. The optical properties change when the product is warmed. At a dull red heat all the water is expelled, but is reabsorbed when the substance has cooled. A soln. of potassium carbonate changes it into potash-natrolite; and water changes it into natrolite. B. von Ammon said the product is soluble in hydrochloric acid. W. Heldt, and F. Singer made some observations on this hydrate—*vide infra*, permutite.

J. Lemberg¹³ obtained a number of *hydrated kaliophilites*, or **hydrates of potassium aluminium orthosilicate**, (i) by digesting kaolinite with a 37 per cent. soln. of potash-lye; (ii) by treating various hydrated silicates—e.g. nosean hydrate, cancrinitic silicates, etc.—with a soln. of potassium carbonate; (iii) by the action of a 64 per cent. soln. of potassium carbonate or silicate at 200° on nephelite; and (iv) by the action of a soln. of potash-lye in leucite, or analcite in the presence of potassium chloride. The product of the last-named operation has the composition $\text{KAlSiO}_4 \cdot \text{H}_2\text{O}$; and, according to K. D. Glinka, this hydrate is formed when the potassium hydroxide soln. of aluminium silicate is neutralized with hydrochloric acid; and when hydrargillite, halloysite, or calcined kaolinite, and silica are digested with potash-lye, the resulting soln., when neutralized with hydrochloric acid, furnishes the hydrate $\text{KAlSiO}_4 \cdot 1\frac{1}{2}\text{H}_2\text{O}$.

J. Lemberg also claimed to have made tetrahedral crystals with the composition $\text{NaAlSiO}_4 \cdot \text{NaOH} \cdot \frac{1}{2}\text{H}_2\text{O}$ (i) by digesting kaolinite with a 50 per cent. soln. of sodium hydroxide; (ii) by treating kaliophilite with a mixed soln. of sodium silicate and hydroxide; and (iii) by the action of sodium hydroxide on nephelite. Warm water removes the sodium hydroxide from the complex. He also obtained doubly refracting needles of the complex $6\text{NaAlSiO}_4 \cdot \text{Na}_4\text{SiO}_4 \cdot 4\text{H}_2\text{O}$, by digesting at 200° kaolinite, kaliophilite, nephelite, analcite, leucite, or albite in sodium silicate melted in its water of crystallization. By digesting sodalite or nosean in an aq. soln. of sodium trisilicate at 200° , he obtained icositetrahedral crystals of the complex $\text{NaAlSiO}_4 \cdot \text{Na}_2\text{Si}_2\text{O}_7$.

Hydronephelite is possibly a member of a fairly well-defined group of hydrated aluminosilicates of the alkalis and alkaline earths, which are called **zeolites**. The term was first used by A. Cronstedt,¹⁴ and was intended to emphasize their intumescence when heated rapidly as in the blowpipe flame—from $\xi\omega$, to boil; and $\lambda\theta\sigma\varsigma$, a stone. For a time, the term was applied to other minerals—e.g. lapis lazuli, tourmaline, and gadolinite. T. Bergman showed that the zeolites are peculiar in being gelatinized by nitric acid, and this characteristic was emphasized by J. B. L. Romé de l'Isle. A. G. Werner subdivided the zeolites into those with granular, fibrous, radiating, and lamellar structures; most of the minerals regarded by him in the zeolites are similarly regarded at the present time. A. Breithaupt accepted A. G. Werner's name, for, as he expressed it, *diese schöne natürliche Gruppe*. The zeolites are usually well crystallized; they are fairly soft, and their sp. gr. is low. F. Mohs, indeed, proposed to call them *Kuphonspars*—from $\kappa\upsilon\phi\omicron\varsigma$, light—in allusion to their low sp. gr.; and G. A. Kenngott abbreviated the term to *kuphiu*. The zeolites do not form a family of minerals with related crystalline forms, as in the case of the felspars. The family, indeed, includes a number of sub-groups widely diverse in form and composition. A. N. Winchell has based a theory of the composition of zeolites on the variation in composition by the replacement of Ca by Na or K, and the simultaneous replacement of Al

by Si. Table XXI contains a list of the more important members of the zeolite family. A. E. Fersman studied the zeolites of Russia; and T. H. Smith, those of Ardglen, New South Wales.

TABLE XXI.—THE MEMBERS OF THE ZEOLITE FAMILY.

Zeolite.	Molecular ratio.				R''	Crystal system.
	R''Q ₂	Al ₂ O ₃	SiO ₂	H ₂ O		
Thomsonite	1	1	2	2.5	Ca, Na ₁	Rhombic
Gismondite	1	1	2	4	Ca, Na ₁	Monoclinic
Natrolite	1	1	3	2	Na ₁	Rhombic
Soesite	1	1	3	3	Ca	Monoclinic
Levynite	1	1	3	5	Ca	Hexagonal
Analcite	1	1	4	2	Na ₂	Cubic
Eudomophite	1	1	4	2	Na ₂	Cubic
Laumontite	1	1	4	4	Ca	Monoclinic
Gmelinite	1	1	4	6	Ca, Na ₁	Trigonal
Chabazite	1	1	4	6	Ca, Na ₁	Trigonal
Faujasite	1	1	5	10	Ca, Na ₁	Cubic
Phillipsite	1	1	5	5	Ca, K ₁	Monoclinic
Epistilbite	1	1	6	5	Ca	Monoclinic
Heulandite	1	1	6	5	Ca	Monoclinic
Brewsterite	1	1	6	5	Sr, Ba, Ca	Monoclinic
Desmine	1	1	6	5	Ca	Monoclinic
Stilbite	1	1	6	6	Ca	Monoclinic
Harmotome	1	1	5	6	Ba, K ₁	Monoclinic
Mordenite	1	1	10	7	Ca, K ₁ , Na ₁	Monoclinic
Edingtonite	1	2	3	3	Ba, K ₁	Tetragonal
Prehnite	2	1	3	1	Ca	Rhombic
Hydronphelite	3	3	3	3	Na ₁ , H	Hexagonal

The peculiar behaviour of the water in zeolites has attracted much attention. F. J. Malaguti and J. Durocher¹⁵ showed that when laumontite loses its water, the mineral becomes opaque, but the water is restored on exposure to air, and the mineral again becomes transparent. A. Damour showed that the zeolites lose their water when exposed to a dry atm. or when heated; and regain the lost water on exposure to moist air. As a rule, it is assumed in silicate-chemistry that water which is lost at a low temp. is present as a kind of "water of crystallization," and water which is expelled only at a high temp. is "constitutional water." C. Hersch said that only the water which is expelled from zeolites above 250° is united to the aluminium atoms, and that which is driven off below this temp. is united to the silicon atoms. Hence, he supposed that the zeolites did not contain water of crystallization. W. Fresenius assumed that at each temp. there is a definite proportion of water retained by the zeolite; and that the expulsion and restoration are continuous functions of the temp. Consequently, zeolites tested do not contain constitutional water. Other observations were made by J. Lemberg, C. W. Cross, A. Streng, C. F. Rammelsberg, etc. These will be discussed in connection with the individual zeolites. P. Jannasch showed that the water in the zeolites is not merely hygroscopic water, and F. Rinne later on emphasized the fact that the dehydration curves of the zeolites do not show any abrupt changes such as would be expected if definite hydrates were involved. A. Hamberg also found that the proportion of contained water depended on the partial press. of the water vap. in the atm.; and G. Tammann, and E. Löwenstein observed that the vap. press. of the zeolites changes continuously with the proportion of contained water. F. Zambonini confirmed these observations, and showed that the absorptive power of the dehydrated zeolite depends on the temp. to which it has been heated, and also on the duration of the heating. Similar observations were made by U. Panichi, E. Baschieri, and J. Morozewicz. E. Sommerfeldt measured the heat of hydration

and inferred that the water of the zeolites is adsorbed, and not in a state of solid soln. C. Doelter, and G. Bodländer also regarded the water as being adsorbed. A. Beutel and K. Blaschke, and G. Stoklossa measured the speed of rehydration of the zeolites hydrated between definite ranges of temp., and obtained curves showing such a large number of definite hydrates that it would appear as if some other factor is involved. R. Rinne examined the effect of water on the optical properties, and showed that the crystals which have become opaque appear to be transparent if immersed in oil. He showed that important mol. changes accompany the loss of water; and assumed that the water forms a solid soln. with the silicate. G. Friedel, and E. Mallard likened the water in zeolites to the water in a sponge; F. Zambonini, and O. Bütschli assumed that the structure of the zeolites is mycelial like that of the hydrogels; and A. Johnsen supposed that the water and anhydrous silicate form two interpenetrating cubic lattices, that the water has a free passage in the network of silicate mols.; and that with the loss of water there is a disturbance of the crystalline structure and a reorientation to form the anhydride. F. Rinne said that there is no sharp line of demarcation between crystalloids and colloids, and that the zeolites belong to an indefinite region between the two classes; accordingly he regarded the zeolites as crystalline substances in an *amikroskopisch Kolloidzustand*—not analogous to A. F. Rogers' *metacolloidal state*—represented by micro-crystalline substances of colloidal origin. G. Friedel, and F. Grandjean showed that gases or vapours other than water can be taken up by dehydrated zeolites—e.g. ammonia, hydrogen sulphide, iodine, mercury, mercuric sulphide or chloride, benzene, ether, alcohol, etc.

One of the most interesting properties of the zeolites as well as of many other silicates is the mutability of the bases. H. S. Thompson¹⁹ first established this fact by showing that when a soln. of ammonium sulphate is filtered through soil, the filtrate contains calcium sulphate, and an ammonium salt is retained. J. T. Way made an extensive series of experiments on this subject, and showed that the hydrated silicates in the soil were responsible for the phenomenon. The action was considered to be quite different from adsorption. The facts were subsequently confirmed by the work of H. Eichhorn, W. Henneberg and F. Stohmann, O. Küllenberg, F. Rautenberg, F. Brustlein, E. Peters, G. J. Mulder, C. J. Frankfortner and F. W. Jensen, and E. Heiden. The extensive researches of J. Lemberg, and S. J. Thugutt showed that the alkalies in these aluminosilicates can be largely replaced by alkaline earths, ammonium, thallium, silver, copper, manganese, nickel, ferrous-iron, lead, and other metals, when the silicate is digested with salts of those metals. Thus, 93 per cent. of the sodium in sodium-permutite is replaced by silver when immersed in a soln. of silver nitrate. Similarly also, F. Singer showed that the alumina of these aluminosilicates can be replaced by boric, vanadic, ferric, manganic, cobaltic, and chromic oxides; and I. D. Riedel found that the silicic acid can be replaced by boric, phosphoric, nitric, sulphuric, and other inorganic acids. The name **permutite**—from *permutare*, to change—is applied to an artificial zeolite or hydrated aluminosilicate whose bases are easily replaced by other metals; and the products of the replacement can be easily restored to the primitive form. Thus, when sodium-permutite is introduced into a soln. of an ammonium salt, part of the sodium is replaced by an eq. quantity of ammonium; and the ratio Na:NH₄, for equilibrium, is determined by the temp. and conc. of the soln. An acid sodium silicate, described by T. P. Hilditch and co-workers, and sold under the trade-name *doucil*, belongs to this class. Methods of preparation have been described by A. Messerschmitt, P. Schuler, and many others.

G. J. Mulder first assumed that the law of mass action was applicable to the equilibrium conditions; consequently, added M. Dittrich, the exchanges are not adsorption phenomena, but purely chemical processes. J. Lemberg likewise concluded that in these purely chemical processes, mass plays the same rôle as it does in the theory of mass action, so that there is an incomplete exhaustion of the soln., and a mutual replacement of the bases. Consonant with A. W. Williamson's

well-known theory of dynamic equilibrium, J. M. van Bemmelen suggested the following *modus operandi* of the exchange:

If we assume with the physicists in explanation of electrolysis that in a dil. acid or salt soln. a few individual mols. are in a state of dissociation, it is conceivable that the potash of the mols. in soln. is fixed by the adsorbent, whereupon fresh dissociation and binding can take place until equilibrium is attained.

H. P. Armsby wrote on the application of the law of mass action to the phenomenon. Subsequent observations have shown that the primary action described by this law is obscured by secondary effects. R. Gans regarded the permutites and saline soln. as a single homogeneous phase, and he observed that the law of mass action is applicable to soln. of small conc.

In the reaction $\text{Na-Pe} + \text{NH}_4 \rightleftharpoons \text{NH}_4\text{-Pe} + \text{Na}^+$ (when Pe stands for permutite), let x denote the number of millimols transformed; m , the number of grams of permutite; n , the maximum number of milli eq. transformable per gram of permutite; g , the number of millimols of NH_4 originally present in the soln.; and v , the vol. of the soln. R. Gans (wrongly) assumed that the system is homogeneous, in which case the conc. of the different salts in equilibrium are $C_{\text{NH}_4\text{Pe}} = x/v$; $C_{\text{NaPe}} = (nm - x)/v$; $C_{\text{NH}_4\text{Cl}} = (g - x)/v$; and $C_{\text{NaCl}} = x/v$. From the law of mass action, therefore, $x^2 = K(nm - x)(g - x)$. This agrees with observations only when the conc. of ammonium chloride is small, so that x is negligibly small in comparison with nm , and then $x^2 = Knm(g - x)$. An analogous expression is obtained by assuming that the partition law (2, 17, 11) is applicable to the permutite considered as a solid soln. of two permutites.

R. Gans prepared permutites, or colloidal hydrated aluminosilicates, with a composition $\text{RO} : \text{Al}_2\text{O}_3 : \text{SiO}_2 = 1 : 1 : 3-4$, by the action of a soln. of an alkali aluminate on silicic acid, but not by the interaction of an alkali silicate and aluminium hydroxide. Although the permutites are colloidal, R. Gans agreed that they are definite chemical compounds, and not adsorption products. R. Gans made artificial zeolite, or permutite, by fusing together a mixture of china clay, sodium carbonate and quartz, in the required proportions. The cold, vitreous, hard mass was pulverized, and the soluble sodium aluminate and silicate were removed by leaching with cold water. A mixture of 2.5-3 parts of china clay, 5-6 of alkali carbonate, and 1.5-2.4 of borax, treated in a similar way, gave a good result. The permutite so obtained should be granular or scaly, and with a high porosity. The composition approximates $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 6\text{H}_2\text{O}$. F. Singer has given a large number of recipes for preparing permutites. The sodium-permutite so prepared can be converted into ammonium-permutite by treatment with a 10 per cent. soln. of ammonium chloride. By a similar method C. Massatsch, Y. K. Lee, T. P. Hilditch, and co-workers, etc., have prepared artificial zeolites or permutites.

A. Günther-Schulze found that the exchange of the base in sodium-permutite by silver is dependent on the ionic conc. of the silver in the soln. rather than on the total conc. of the silver salt. The silver and sodium are capable of diffusion in the solid permutite; and from the fact that at 20° sodium-permutite has an electrical conductivity of 6.53×10^{-4} mhos, and silver permutite, 4.48×10^{-4} , he calculated the diffusion constants of sodium and silver to be respectively 1.30×10^{-8} and 1.90×10^{-8} sq. cm. per sec. The porosity of permutite is 30 per cent. The same diffusion constant is obtained from the diffusion experiments when it is assumed that the active surface of permutite is 9 or 10 times as great as that of an equally large, non-porous mass. A. Günther-Schulze also measured the sp. resistance of 21 permutites at 18°, and found for Li-permutite, 1800 ohms; Na^+ , 1780; K⁺, 1160; Rb⁺, 1400; NH_4^+ , 1700; Mg^{++} , 8130; Ca^{++} , 8330; Sr^{++} , 8770; Ba^{++} , 10,200; Cu^{++} , >90,000; Ag^+ , 2220; Zn^{++} , 11,700; Cd^{++} , 16,200; Pb^{++} , >150,000; Mn^{++} , 11,200; Ni^{++} , 5000; Co^{++} , 5000; Fe^{++} , 6600; Fe^{+++} , 320; Al^{+++} , 420; and Cr^{+++} , 730 ohms. The mean temp. coeff. is $R = R_{18} \{1 + a(\theta - 18)\}$, where $a = 4.1 \times 10^{-2}$. The electrical conductivities, he said, fall into three groups, those of the alkali metals, silver, and thallium, $50-90 \times 10^{-5}$; those of the alkaline earth metals, $9-11 \times 10^{-5}$; and the rest with very slight conductivities. The equilibrium

constants of the basic exchange of sodium-, potassium-, or ammonium-permutite with salts of copper, magnesium, zinc, nickel, cobalt, aluminium, barium, strontium, calcium, thallium, silver, manganese, chromium, lead, rubidium, and uranyl fall into similar groups as the conductivities, excepting that silver and thallium, in spite of the strong ionization of their permutites, are almost entirely removed from soln. while nickel and cobalt remain in soln. Usually, the higher the at. wt. of the metal, the more readily is it removed from soln. by the permutite—aluminium is exceptional. The subject was discussed by V. Rothmund and G. Kornfeld, and C. J. Frankforter and F. W. Jensen.

A. Günther-Schulze examined the relation between the water content of the permutite and the mobility of the cation as shown by the readiness with which the basic exchange occurs. The permutites of the alkali and alkaline-earth metals contain $5\text{H}_2\text{O}$, and it is generally considered that, of these, three are water of crystallization and two "water of constitution." With potassium-permutite, however, the water content varies continuously according to the temp. and vap. press., and no distinction was found between the first three and the last two mol. proportions. The increase in the mol. vol. of potassium-permutite at different stages of hydration is proportional to the number of mols. of water added. So long as the permutite is not completely dehydrated, it can again be fully hydrated, but after ignition it takes up only about $1.25\text{H}_2\text{O}$. The permutites of the metals copper, silver, chromium, aluminium, formed by basic exchange from alkali metal permutites, contain from $6-8\text{H}_2\text{O}$; but when formed from ignited potassium permutite the water deficiency of this persists in the derived permutites. The mobility of the cation does not appear to be influenced by the water content. Ignited potassium-permutite comes to the same stage of equilibrium with a silver nitrate-potassium nitrate soln., for instance, as the fully hydrated permutite, but equilibrium is reached more slowly, because, through partial sintering during ignition, the high porosity of the permutite is lost. The ignited permutite is very similar in character, in fact, to natural zeolites.

According to A. Günther-Schulze, the laws governing the influence of two salts with the same anion on the ionization are true for solid permutite, in exactly the same way as for salts in soln. By the continual replacement of the cation of a strongly ionized permutite by that of a weakly ionized permutite, the mobility of the former is reduced, since the non-ionized, and therefore stationary, cation of the second permutite reduces the space available for the movement of the first cation. Permutite takes up a vol., determined by every type of cation in it, since each pure permutite has a different mol. vol., which depends on the ionic vol. of the base. The mol. vol. changes with base interchange proportionally with the amount of interchange as long as the amount of water of crystallization remains constant. This will also affect the space available for the migration of the cation. Most permutites contain $5\text{H}_2\text{O}$, but chromium permutite contains $13\text{H}_2\text{O}$. The mols. of water enter into the interior of the molecule, which is thereby considerably loosened, so that the mobility of the chromium cation is very much increased, and in the case of pure chromium-permutite has a value of the same order as that of the chromium ion in aq. soln. In those cases where the base interchange brings about a very small electrolytic conductivity, the interchange is very slow, so that as much as ten days are required for complete reaction. A. Günther-Schulze, and R. Lorenz discussed the "atomic radii" of the cations in permutites.

G. Wiegner argued that the reaction between permutite and neutral salt soln. has all the characteristics of an adsorption process; cations are adsorbed from the salt soln. and equivalent cations are expelled from the hydrogel of aluminosilicic acid. He represented his results by the isothermal adsorption formula $x/m = kc^{1/2}$. D. J. Hissink suggested that the exchange of cations between the permutite and the soln. is not an adsorption process, but rather an absorption. V. Rothmund and G. Kornfeld showed that the resulting mixed permutite is to be regarded as a single solid phase; the composition of this solid soln. depends on the relative conc.

of the cations in the soln. They observed that with univalent cations the composition of the permutite is independent of the total conc. of the soln., but with bivalent cations, the total as well as the relative conc. must be considered. They showed that with silver permutite, and soln. of the nitrates of potassium, rubidium, lithium, ammonium, and thallium; and with sodium permutite and ammonium and thallium nitrates, if C_1 and C_2 represent the conc. of the two bases in soln., and c_1 and c_2 their respective conc. in the permutite in equilibrium with the soln., these four magnitudes have the empirical relation $(C_1/C_2)(c_1/c_2)^n = K$, where n is less than unity. The values of the constants n and K vary considerably. U. Pratolongo measured the equilibrium state when ammonium or potassium chloride is adsorbed from its soln. by permutite, (i) when the conc. of the salt soln. is increasing, and (ii) when decreasing. The systems are tervariant, for the solid phase behaves as if it had a variable conc. The systems also exhibited the phenomenon of chemical hysteresis or false equilibrium. F. W. Hisschemöller found *l'hystérèse chimique* can be removed by repeated transformations at the ordinary temp. The position of the real line of equilibrium is displaced by repeated transformations with warm soln. By keeping the permutite for some time in the dry state, the positions of both the false and true equilibria change, and the hysteresis diminishes but does not disappear. With a permutite which has been kept for some time, a single transformation with ammonium chloride results in the almost complete disappearance of the hysteresis. The position of the false and true equilibria is independent of the dilution and the size of the particles in the transformation of sodium permutite \rightleftharpoons ammonium permutite. The transformation sodium permutite \rightleftharpoons calcium permutite also showed hysteresis, which was not suppressed by a single transformation.

The subject attracted the attention of J. von Liebig and agricultural chemists because it was obvious that these reversible exchanges must play an important rôle in the fertilization of soils. This phase of the subject was discussed by J. H. Abersson, H. P. Arnsby, J. M. van Bemmelen, H. Brehm, F. Brustlein, E. Bussmann, P. Ehrenberg, H. Eichhorn, R. Gans, P. Gaubert, E. Heiden, W. Henneberg and F. Stohmann, D. J. Hissink, H. Kappen, O. Kellner, W. Knop, G. J. Mulder, E. Peters, W. Pillitz, U. Pratolongo, E. Ramann and co-workers, S. Rostworowsky and G. Wiegner, F. Ullik, etc. The subject also attracted the attention of mineralogists—F. H. Campbell, F. W. Clarke and G. Steiger, M. Dittrich, C. Doelter, I. Zoch, H. W. Foote and W. M. Bradley, J. Lemberg, H. Schneiderhöhn, S. J. Thugutt, etc. Various industrial applications have also stimulated the investigation of the various reactions involved. For instance, if water containing calcium or magnesium chloride percolates through a column of sodium-permutite, a soln. of sodium chloride free from calcium or magnesium is obtained, and calcium or magnesium permutites are formed. The original permutite is restored by percolating a conc. soln. of sodium chloride through the permutite, the calcium or magnesium is replaced by sodium. These facts are at the base of the permutite process for softening hard water. In working with say a water hardened with calcium sulphate, calcium permutite (insoluble) and sodium sulphate (soluble) are formed; during regeneration, with brine, permutite (insoluble) and calcium chloride (soluble) are formed. Obviously in these exchanges, balanced reactions are in question:

Again, if sodium or calcium-permutite be treated with a soln. of manganese salt, a manganese-permutite is produced; and if a soln. of potassium permanganate be used, the potassium-manganese-permutite which results is also covered with a finely divided higher manganese oxide. The product is used for removing iron from water and also for oxidizing organic matter and bacteria in water. Regeneration is effected by treatment with a soln. of potassium permanganate. The

purification of water by the removal of lime, etc., was discussed by R. Gans, W. M. Taylor, F. Beyschlag and R. Michael, H. Noll, H. Lührig and W. Becker, I. D. Riedel, P. Siedler, J. Don, A. Kolb, J. Bracht and G. Hausdorff, etc., and the filtration of molasses and sugar syrups by R. Gans, H. Claassen, and H. Rümpler.

J. Morozewicz prepared **sodium dialuminium triorthosilicate**, $\text{Na}_2\text{Al}_2(\text{SiO}_4)_3$, or *soda-garnet*, which he called *lagoriolite*—after A. Lagorio—by fusing at a dark red heat mixtures of silicic acid and hydrargillite, $\text{Al}(\text{OH})_3$, with sodium and calcium sulphates and carbonates. The square plates are flattened cubes which are either isotropic or birefringent with twin lamellæ. Analyses gave the formula $3(\text{Na}_2\text{Ca})\text{O}, \text{Al}_2\text{O}_3, 3\text{SiO}_2$ with $\text{Na}_2\text{O} : \text{CaO} = 3 : 2$; in one analysis, there was only a trace of calcium, and in all there were small quantities of sulphuric anhydride. This is a typical garnet formula, and lagoriolite forms a connecting link between the garnet and the nosean groups. The largest amount of alkali yet found in natural garnet is 4.22 per cent. in melanite from the phonolite of Oberschaffhausen—*vide* the garnets.

There is a small group of minerals whose members are assumed to be derivatives of nephelite with which they are commonly associated. These minerals include sodalite, haüyne, noselite or nosean, cancrinite, davyne, lapis-lazuli, and microsommitte. The group can be called the **sodalite family**. In no case has the exact composition been established, and they have not the same interest to the chemist as to the mineralogist. The following formulæ representing the composition of the idealized minerals are most in favour—the first four were suggested by W. C. Brögger and H. Bäckström, and the last two by F. W. Clarke :

Sodalite	Cubic, $\text{Al}_2(\text{SiO}_4)_3\text{Na}_4(\text{AlCl})$
Haüyne	Cubic, $\text{Al}_2(\text{SiO}_4)_3\text{Na}_2\text{Ca}(\text{AlSO}_4\text{Na})$
Nosean	Cubic, $\text{Al}_2(\text{SiO}_4)_3\text{Na}_4(\text{AlSO}_4\text{Na})$
Lazurite	Cubic, $\text{Al}_2(\text{SiO}_4)_3\text{Na}_4(\text{AlS}_2\text{Na})$
Cancrinite	Hexagonal, $\text{Al}_2(\text{SiO}_4)_3\text{Na}_2\text{H}(\text{AlCO}_3)$
Microsommitte (and davyne)	Hexagonal, $\text{Al}_2(\text{SiO}_4)_3(\text{Na}, \text{K})_3\text{Ca}(\text{AlSO}_4\text{Cl}_2)$

C. F. Rammelsberg¹⁷ regarded them as nephelites associated with more or less anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$, and with NaCl , Na_2SO_4 , Na_2CO_3 , etc., as *Nebenmoleküls*; or, as J. Morozewicz expressed it, the alkali salts in the sodalite family *die Rolle des Kristallwassers spielen*. Somewhat similar explanations were given by V. Goldschmidt, J. Lemberg, G. Cesaro, C. and G. Friedel, H. Rauff, F. Zambonini, etc. K. Haushofer assumed that the chlorine of sodalite is directly associated with the aluminium; and A. Safarik suggested that in sodalite, the twelve hydrogen atoms of $(\text{H}_4\text{SiO}_4)_3$ are replaced by four sodium and three aluminium atoms, leaving one aluminium valency for a chlorine atom. Similar ideas were advocated by P. Groth, F. W. Clarke, W. C. Brögger and H. Bäckström, S. Hillebrand, etc. J. Jakob assumed that nephelite can take up chromophore groups like Na_2S , Na_2S_2 , etc., and become coloured; similarly also with sodalite, nosean, haüyne, etc.

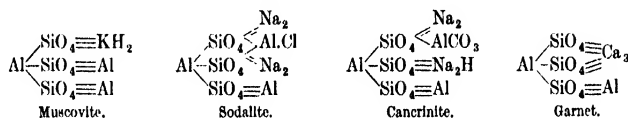

What was regarded as a blue variety of sodalite, occurring at Miask, Ural, was shown by G. Rose¹⁸ to present a unique example of a silicate united with a carbonate; or a compound of nephelite and calcspar. He called it **cancrinite**, after Count Cancrin. A. Breithaupt, C. F. Rammelsberg, and A. des Cloizeaux regarded cancrinite as a variety of nephelite or davyne. H. Fischer, H. Rosenbusch, and F. Zirkel stated that it is not homogeneous and therefore as a mineral species *ist definitiv zu streichen*. J. D. Dana, L. Saemann and F. Pisani, H. Rauff, and A. E. Törnebohm, however, obtained homogeneous specimens, and proved that cancrinite is a definite mineral 'species.' Analyses were made by G. Rose, G. Tschermak, A. Koch, G. Lindström, N. von Kokscharoff, M. R. Whitney, F. W. Clarke, H. Rauff, G. Strüver, J. Lemberg, P. von Puzyrewsky, F. Zambonini, W. C. Brögger, L. Finckh, S. J. Thugutt, C. F. Rammelsberg, etc.

F. W. Clarke's formula for the idealized mineral is $\text{Al}_2(\text{SiO}_4)_3\text{Na}_4\text{H}(\text{AlCO}_3)$, or **sodium aluminium hydrocarbonatetriorthosilicate**; and P. Groth's $(\text{Na}_2, \text{Ca})_4\text{H}_6(\text{SiO}_4)_9\text{Al}_3(\text{NaCO}_3)_2$ —*vide supra*. Other suggestions have been made

by C. F. Rammelsberg, S. J. Thugutt, J. Morozewicz, etc. A. Johnsen studied the rôle of the contained water. J. Lemberg made cancrinite (i) by heating under press. a mixture of alumina, sodium silicate, and a soln. of sodium carbonate; (ii) by the action of sodium carbonate, fused in its water of crystallization, on nephelite; and (iii) by heating to 215° a mixture of labradorite and a soln. of sodium carbonate. He also prepared cancrinitic substances by the action of a soln. of sodium carbonate or a mixture of soln. of sodium carbonate and hydroxide at 200° on kaolinite, analcite, leucite, vitrified orthoclase, nephelite, kaliophilite, sodalite, thomsonite, zoisite, prehnite, scolecite, paragonite. S. J. Thugutt also made similar observations on some of these mineral transformations. C. and G. Friedel obtained a cancrinite rich in potash by treating muscovite with a mixture of sodium hydroxide and carbonate at 500°. W. Eitel obtained lime-cancrinite by heating mixtures of calcium carbonate and nephelite (*q.v.*) under press. between 100 and 115 kgrms. per sq. cm., so that the carbonate was not decomposed. At lower press., say 65 kgrms. per sq. cm., no cancrinite was formed, and it is concluded that if in nature an alkali magma is heated in contact with a limestone above 1253°, at a press. above 65 kgrms. per sq. cm., cancrinite will be formed as a primary mineral of the igneous rock, but at lower press., anorthite or plagioclase will be formed. There is no evidence of the formation of cancrinite from nephelite at low temp. and press. The formation of cancrinite in nature has been discussed by G. Rose, C. F. Rammelsberg, G. von Rath, S. J. Thugutt, G. Strüver, J. Lemberg, W. C. Brögger, F. Zambonini, A. E. Törnabohm, B. J. Harrington, etc. For W. Eitel's observations, *vide supra*, nephelite.

Cancrinite usually occurs massive; prismatic crystals are rare. The colour is white, grey, yellow, green, blue, or reddish-brown. G. A. Kennigott noted a rose-red colour due to the presence of hæmatite; and S. J. Thugutt, a citron-yellow colour due to the presence of mosandrite or cainosite. W. C. Brögger found the crystals of cancrinite are hexagonal bipyramids with the axial ratio $a:c = 1:0.44095$. The cleavage of the crystals is well-defined. The sp. gr. varies from 2.42-2.50; S. J. Thugutt gave 2.46. The hardness is 5-6. H. Rosenbusch gave for the indices of refraction $\omega = 1.5244$, and $\epsilon = 1.4955$; and for the birefringence $\omega - \epsilon = 0.0289$; A. Michel-Lévy and A. Lacroix gave $\omega = 1.522$, $\epsilon = 1.499$, and $\omega - \epsilon$ by direct observation, 0.028. W. Eitel gave for the artificial mineral, $\omega = 1.550$ and $\epsilon = 1.519$. P. von Puzyrewsky, H. Rauff, and S. J. Thugutt found that when cancrinite is heated to redness, carbon dioxide is given off, and then water. H. Rauff, and F. Zambonini found the dehydration curve is continuous. E. Cohen, M. R. Whitney, and S. J. Thugutt also studied the action of heat on mineral. W. Eitel gave 1253° for the m.p. of cancrinite under press. S. J. Thugutt found that up to about 2.5 per cent. of moisture is adsorbed from the air by the powdered mineral. H. Rose, J. Lemberg, and J. Roth showed that boiling water extracts sodium carbonate from cancrinite; and F. W. Clarke showed that when moistened with cold water, phenolphthalein is reddened. S. J. Thugutt showed that when heated with water to 220°-231°, for 204 hrs., sodium aluminate is formed. A. Kaiser said that dil. acids attack cancrinite more rapidly than nephelite or davyne. According to J. Lemberg, an aq. soln. of potassium carbonate changed very little during 7 months at 100°, but at 210°-215°, the potassium and sodium were exchanged; and a soln. of sodium carbonate at 200° had no appreciable action. With a soln. of calcium chloride at 180°-190°, part of the sodium was replaced by calcium, water was absorbed, and some calcium carbonate was formed. An aq. soln. of sodium silicate at 100°, for 8 months, converted cancrinite into an analcite. An aq. soln. of ammonium chloride extracts sodium carbonate from cancrinite; and a soln. of magnesium sulphate acts similarly and forms a hydrated magnesium aluminosilicate. F. W. Clarke and G. Steiger heated cancrinite and ammonium chloride in sealed tubes at 350°, and found about 4.71 per cent. of ammonia was absorbed by the solid. The product obtained by the action of a soln. of calcium chloride at 180°-190° was

called *lime-cancrinite* by J. Lemberg. An analogous product was found by J. Lemberg among the products from Vesuvius. The composition was $10\text{CaAl}_2\text{Si}_2\text{O}_3 \cdot 3\text{CaCO}_3$, which F. Zambonini regards as a solid soln. of $\text{CaAl}_2\text{Si}_2\text{O}_8$ and $\text{Ca}_2[\text{Al}_2\text{Ca}(\text{CO}_3)_2]$. It is here assumed that complex univalent groups like AlCl_2' , AlSO_4' , AlCO_3' , $\text{AlSO}_4\text{Cl}_2'$, and AlSiO_3' , and bivalent groups like AlCl'' , $\text{AlSO}_4\text{Na}''$, AlSNa'' , $\text{AlS.S.Na}''$, and $\text{AlS.S.S.Na}''$, play a part in building up the mols. W. C. Brögger and H. Bäckström emphasized the relationship between garnet and the first four minerals of this series, which they called *alkali garnets* on account of their formal relationship to ordinary (lime) garnet. F. W. Clarke also emphasized the relationship between nephelite and muscovite, and this series of minerals. These postulates, and the assumption that the formula of muscovite is $(\text{AlSiO}_4)_2 : \text{AlSiO}_4\text{KH}_2$, led F. W. Clarke to the constitutional formulæ typified by those for sodalite and cancrinite which follow :

Similar formula apply to hăiïne, noselite, and lazurite ; while the composition of microsommitte has to be represented as a mixture of two compounds each with a formula of this type. J. Lemberg¹⁹ was able to prepare a substance with the AlCO_3' of cancrinite replaced by AlSiO_3' by the action of sodium silicate soln. on nephelite. S. J. Thugutt made a large number of products, like hydrated sodalites, by the action of sodium salts on hydrated nephelite. J. Lemberg, and S. J. Thugutt regarded sodalite as a mol. association of sodium chloride, because the salt is volatilized when sodalite is ignited ; and it is argued that if the chlorine were directly united with aluminium, aluminium chloride would be volatilized ; similarly, sodalite is hydrolyzed by water and sodium chloride separated. The arguments, of course, are not conclusive either one way or another. The hardness of these minerals is about 5½. A. Brun gave 1450° for the m.p. of hăiïne, and C. Doelter gave 1210°–1225° for hăiïne, and 1140° for nosean. The index of refraction, by K. Zimanyi, F. Zambonini, and P. Gaubert, ranges from 1.4950 to 1.5060 ; and it increases with increasing proportions of lime. T. Liebisch found nosean gave only a feeble fluorescence in ultra-violet light, but blue hăiïne gave a bright orange-yellow fluorescence. The phosphorescence was also marked. C. Doelter found that pale hăiïne becomes intense blue or violet when exposed to radium rays. This colour is bleached by exposure to sunlight or to ultra-violet rays. G. vom Rath said that these minerals dissolve in hydrochloric or nitric acid with the separation of gelatinous silica, and the evolution of hydrogen sulphide. J. Lemberg found that a soln. of calcium chloride attacks hăiïne more rapidly than it does sodalite ; that when hăiïne is heated 50 hrs. in molten sodium chloride it is converted into sodalite ; and that when nosean hydrate is digested with a soln. of sodium silicate for 240 hrs. at 210°–215°, analcite is formed. C. R. van Hise discussed the natural transformations of nosean and hăiïne.

T. Thomson²⁰ applied the term **sodalite** to a mineral which he obtained from Greenland, and which was named in allusion to the contained sodium. P. T. Weibye called a blue mineral from the islands in the Langesund fiord, Norway, *glauconite*— $\gamma\lambda\alpha\upsilon\kappa\acute{o}\varsigma$, sea-green—a name previously in use for a variety of scapolite (*q.v.*). W. C. Brögger and H. Bäckström showed that a similar mineral from Lake Baikal is sodalite. Analyses of sodalite were made by D. Borkowsky, C. F. Rammelsberg, etc. According to the above hypothesis, sodalite is **sodium aluminium chlorotriorthosilicate**, $\text{Na}_4\text{Al}_2(\text{SiO}_4)_3(\text{AlCl})$. Sodalite has been prepared from nephelite, kaolinite, and muscovite, as well as from the simpler components. J. Lemberg made sodalite by fusing nephelite with sodium chloride ; S. J. Thugutt, by heating natrolite with a soln. of sodium hydroxide and aluminium chloride at 195° in an

autoclave, and also by digesting kaolinite with sodium chloride and hydroxide at about 212° ; Z. Weyburg, by fusing a mixture of silica, alumina, soda, and a large excess of sodium chloride; and C. and G. Friedel, by digesting muscovite with a soln. of sodium chloride and hydroxide at 500° ; J. Morozewicz fused kaolinite with sodium carbonate and chloride, and obtained a substance resembling sodalite, $\text{NaAlSiO}_4 \cdot \text{NaCl}$; but when nephelite was used in place of kaolinite, a sodalite richer in sodium chloride was obtained, namely, $3\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_8 \cdot 2\text{NaCl}$.

C. F. Rammelsberg¹¹ analysed a green sodalite from Monte Somma, but missed nearly 3 per cent. of molybdic oxide, which G. Freda showed was present. Hence F. Zambonini called it *molybdato-sodalite*. S. J. Thugutt prepared a large number of sodalites in which the sodium chloride of sodalite was replaced by other salts; but unlike the mineral, the artificial products were hydrated. Others have obtained anhydrous products by fusion processes. Over fifty such products have been obtained, but there is usually little or no evidence to show that chemical individuals are involved—rather the contrary in many cases. A. Gorgeu, S. J. Thugutt, and Z. Weyberg reported five *bromosodalites*; J. Lemberg, A. Gorgeu, and S. J. Thugutt, three *iodosodalites*; S. J. Thugutt, *chloratosodalite*, *bromatosodalite*, *iodatosodalite*, *perchloratosodalite*, *sulphitosodalite*, *selenitosodalite*, and *selenatosodalite*; J. Lemberg, S. J. Thugutt, and Z. Weyberg, five *chromatosodalites*; S. J. Thugutt, *molybdato-sodalite*, and *tungstosodalite*; J. Lemberg, and S. J. Thugutt, two *nitratosodalites*; J. Lemberg, C. Bergemann, and S. J. Thugutt, three *phosphatosodalites*; S. J. Thugutt, *arsenitosodalite*, *arsenatosodalite*, *vanadatosodalite*, *hyposulphitosodalite*, and *sulphohydro-sulphosodalite*; J. Lemberg, *hydrozysodalite*, *metasilicatosodalite*, and *boratosodalite*; S. J. Thugutt, *formatosodalite*, *acetatosodalite*, and *oxalatosodalite*; J. Lemberg, *potash-sodalite*; S. J. Thugutt, *sulphatopotash-sodalite*, *molybdatopotash-sodalite*, and *phosphatopotash-sodalite*; K. Heumann, *sulphopotash-sodalite*; S. J. Thugutt, *lithia-sodalite*, *bromolithia-sodalite*, and *sulpholithia-sodalite*; J. Lemberg, S. J. Thugutt, and Z. Weyberg, three *calcium-sodalites*; Z. Weyberg, two *bromocalcium-sodalites*; and K. Heumann, and J. Szilasi, *sulpho-silver-sodalite*, *sulpho-lead-sodalite*, and *sulpho-tin-sodalite*; J. Lemberg, and S. J. Thugutt could not make *magnesia-sodalite*, and *strontia-sodalite*. The constitution has been discussed by J. Lemberg, S. J. Thugutt, P. G. Silber, W. and D. Asch, and R. Hoffmann. The *hackmannite* of L. H. Borgström¹²—named after V. Hackmann—occurs in cubic crystals at Lujaur-Urt, Lapland, can, according to W. C. Brögger and H. Bäckström, be regarded as sodalite contaminated with 6.23 per cent. of a white ultramarine compound, which gives off hydrogen sulphide when the mineral is treated with dil. hydrochloric acid; but, added S. J. Thugutt, nearly all sodalites give off some hydrogen sulphide when treated with acid. Hackmannite shows the evanescent pink coloration described below.

Sodalite crystallizes in the cubic system, and, by twinning, the crystals may form hexagonal prisms; the dodecahedron is a common form. Sodalite may also occur massive, and in nodules resembling chaledony. The colour may be white, grey, green, yellow, red, or blue. The cause of the blue coloration is not certain; it disappears when the mineral is heated. As noted⁷ by the mineralogists, E. Vredenburg, T. L. Walker and A. L. Parsons, and J. Currie,²³ some red and rose-coloured sodalites keep their colour in darkness, but are bleached in daylight. W. C. Brögger and H. Bäckström studied the corrosion figures. The sp. gr. ranges from 2.14–2.40; and the hardness from 5–6. R. Cusack gave 1127° – 1133° for the m.p.; A. Brun, 1250° – 1310° ; and A. L. Fletcher, 1177° – 1183° . Sodium chloride is given off when sodalite is heated to a high temp. The index of refraction for Na-light, measured by L. H. Borgström, K. Feussner, P. Franco, F. Zambonini, and K. Zimanyi, ranges from 1.4827–1.4868. T. Liebisch found sodalite to be strongly fluorescent after exposure to the mercury arc-lamp; it phosphoresces in ultra-violet light only at the temp. of liquid air; and X-rays have no effect. F. Kreutz found that sodalite is coloured violet to peach-blue by exposure to cathode rays. F. W. Clarke noted that sodalite moistened with water has an alkaline reaction. G. Rose found that boiling water extracts sodium chloride from sodalite. Connected with this is J. Lemberg's observation that a soln. of silver nitrate colours sodalite brown. S. J. Thugutt examined the action of soln. of sodium and potassium carbonates, sodium and potassium chlorides, calcium chloride, etc., on sodalite; and J. Lemberg, the action of soln. of calcium chloride, magnesium sulphate, etc.—*vide supra*. H. Schneiderhölz investigated the action of various salt soln. on sodalite. F. W. Clarke and G. Steiger observed the action

of ammonium chloride vap. Sodalite is decomposed by acids with the separation of gelatinous silica—rapidly when heated, slowly when cold. The transformations of sodalite in nature have been studied by C. F. Rammelsberg, N. V. Ussing, C. R. van Hise, etc.

In 1803, C. G. Gismondi²⁴ described a blue or bluish-green mineral from Latium, and he called it *latialite*: T. C. Bruun-Neergaard called it **häüyne**—after R. J. Häüy—and J. D. Dana, *häüynite*. In 1612, M. Freher²⁵ mentioned a bluish mineral from Laacher-See, which C. W. Nose, and J. J. Nöggerath designated *sapphirin*. C. W. Nose also called it *spinellan*; M. H. Klaproth, *nosian*—after C. W. Nose; C. C. von Leonhard, *nosine*; and E. F. Glocker, **nosean**. L. N. Vauquelin²⁶ first analyzed häüyne, and a more complete analysis was made by C. G. Gmelin, who reported the alkalis as “potash.” M. H. Klaproth also analyzed nosean. The relationship between nosean and häüyne was not suspected until J. J. Nöggerath published analyses of the two minerals in which special attention was paid to the alkali contents. As a result, it appeared as if the two minerals were closely related, and E. F. Glocker, J. F. L. Hausmann, W. H. Miller, A. des Cloizeaux, C. Hintze, C. Doelter, etc., regarded them as varieties of the same mineral species. G. Rose showed the crystallographic relationship of nosean and häüyne to sodalite; and M. R. Whitney represented them by analogous formulæ. Analyses of häüyne were reported by G. vom Rath,²⁷ J. Lemberg, C. F. Rammelsberg, L. Ricciardi, E. Casoria, A. Sauer, C. Doelter, N. Parravano, W. C. Brögger, and H. Bäckström, etc.; and analyses of nosean by C. Doelter, G. vom Rath, A. Sauer, etc. As indicated by the idealized formulæ—*vide supra*—häüyne may be regarded as nosean with part of the sodium replaced by calcium. Hence, **nosean** becomes **sodium aluminium sulphatotriorthosilicate**, $\text{Al}_2(\text{SiO}_4)_3\text{Na}_4(\text{AlSO}_4\text{Na})$; and häüyne, **sodium calcium aluminium sulphatotriorthosilicate**.

L. A. Necker²⁸ applied the term *berzeline* to a mineral analyzed by C. G. Gmelin. It was described by G. A. Kenngott, W. Haidinger, and A. des Cloizeaux, and shown by G. vom Rath to be a white variety of häüyne. A mineral was discovered by F. von Ittner in the phonolitic rocks near Kaiserstuhl, Baden, and named *itnerite* by C. G. Gmelin. It was co-related with nosean by E. F. Glocker, C. F. Rammelsberg, etc.; and analyzed by J. Lemberg, L. von Werveke, etc. Another mineral resembling ittnerite was found in the same locality by F. von Kobell, and named *sclopsite*—from *σκόλος*, a splinter—in reference to its fracture. It was examined by L. von Werveke, S. J. Thugutt, J. Lemberg, etc. H. Rosenbusch, H. Fischer, etc., allowed that both ittnerite and sclopsite are alteration products of häüyne and nosean.

Minute prismatic crystals of a mineral from Monte Somma, Vesuvius, were described by A. Seacchi²⁹ as belonging to the hexagonal system, with the axial ratio $a : c = 1 : 0.41834$. The mineral was called *microsommitte*; A. P. DeFrénoy called a similar mineral *acandonde*. Judging from the analyses by A. Seacchi, B. Mierisch, and H. Rauff, the composition varies considerably, but approximates very roughly to a mixture or solid soln. of sodalite and nosean minerals. Potassium takes the place of some sodium. F. W. Clarke gave $\text{Al}_2(\text{SiO}_4)_3\text{Na}_3\text{Ca}\{\text{Al}(\text{SO}_4)\text{Cl}_2\}$. J. Lemberg synthesized the mineral by acting on powdered nephelite at a red heat with calcium chloride and then with sodium chloride. The sp. gr. is 2.42–2.53, according to A. Seacchi; H. Rauff gave 2.444; and F. Zambonini, 2.60 at 15°. The hardness is 6. E. Bertrand said the crystals are optically positive. F. Zambonini gave for the indices of refraction for Na-light, $\epsilon = 1.5298$, and $\omega = 1.5218$; and for the birefringence, $\epsilon - \omega = 0.008$. G. Cesaro gave 0.007. C. Doelter found the colour of blue häüyne is darkened by exposure to radium rays, while ultra-violet light acts in the converse way. Hydrochloric acid decomposes it with the separation of gelatinous silica. F. Grandjean found that at 300°, microsommitte absorbs vap. of ammonia, iodine, mercury, sulphur, etc.; and F. Zambonini said that the chlorine is thereby displaced by iodine, etc.

The mineral *dayne* discovered by T. Monticelli and N. Covelli at Monte Somma, Vesuvius, was analyzed by A. Seacchi, F. Zambonini, H. Rauff, and H. Traube. H. Rauff, and F. Zambonini could explain its composition only on the assumption that it is a mixture or solid soln. of other sodalitic minerals. The optical properties of the hexagonal crystals were examined by F. Zambonini, H. Traube, E. Bertrand, and H. Rauff. A. Breithaupt gave 2.429–2.53 for the sp. gr., and 6½–7 for the hardness. H. Rauff showed that alkali chlorides are volatilized when the mineral is ignited; E. Kaiser, that carbon dioxide is evolved by the action of acids; F. Zambonini, that boiling water extracts chlorides; F. Grandjean, that at 250° iodine vap. is absorbed; S. J. Thugutt, and B. Mierisch

also studied the properties of the mineral. T. Monticelli and N. Covelli's *cavolinite* from Monte Somma is considered to be a variety of davyne, nephelite, or microsommitite—A. Scacchi, and E. Bertrand favour the last hypothesis. L. J. Spencer described a related mineral from St. John's Island, Red Sea.

W. F. Hillebrand found a mineral at the Zuni Mine, Anvil Mt., Colorado, which he named *zunylite*. The analyses corresponded with $H_2Al_2Si_2(O,F,Cl)_4(SiO)_4$, or, according to P. Groth, $Al_2\{Al(OH,F,Cl)_2\}_2(SiO)_4$, by analogy with dumortierite. The crystals belong to the cubic system, and W. C. Brögger and H. Bäckström suggested that it is related to the sodalite and garnet families; hence F. W. Clarke writes $Al_2SiO_4 \cdot Al\{[Al(OH)_2]_2, AlF_2\}_2$, with some fluorine replaced by chlorine.

J. Lemberg³⁰ obtained nosean by fusing nephelite or sodalite with sodium sulphate. J. Morozewicz prepared nosean crystals by fusing at 600°–700° a mixture of kaolinite, sodium carbonate, and sodium sulphate; and from the more complex mixture of calcium silicate, carbonate, and sulphate, and potassium and iron silicates, he obtained blue crystals of haiüyne. Z. Weyberg obtained nosean by melting a mixture of sodium carbonate and sulphate, and kaolinite. J. Lemberg obtained very little haiüyne by fusing anorthite with sodium sulphate.

C. and G. Friedel heated muscovite and a soln. of sodium hydroxide, sulphate and carbonate to 500° in an iron tube, and obtained a nosean with 1.78 per cent. of water. Hydrated noseans were made by J. Lemberg by the prolonged action of a soln. of sodium hydroxide and sulphate on kaolinite, analcime, leucite, orthoclase, sanidine, breviceite, albite, labradorite, nephelite, and lime-cancrinite. S. J. Thugutt made a number of experiments in this direction. The products, *nosean hydrate*, approximated $3-4(Na_2Al_2Si_2O_8) \cdot Na_2SO_4 \cdot 3-4H_2O$.

The colour of nosean may be grey, blue, brown, or black; haiüyne may be sky-blue, greenish-blue, asparagus-green, red, or yellow. In some cases the colour is produced by inclusions—e.g. green by agirito, red by hematite, and black by ilmenite—in other cases the colour appears to be of the nature of ultramarine (*q.v.*) and may be due to the presence of a sulphide or rather colloidal sulphur vap., and blue haiüyne is bleached in a stream of air. P. Gaubert³¹ made some experiments on this subject. The crystals belong to the cubic system. Observations on the crystals were made by G. vom Rath, G. Strüver, C. F. Rammelsberg, A. Michel-Lévy and A. Lacroix, W. Bruhns, R. Brauns, and L. L. Hubbard. Twinning is well marked; and the cleavage is distinct. W. C. Brögger and H. Bäckström studied the corrosion figures. The sp. gr. ranges from 2.27 to 2.50; the hardness is 5.15. A. Brun gave 1450° for the m.p. of haiüyne. The index of refraction given by K. Zimanyi, F. Zambonini, and P. Gaubert varies from 1.4890 to 1.5060. T. Liebisch studied the fluorescence and phosphorescence of the mineral; and C. Doelter, the coloration by radium rays. Sunlight and ultra-violet light bleach the coloured mineral. G. Rose found that boiling water extracts a sulphate from nosean and haiüyne; and G. vom Rath showed that hydrochloric or nitric acid dissolves the mineral with the separation of silica, and in the case of hydrochloric acid, with the evolution of some hydrogen sulphide. H. Schneiderhölz, and J. Lemberg studied the action of salt soln. and sodium hydroxide on haiüyne.

The intense blue-coloured stone, called **lapis-lazuli**, is more or less opaque, and it contains a number of impurities. The most prized stones have a deep blue colour and have but few impurities; in some cases the colour is pale blue passing into reddish-violet; and in other cases the colour is green. Lapis-lazuli is generally cut with a flat surface and employed as an ornamental stone in bijouterie; it is also used like agate for paper-weights, seals, knife-handles, etc.; and it has been used for inlaying and mosaics on the walls and ceilings of palaces, and the columns of churches. Formerly the blue pigment ultramarine was prepared from lapis-lazuli, but it is now made synthetically. It is used in the manufacture of paints, wallpapers, printing inks, mottled soaps, etc.; as a bleaching agent for neutralizing the yellow tint of paper, linen, cotton, whitewash, soap, starch, sugar, etc.; in making laundry blue; and in calico-printing. Commercial ultramarine is sometimes adulterated with gypsum, talc, kieselguhr, etc.

Lapis-lazuli or *azure-stone* was known to the ancient Greeks, even before the Mycenaean age, because beads and discs cut from the stone have been found in the ruins of ancient Troy. The description of the *σάπφειρος*, by Theophrastos (43, c. 320 B.C.) in his *Περὶ λίθων*, and of the *sapphiros* by Pliny, in his *Historia naturalis* (37. 8, 77 A.D.), apply to lapis-lazuli. The Greeks seem to have called it *κύανος*, a term now reserved for cyanite; but J. Beckmann³² has shown that the *cyanus* of the ancients was probably a kind of mineral- or mountain-blue coloured with copper; and that their *cæruleum* may have been sometimes lapis-lazuli and sometimes copper ochre. He also showed that the sapphire of the *Bible*—*e.g.* *Job* (28. 6)—was probably lapis-lazuli, because there is an allusion to the inclusions of specks of gold, just as Pliny, in his *Historia naturalis* (37. 9, c. 77), said that the blue sapphire is interspersed with spangles of gold which sparkle like the stars in the blue sky—the specks of gold are grains of pyrites—*vide* J. Braun, and St. Epiphany. In the middle of the sixteenth century, G. Agricola called the stone *sapphirus*; and A. B. de Boodt, *lapis-lazuli*—from *lapis*, a stone, and *lazulus*, a Latinized form of the Persian term for blue. According to L. Salmassius, and J. Beckmann, *lazuwardi* is the Persian word for lapis-lazuli and for a blue colour; the term was mutilated in the Arabian writings where it appears as *lazul* or *lazar*. The Spanish *azul*, blue, has the same origin. According to J. A. Fabricius, the term *lazarium* was used by M. Leontius in the sixth century; by L. A. Muratori in the eighth century; by T. Nonnius in the tenth century; and by M. Arethas in the eleventh century. About this time lapis-lazuli was confused with blue cupriferous ochres, for Constantinus Africanus and some subsequent writers refer to its medicinal qualities, and these are possessed not by lapis-lazuli, but by the copper ochres. Lapis-lazuli is called *pietre d'azure* and *outramer* in France—*e.g.* by A. des Cloizeaux—and *Lazurstein* in Germany—*e.g.* by J. G. Wallerius in 1747. The term *ultramarinum*—beyond the sea—is late Latin, and probably originated in Italy, being used for many articles brought to Europe from abroad; the Romans used the term *marinum* with a similar meaning. J. Beckmann could not find the name ultramarine in use for the lapis-lazuli before the fifteenth century. In 1502, C. Leonardus employed the term *azurum ultramarinum*; and V. Biringucci, in 1540, clearly distinguished the real ultramarine *azzurro ultramarino* from the cupriferous blue, which he called *azzurro dell'Allemagna*. J. R. Spielmann, and G. Fallopius have made some remarks on this subject. For use as a pigment, lapis-lazuli was finely powdered, and the admixed impurities removed by washing. The process was described by A. B. de Boodt, F. Haudiequer de Blancourt, V. Biringucci, etc. The prepared pigment was called ultramarine. The process of preparation appears to have been somewhat as follows:

The finest selected lapis-lazuli was heated to dull redness, quenched in water, and ground to an impalpable powder. The powder was mixed with paste made of oil, resin, and wax. When the powder was mixed with the resinous paste, and kneaded in warm water, the blue particles floated on the water; the product was washed with an alkaline soln. to remove the resinous matters, and finally collected by settling. There is here a foreshadowing of the modern flotation process.

The mines in Badakshan, Afghanistan, are said to yield the finest quality of lapis-lazuli. They were mentioned by Marco Polo in 1271, and described by J. Wood. The stones from this locality have been conveyed *viâ* Bukhara into Russia, and also passed into the European markets through China and Persia. The places through which the stone has passed—Bukhara, China, and Persia—have been erroneously stated to be the localities where it is found. The mines west of Lake Baikal, Siberia, were described by N. Werssiloff—the colour of the product ranges from green to light and dark blue, and violet. According to M. Aracena, light blue lapis-lazuli occurs in the Andes of Ovalle, Chili. T. Monticelli and N. Covelli, L. Wiser, A. Scacchi, and G. vom Rath said that lapis-lazuli is found very rarely in the ejected masses from Monte Somma, Vesuvius. The occurrence of lapis-lazuli in the Albanian Hills was mentioned by G. Strüver,

F. de St. Fond, and L. de M. Spada. W. C. Brögger and H. Bäckström add that it probably is always formed as a result of contact metamorphism with limestone.

A. Cronstedt,³³ I. S. R. I. Eques a Born, and J. B. L. Romé de l'Isle regarded lapis-lazuli as a zeolite coloured blue by iron; and L. A. Emmerling, as a peculiar kind of silica. R. J. Haüy was at first doubtful if lapis-lazuli should be regarded as a definite mineral, but he said *j'ai cru devoir, sur ce point, me conformer à l'usage*, and called it *lazulite*; later, after the discovery of crystals of lapis-lazuli in Siberia, his doubts were removed. C. C. von Leonhard suggested that lapis-lazuli is altered haüyne; A. Breithaupt classed it with sodalite, nosean, haüyne, and leucite under the generic term *alkalites*; J. F. L. Hausmann regarded it as a variety of haüyne; and A. des Cloizeaux, as a variety of haüyne mixed with other minerals. The fact that ultramarine gives off hydrogen sulphide when treated with acids soon led chemists to assume, as J. B. A. Dumas expressed it:

La lapis est évidemment formée de deux substances distinctes. L'une fort abondante, et vraisemblablement incoloree, consiste essentiellement en silice, alumine, et soude. L'autre, plus rare et essentiellement colorée, se compose de soufre uni à quelque corps. . . .

N. von Nordenskjöld suggested that the colour of lapis-lazuli is due to the presence of a blue pigment, and the idea was developed by H. Fischer, F. Zirkel, and H. Vogelsang, who showed that lapis-lazuli is a heterogeneous aggregate containing a blue isotropic mineral and a number of colourless ones—calcspar, scapolite, feldspar, and nephelite. The last-named added:

The pigment of the heterogeneous aggregate called lapis-lazuli is a blue haüyne-like substance which is itself quite homogeneous and occurs of a higher degree of purity in lapis-lazuli than in haüyne or nosean.

W. C. Brögger and H. Bäckström reserved the name *lazurite* for the blue pigment in lapis-lazuli, a name previously employed by F. von Kobell, and C. F. Naumann as a synonym for lapis-lazuli; and not to be confounded with lazulite, a name employed for a hydrated magnesium aluminium phosphate (5. 33, 23).

The lapis-lazuli was analyzed by M. H. Klaproth³⁴ in 1797; by F. Clément and J. B. Désormes, F. Varrentrapp, R. Hoffmann, C. G. Gmelin, C. F. Rammeisberg, F. Field, W. C. Brögger and H. Bäckström, J. Szilasi, etc. The variations in composition are wide, showing that mixtures are involved. The first of the following analyses is by W. C. Brögger and H. Bäckström, and the second by F. Varrentrapp. The first sample was powdered, and the blue pigment separated from the gangue by *J. Thoudet's solution* (an aq. soln. of potassium and mercuric iodides in the proportions 1·24 : 1).

SiO ₂	Al ₂ O ₃	CaO	Na ₂ O	K ₂ O	SO	S	Cl
32·52	27·61	6·47	19·45	0·28	10·46	2·71	0·47
45·50	31·76	3·50	9·09	—	5·89	0·95	0·42

The proportion of iron oxide varies from 0·1 to 4·2 per cent. W. C. Brögger and H. Bäckström showed that lazurite belongs to the sodalite family, in which the bivalent sulphate group (AlSO₄.Na)⁺ of nosean is replaced by the bivalent sulphide group (AlS.S.S.Na)⁺. He therefore writes the formula Al₂(SiO₄)₃Na₄(AlS₃Na), making lazurite into **sodium aluminium trisulphotriorthosilicate**—*vide supra*. E. W. Büchner, and J. F. Plicque showed that carefully selected specimens of the blue pigmentary matter have proportions of silica, alumina, and soda similar to those in natrolite.

Lapis-lazuli occurs compact and massive, and also crystalline, in cubes, or more frequently, in dodecahedra. The crystals were described by A. Lévy, G. vom Rath, N. von Nordenskjöld, A. Dufrénoy, H. Fischer, etc. The colour may be azure-blue, violet-blue, or greenish-blue. The dodecahedral cleavage is imperfect; and the fracture is uneven. The sp. gr. ranges from 2·38–2·45; and the hardness 5·0–5·5. It can be heated to an elevated temp. without losing its colour, but at a

white-heat, or in the blowpipe flame it intumesces, and melts to a white or yellow glass. T. L. Watson gave for the indices of refraction $\alpha=1.604$, $\beta=1.633$, and $\gamma=1.642$; the optic axial angle, $2V$, is large, and the optical character is negative. According to G. Bergeron, Chilean lapis-lazuli phosphoresces when warmed by the flame of alcohol, but, added H. Fischer, the phenomenon does not recur when the stone is heated a second time. The powder is rapidly decolorized when treated with hydrochloric acid, and decomposed with the separation of gelatinous silica, and the evolution of hydrogen sulphide.

Attempts to make the esteemed ultramarine blue artificially must be very old. In 1700, F. Haudicquer de Blancourt³⁵ claimed to have made it, but J. B. A. Dumas added that *nous sommes d'ailleurs fort loin de croire qu' Haudicquer ait possédé ce précieux secret*. A. S. Marggraf made some trials in this direction in 1758. A blue substance was observed occasionally to present itself in the refuse of certain processes of chemical manufacture. J. W. Goethe noticed a blue vitreous substance in the lime-kilns at Palermo about 1787; and sometimes, when limestone or whiting is calcined in pottery kilns, blue patches are developed. H. Puchner observed the development of a blue colour during the calcination of humoidal calcareous sand. H. Fleissner and co-workers have discussed the formation of ultramarine blue in blast-furnace slags. In 1814, L. J. Tassart noticed a blue substance was formed in a kiln used for melting Glauber's salt; F. Kuhlmann also found that a blue substance was formed in the bricks of a sodium sulphate kiln which had been used for some time. L. N. Vauquelin showed that the composition of L. J. Tassart's blue substance was virtually the same as that of natural ultramarine; and added:

It ought to be possible to imitate nature in the production of this precious colour; and I hope to make some experiments with this object in view.

F. Clément and J. B. Désormes' analysis of lapis-lazuli indicated the lines on which experiments to make artificial ultramarine should proceed. These observations stimulated the *Société d'Encouragement pour l'Industrie Nationale* in 1823, to offer a prize of 6000 francs for *un procédé propre à donner artificiellement et industriellement l'outremer* at a cost not exceeding 300 francs per kilogram. The prize was obtained by J. B. Guimet in 1828; and, about the same time, C. G. Gmelin independently devised a method of making the same product. The priority question—discussed by E. W. Büchner, J. L. Gay Lussac, J. C. Poggendorff, J. S. C. Schweigger, C. Leuchs, C. Schirges, H. Wichelhaus, J. F. L. Mérimée, A. Loir, and R. von Wagner—favours *incontestablement*: J. B. Guimet. J. Heintze has claimed that F. A. Köttig prepared artificial ultramarine at the Meissner Porzellanmanufaktur, in 1828; and F. Varrentrapp made an analysis of the Meissen ultramarine.

In C. G. Gmelin's process for making ultramarine, a mixture of two parts of sulphur and one part of sodium carbonate, was fused in a Hessian crucible, and a mixture of sodium silicate and aluminate gradually added. The product was heated for an hour. In general, it may be said that ultramarine blue is formed whenever an aluminous silicate—say china clay—is calcined with sodium sulphide, or with some mixture which will form sodium sulphide in the course of the process of manufacture. Actual recipes are usually regarded as trade secrets, and rightly so. Three different grades of ultramarine blue are manufactured with different proportions of sulphur and silica. The following, by C. Fürstenau, illustrate three types of recipe:

Grade.	China clay.	Soda ash.	Glauber's salt.	Carbon.	Sulphur.	Silica.
Pale .	100	8	120	25	16	—
Medium .	100	100	—	4	50	—
Dark .	100	103	—	16	117	16

The varieties with a small proportion of sulphur and silica are usually paler, and more readily attacked by a soln. of alum than those with a high proportion

of these constituents. In the manufacturing process, an intimate mixture of the finely ground constituents is roasted in a muffle, shaft-kiln, or other suitable furnace. The cold product is washed; ground to an impalpable powder; levigated with water; passed through a filter-press; dried in a stove; and sifted. Mixtures low in silica are usually green after the calcination—*ultramarine green*. This can be regarded as an intermediate product, for, when crushed and roasted again, it is converted into ultramarine blue which is washed, etc., as before.

Modifications of the process of manufacture have been described by C. P. Prückner,²² P. J. Robiquet, J. de Tiremon, L. Elsner, C. Brunner, J. P. Dippel, C. Leuchs, G. E. Habich, C. Stölzel, J. G. Gentele, H. Ritter, G. E. Lichtenberger, C. Böttinger, J. Zeltner, A. Lehmann, R. Hoffmann, O. Ilgen, G. Guckellberger, L. E. Nottelle and M. J. Corblet, M. Sauvageot, L. Bock, F. Knapp, L. J. B. Bouillet, etc. Again, E. W. Büchner, and J. F. Plicque showed that by heating powdered natrolite in a stream of carbon disulphide, and then in a stream of sulphur dioxide, some clear blue patches are formed. F. Singer made ultramarine blue, and several analogous bodies by heating zeolites and related products with sulphides or oxysulphides of the alkalies or alkaline earths. Several wet methods have been described by F. Knapp, R. W. E. Melvor, etc.; but the dry processes are used almost exclusively on a manufacturing scale. The general manufacture has been described by H. L. J. Rawlins, E. Rohrig, J. Wunder, J. Jordan, L. Bock, J. Pichot and P. Grangier, R. Hoffmann, K. Iwabuchi, G. Fürstenau, etc.

Analyses of samples of artificial ultramarine have been made by L. Elsner, C. Brunner, E. Breulin, H. Wilkens, H. Ritter, G. Scheffer, G. Guckellberger, A. Böckmann, J. F. Plicque, R. Lussy, R. de Forcrand, T. Morel, K. Heumann, E. Dollfus and F. Goppelsröder, J. Philipp, E. Guimet, B. Unger, C. Stölzel, etc. The extremes are 25.88–46.81 per cent. SiO_2 ; 23.71–38.89, Al_2O_3 ; 14.97–23.0, Na_2O ; up to 1.65, K_2O ; up to 3.24, Fe_2O_3 ; up to 1.11, CaO ; up to 3.47, SO_3 ; up to 1.0, Cl; sulphur evolved as hydrogen sulphide by treatment with dil. acids, 1.32–2.38; sulphur unaffected by this treatment, 3.50–10.0; and total sulphur, 3.55–14.00. H. J. L. Rawlins', and E. J. Parry and J. H. Coste's analyses range from

SiO_2	Al_2O_3	Na_2O	S
38.9–42.7	24.0–29.5	18.7–21.0	10.8–15.4

Omitting the oxygen and hydrogen, J. Jordan gave for white (R. Hoffmann), green and blue (J. Philipp), light blue, violet, and red (J. Wunder) ultramarines:

	White.	Green.	Blue.	Blue.	Violet	Red.	Light Blue.
Si . .	17.0	17.51	16.87	17.29	19.4	19.3	19.7
Al . .	16.6	15.81	15.39	12.55	13.1	13.3	13.1
Na . .	21.5	17.02	15.60	14.66	11.7	8.1	11.9
S . .	6.4	7.91	5.69	11.98	13.3	15.2	12.7

The similarity in the composition of different colours indicates that the actual colouring matter possibly represents but a small proportion of the total mass; and P. Rohland suggested that a small proportion of the tinctorial agent is disseminated in a state of solid soln. in the colourless body.

The sodium of ultramarine blue can be completely replaced by silver and other univalent and bivalent radicles; but the attempt to replace sodium by trivalent elements results in the decomposition of red, blue, or violet ultramarine. P. G. Silber found that when an aq. soln. of silver nitrate and ultramarine blue is heated for 15 hrs. in a sealed tube at 120°–140°, the sodium is replaced by silver, forming silver ultramarine. For reasons indicated below, it is assumed that in silver ultramarine one-third of the silver is bound to the sulphur.²³ L. Braunschweiger studied the action of silver salts on ultramarine. According to J. Szilasi, J. Philipp, C. Unger, L. Bock, K. Heumann, C. Chabré and F. Levallois, and R. de Forcrand and M. Ballin, if silver ultramarine be digested with the chlorides, or iodides of ammonium, potassium, lithium, calcium, barium, zinc, silver, cadmium, mercury (ous), lead, manganese, or iron (ous), the silver is replaced by the metal of the halide, and ammonium (blue), silver (grey), potassium (blue), lithium (blue), calcium (blue),

barium (yellowish-brown), *zinc* (violet), *cadmium* (orange-yellow), *mercurous* (bluish-grey), *lead* (brownish-yellow), *manganese* (grey), and *ferrous* (dark bluish-grey), *ultramarines* respectively are formed. Mercuric salts are reduced by ultramarine blue. R. de Forcrand heated silver ultramarine with various organic iodides and so obtained *ethyl*, *amyl*, *benzyl*, and *phenyl ultramarines*. These products give ordinary ultramarine blue when heated with sodium chloride, and they do not yield hydrogen sulphide with cold hydrochloric acid. C. Chabrie and F. Levallois could not make substitution products with ethyleng, naphthalene, and triphenyl-methyl radicles. E. Guimet, J. F. Plicque, and D. Morel replaced the sulphur of ordinary ultramarine by selenium and tellurium, forming respectively *selenium* and *tellurium ultramarines*. The former is red, the latter yellow. F. Knapp, J. Hofmann, and C. Nöllner obtained a light blue *boron ultramarine* by fusing a mixture of borax, boric acid, sodium or potassium sulphide, sulphate, or thio-sulphate. Here boron takes the place of aluminium, and a polybasic boric acid takes the place of silica in ultramarine blue at 280°, and subsequently heating the product in a stream of chlorine and steam at 160°. C. Winkler said that germanium seems to be able to replace silicon in ultramarine; for, if a mixture of soda and sulphur is heated in a crucible used for roasting germanium sulphide, a blue colour is produced, although *germanium ultramarine* was not isolated.

E. Fischer obtained crystals of ultramarine from a works at Hannover. C. Grünzweig and R. Hoffmann, and H. Vogelsang showed that the crystals belong to the cubic system, and W. C. Brögger and H. Bäckström found them to be dodecahedra. Ultramarine blue, red, or violet, dried to constant weight in a desiccator, loses 1-3 per cent. of water when heated to 100°. When ultramarine white is heated in air or oxidizing agents it furnishes first green and finally blue ultramarine. P. Ebell stated that ultramarine will stay suspended in purified water for months when it is in a finely divided state. The settling was also studied by F. Schubert and L. Radlberger. P. Rohland said that ultramarine has hydraulic qualities like portland cement. J. Wunder investigated the absorption spectrum of green, blue, and violet ultramarines. Many properties of ultramarine are indicated in the next few paragraphs. C. Doelter found that ultramarine blue is only darkened slightly by exposure to radium rays; violet and white ultramarines are not changed. The effect with natural ultramarine is much more marked—*vide* haüyne. Ultramarine blue is decomposed by dil. acids, and R. Hoffmann found that about one-fourth of the contained sulphur is given off as hydrogen sulphide, and three-fourths remains in an ionized form among the products of decomposition; neither red nor violet ultramarine furnishes hydrogen sulphide when decomposed by dil. acids. The red product is decomposed by dil. acids more slowly than violet or blue. The action of acids has been studied by J. G. Gentele. F. Schubert, and L. Radlberger found that hydrogen sulphide is evolved when ultramarine is boiled with a 0.25 per cent. soln. of malic acid. B. von Szyszkowsky showed that carbon dioxide decomposes ultramarine suspended in water, and hydrogen sulphide is evolved; the action is retarded in the presence of neutral salts. According to J. Wunder, by treating ultramarine blue with hydrogen chloride at 170°-250°, about one-sixth the sodium is converted into soluble chloride, and with ultramarine violet, one-third of the sodium is converted into soluble chloride, and ultramarine red is formed. J. Zeltner, and R. Rickmann studied the action of hydrogen chloride. When ultramarine violet is treated with iodine and hydrochloric acid, J. Wunder found that half the sulphur behaves as if it were present as a thiosulphate. J. G. Gentele studied the action of ammonium chloride. L. Wunder found that sulphur monochloride in a sealed tube at 200°, converts ultramarine blue into ultramarine white; a soln. of phosphorus in carbon disulphide converts ultramarine blue into ultramarine violet; and the ultramarine blue is partially decomposed if mixed with phosphorus tri- or penta-chloride and heated in a sealed tube at 130°-180°.

and must be completely excluded during the ignition of the mixture employed in

the preparation of ultramarine blue, H. Ritter,³⁷ J. Philipp, C. Böttger, and R. Hoffmann showed that the blue coloration is not produced, and that the resulting **white ultramarine** is converted into the blue product by heating it in a stream of oxygen, sulphur dioxide, or chlorine. J. Philipp found that when a little tin is added to the mixture employed in the preparation of ultramarine, the product is **green ultramarine**; and a green product is sometimes formed in the preparation of the blue—*vide supra*. The green ultramarine is regarded as representing an intermediate stage in the formation of the blue, because green is converted into blue ultramarine by roasting it with sulphur. J. Philipp, however, concluded that sulphur is not taken up during the change from green to blue because the blue product is formed when green ultramarine is heated with water in sealed tubes at 100°—the water removes a little sodium from the green ultramarine. When the green product is heated in chlorine gas, it becomes bluish-violet, and when mixed with sodium sulphide and heated, it becomes grey. G. Scheffer found that if in the preparation of ultramarine blue, the temp. of calcination be higher than is normally required, and air has free access, **red ultramarine** is formed containing less soda and more alumina than ordinary ultramarine blue. According to E. W. Büchner, red ultramarine is formed when the blue product is heated to 300°–400° in oxygen or sulphur dioxide, and if the heating be prolonged, the red passes into **yellow ultramarine**. According to J. Zeltner, if chlorine be passed over the product obtained just before the blue is developed in the ordinary course of manufacture, at 410°, a green substance is first formed, and this then acquires a reddish-yellow colour. Yellow ultramarine changes to blue when heated in a stream of hydrogen or coal gas. If the red product be heated with sodium hydroxide all the chlorine is removed, and **violet ultramarine** is formed. This product goes into the red form when heated in the vap. of nitric acid or hydrochloric acid at 130°–150°; and into the blue form when heated alone to about 520° (P. G. Silber); in hydrogen at 280°–290° (J. Wunder, and C. Grunzweig and R. Hoffmann); or when it is mixed with soda-lye and heated. T. Leykauf made violet ultramarine in 1859 by warming a mixture of moist calcium chloride and ultramarine blue, and in 1872, J. Wunder prepared it by lixiviating the product of the action of chlorine. Violet ultramarine is supposed to be a mixture of red and blue ultramarines.

Many guesses have been made to account for the colour of ultramarine blue and of lapis-lazuli or of lazurite. A. Schrauf,³⁸ H. Vogelsgang, R. Hoffmann, and many others are agreed that the colouring principles of natural and artificial ultramarine in a state of purity are *chemische identische Substanzen*. Most of the suggestions can be arranged in one of the three following groups, although the line of demarcation between the second and third is not always clear.

1. *The colour is produced by a colouring agent or chromophore.*—Before 1758, there was a general impression that the colour was produced by the presence of copper, but A. S. Marggraf showed that this assumption has no foundation, because the blue colour is present when copper is absent. He suggested that iron is the colouring agent. L. Elsner, K. Kressler, L. B. G. de Morveau, C. P. Prückner, and F. Varrentrapp believed that iron sulphide is the tinctorial agent, but here again, C. Brunner showed that quite as good a blue colour can be produced by using materials quite free from iron. C. Unger claimed that the colouring principle is a nitrogenous compound, but E. W. Büchner found ultramarine blues with no nitrogen. W. Stein suggested this principle is ammonium sulphide mixed with the ground mass in a state of *molekularer Vertheilung*. H. Ritter considered that there can be no question of a colouring principle *per se* because the whole of the ultramarine forms a chemical compound, as is evidenced by the fact that one form is colourless and may, under certain conditions be transformed into a coloured form without the introduction of a new substance. The general similarity in the composition of different samples of ultramarine with very different tints supports the view that the actual colouring matter represents but a small fraction of the

whole; and P. Rohland called the colouring principle a *chromophore*—*χρῶμα*, colour; and *φέρειν*, to bear—whose composition has not been elucidated, but which he assumed to be uniformly distributed throughout the ground-mass in a state of solid soln.

C. G. Gmelin, and C. N. Nöllner assumed that the colouring principle is sulphur; and in a more modern guise, the hypothesis of E. Paterno and A. Mazzucchelli, Wo. Ostwald, H. H. Morgan, and J. Hoffmann assumed that the coloration is produced by a blue form of colloidal sulphur. The argument is based largely on analogy since many reactions are known in which colloidal sulphur is formed and a blue colour developed—*e.g.* molten potassium thiocyanate becomes blue at 400°, and the white colour returns at ordinary temp.; sodium chloride or sulphate becomes blue when roasted with sulphur; and alkali polysulphides form blue soln. with many boiling organic solvents, and the mixture becomes white again on cooling. Sulphur vapour is also blue. I. F. Keme found that consonant with the general observation that alkalis increase the dispersion of inorganic disperse systems, the fusion of blue ultramarine with alkalis transforms the colour to a deep red. This is taken to confirm the colloidal hypothesis. It has been urged against this hypothesis that ultramarine blue withstands a red-heat fairly well, even though the blue loses some of its brilliancy, and acquires a greenish tint. The objection is not serious when it is remembered that other colours are produced by colloids in solid soln. with another substance which acts as a protective or stabilizing agent. It is, however, necessary to assume that red, green, and violet colours can also be produced by the same colouring agent—presumably in a different state of subdivision. Wo. Ostwald made green and blue colloidal sulphur. The fact that the alkali ultramarines are alone blue does not favour the hypothesis that its colouring principle is colloidal sulphur. Indeed, L. Wunder states that three conditions must be fulfilled in order that ultramarine may be coloured blue: (i) an alkali must be present—if a mercurous ultramarine has only part of the alkali replaced by mercury, it becomes blue on calcination, but if all the alkali be replaced by mercury, it is colourless when calcined; (ii) a part of the sulphur must be directly united to a metal, for the blue ultramarines develop hydrogen sulphide when treated with dil. acids, while the red and violet ultramarines give sulphur dioxide, not hydrogen sulphide; and (iii) a part of the sulphur must be present in a lower state of oxidation, for ultramarine blue becomes white when treated with strong reducing agents, and the blue colour is restored by oxidizing agents.

2. *Ultramarine is a molecular compound or complex of a silicate and a sulphide.*—

Another set of hypotheses attempts to explain the blue coloration by assuming the colour is a constitutive property, produced by definite mol. complexes. R. Hoffmann tried to establish the individuality or homogeneity of ultramarine blue by microscopic observations; but this test is incapable of distinguishing between chemical individuals and solid soln. Similarly, G. Guckelberger tried to show that ultramarine green is a single substance, and not a mixture of a blue and a yellow ultramarine, or ultramarine blue with adsorbed sodium sulphide. When a mixture of ultramarine blue and water is heated in a sealed tube between 200° and 300°, a colourless insoluble residue free from sulphur is formed, and sodium sulphide passes into soln.; when heated with mercuric oxide, the sulphur is likewise abstracted. Ultramarine is stable with alkalis, but is decomposed by dil. acids with the precipitation of sulphur, and the liberation of hydrogen sulphide. This behaviour supports the view that the colouring principle of ultramarine blue is a combined silicate and polysulphide of sodium and aluminium, but against this hypothesis, K. A. Hoffmann and W. Metzner find that, unlike polysulphides, and thiosulphates, ultramarine blue is not affected by conc. fuming sulphuric acid, or by a mixture of glacial acetic acid and acetic anhydride. R. Hoffmann's conclusion that the sulphur in ultramarine blue is present in a similar state of combination as it is in the polysulphide, Na_2S_4 , cannot be right, since H. Erdmann showed that it does not yield silver sulphide when treated with silver nitrate, but is converted into silver

ultramarine in which sodium is replaced by silver. H. Erdmann suggested that the ultramarines are to be regarded as thiozonides containing the bivalent radicle S_3 . In strict analogy with the ultramarines, H. Erdmann said that the sulphur dyes are transformed by powerful reducing agents into leuco-compounds corresponding with white ultramarines, and in both cases the white compounds are readily oxidized back to the original substance.

R. Hoffmann emphasized the idea that the cause of the colour may be due to the presence of definite sulphides contained in the ultramarine; he believes that the radicle is a kind of sulphonate, and that the various colours are produced by the addition, or subtraction, or substitution of oxygen, sulphur, sodium, etc., without destroying the combination of the silicate mol. which produces the colour. These changes, said he, occur in a similar manner to those in the side chains of organic compounds. R. Hoffmann thus distinguishes the silicate side from the sulphide of the ultramarine mol. without disturbing the combination as a whole. He added:

The formation of green and blue ultramarines, and their behaviour towards various reagents confirm the view that the sodium added in the form of oxide must be more firmly united to the elements of clay than is the sulphide, and that it alone takes part in the further conversion of white to blue and green ultramarines. Consequently, it is possible to distinguish a silicate side from a sulphide side in the ultramarine mol. without in any way disturbing the combination of elements as a whole. . . . The formation of ultramarine by the ordinary method of preparation, and its chemical behaviour, are sufficiently explained by assuming the existence of a sodium silico-aluminate in which that part of the oxygen which is in closest combination with sodium can be replaced by sulphur—such silico-sulphonates behaving like free sodium monosulphonate from which higher sulphonates may be produced by combination with sulphur and loss of sodium, without the silico-sulphonate being decomposed.

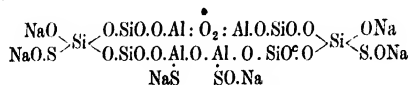

W. C. Brögger and H. Bäckström assume that white ultramarine has the composition $Al_2(SiO_4)_3Na_4\{Al(NaS)\}$; green ultramarine, $Al_2(SiO_4)_3Na_4\{Al(NaS_2)\}$; and blue ultramarine, $Al_2(SiO_4)_3Na_4\{Al(NaS_3)\}$. All these are derived from the parent silicate, $Al_2(SiO_4)_3Na_3$. It is further assumed that many artificial products are mixtures of these four typical compounds—*vide lapis-lazuli*. R. Hoffmann gave for the fundamental silicate $Na_2Al_2Si_3O_{10}$; for ultramarine blue, $Na_4Al_4Si_6O_{20}.Na_2S_4$; ultramarine red, $Na_2Al_4Si_6O_{19}.Na_2S_3O_3$; and for ultramarine yellow, $Na_2Al_4Si_6O_{19}.Na_2S_5O_3$. As previously indicated, F. Singer prepared a number of ultramarine colours by substituting sodium sulphide for water in hydrated nephelite and it has therefore been argued that ultramarine is a mol. compound of nephelite with sodium polysulphide. Thus, white ultramarine has been represented as $6(NaAlSiO_4).2-4Na_2S$; green ultramarine, $6(NaAlSiO_4).2-4NaS$; and blue ultramarine, $6(NaAlSiO_4).1-2NaS_2$. L. Bock regards the ultramarines as definite compounds based on $Al_2O_3.3SiO_2$. Starting with ultramarine green,

in the formation of ultramarine blue, the introduction of groups $SONa'$ is postulated; and in ultramarine violet, the groups NaS_2O_3' —*vide infra*. J. Jakob assumed that the chromophore groups are Na_2S , Na_2S_2 , etc.

3. *Ultramarine is a compound containing labile chromophore radicles.*—The colour is regarded more or less as an accidental circumstance dependent on the nature of chromophore radicles associated with the fundamental alkali aluminosilicate. This means that ultramarine is a definite chemical individual with a specific structural formula. W. and D. Asch assume that the aluminosilicate is associated with the complex S_2O_7'' , or $-O.SO_2.O.SO_2.O-$, which is prone to split off oxygen atoms, and take them up again, and to exchange all or part of the oxygen atoms for sulphur. In conformity with the views of O. N. Witt, M. Schütze, R. Nietzki, G. Krüss and co-workers, H. W. Vogel, E. Koch, etc., these complexes

are regarded as chromophores, and it is assumed that the simpler forms furnish yellow pigments, while with increasing mol. wt., the colour changes to orange, red, bluish-violet, violet, blue, bluish-green, and green; and conversely. The nature of the base is assumed to be of importance, so that the effect produced by the one may be masked by the other. According to J. and L. Wunder, the facts are summarized in the formula:

corresponding with the empirical formula $\text{Si}_6\text{Al}_4\text{Na}_6\text{S}_4\text{O}_{22}$ for ultramarine blue. W. and D. Asch introduce an atom of oxygen between the aluminium atoms and sulphur, and use hexite and pentite rings for the silicate part of the mol. In the corresponding ultramarine violet, L. Wunder assumes that the SNa-group is hydrolyzed and replaced by OH, and that the univalent O : SNa-group is transformed into the univalent radicle NaS_2O_3 . This agrees with the empirical formula $\text{Si}_6\text{Al}_4\text{Na}_5\text{HS}_4\text{O}_{23}$ for ultramarine violet. When this product is transformed into ultramarine red, $\text{Si}_6\text{Al}_4\text{Na}_3\text{H}_3\text{S}_4\text{O}_{23}$, it is assumed that the two univalent S.O.Na-groups are hydrolyzed to S.OH. Hence, red ultramarine is considered to be an acid whose sodium salt is violet ultramarine. These formulæ agree with the hydration of ultramarine by water above 100° , and it is assumed that the four bivalent SiO-groups can be hydrated to bivalent $\text{Si}(\text{OH})_2$. Dil. acids are supposed to attack the bivalent Al.SNa-group: $\text{Al.SNa}'' + 2\text{HCl} = \text{AlCl}'' + \text{NaCl} + \text{H}_2\text{S}$. Acids attack both side groups in accord with the equation: $\text{SiONa}(\text{S.ONa}) + 2\text{HCl} = \text{SiONa}(\text{S.OH})'' + 2\text{NaCl} = \text{SiO}'' + \text{H}_2\text{O} + \text{S} + 2\text{NaCl}$, and in the decomposition of ultramarine blue by acids, three-fourths of the sulphur separates as milk of sulphur. The fact that when silver ultramarine is formed, one-third of the silver is bound to the sulphur is explained by assuming that there are three S.ONa-groups in the mol. of ultramarine, and only one is bound directly to the aluminium—each of the other two being united to a silicon atom. Tervalent elements are not able to replace sodium atoms because the mol. does not contain three sodium atoms united to the mol. in the same way. When ultramarine is reduced by a soln. of phosphorus in carbon tetrachloride in a sealed tube at 150° , washed with carbon disulphide, and dried, a flesh-coloured, almost white, substance is formed—*white ultramarine*—it is supposed that the phosphorus takes oxygen from the three S.ONa-groups, and that green ultramarine is formed by the deoxidation of one or two of these groups. Hydrogen chloride and steam between 170° and 250° are not strong enough to attack S.ONa-groups, but they react with the SNa-group, removing one-sixth of the sodium from the mol., $\text{SNa}' + \text{H}_2\text{O} + \text{HCl} \rightarrow \text{H}_2\text{S} + \text{NaCl} + \text{OH}'$. If an oxidizing agent is present at the same time, the S.ONa-group is simultaneously oxidized to a thiosulphate NaS_2O_3 -group. The action of a soln. of iodine on violet ultramarine confirms these assumptions.

§ 41. The Micas

The micas are a family of different, though probably related, minerals. They are all complex aluminium silicates or aluminosilicates. They are usually resolved into three sub-groups or families, whose members have more or less similar characteristics. They have a highly developed basal cleavage; they split into thin plates; and they crystallize in the monoclinic system. They may be classified thus:

Micas	Mica family	Muscovite; biotite
	Clintonite family	Clintonite
	Chlorite family	Clinoclchlore

The members of the *chlorite* family are sometimes called *hydromicas*; they are generally green in colour, and form scales and incrustations on the walls of cavities in dolomites and mica schists; or they may occur massive or earthy as alteration products of ferromagnesian silicates. The *clintonite* family, sometimes called the *brittle micas*, are usually more basic, chemically, than the micas proper. The cleavage laminae are also brittle. The members of another group of micaceous minerals, classed as *vermiculites*, are usually regarded as alteration products of the true micas. Considering only the predominant basic constituents, the principal micas proper are:

Muscovite	Potash mica	$H_2KAl_3(SiO_4)_3$
Paragonite	Soda mica	$H_2NaAl_3(SiO_4)_3$
Lepidolite	Lithia mica	$(HO,F)_2(Li,K)_2Al_2Si_2O_6$
Zinnwaldite	Lithium-iron mica	$(HO,F)_2(Li,K)_2FeAl_2Si_2O_6$
Phlogopite	Magnesia mica	$(H,K,Mg,F)_2Mg_2Al(SiO_4)_3$
Biotite	Magnesium-iron mica	$(H,K)_2(Mg,Fe)_2(Al,Fe)_2(SiO_4)_3$

The early observers included mica in the same class as gypsum, which can also be split into thin flakes. It was afterwards noticed that, unlike talc and gypsum, the cleavage plates of mica are highly elastic, and not pliable. Pliny, in his *Historia naturalis* (36. 45, 37. 73), has a description of a mineral *lapis specularis* which applies very well to mica. The scales of this mineral were strewn over the *circus maximus* at the celebration of games with the object of producing a sparkling whiteness. This shows that a mica schist furnished the material employed; and Pliny's *hammochryos*—from *ἄμμος*, sand; *χρυσός*, gold—was probably a sand containing golden-coloured scales of a biotitic mica. The Hindus appear to have used mica for decoration and other purposes, and they considered it to be endowed with extraordinary properties.¹ Mica has also been found in the graves of prehistoric American races, east of the Mississippi, in localities where the mineral does not occur.

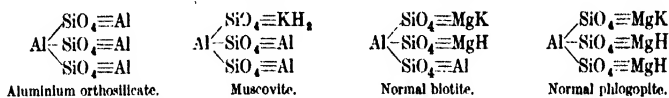

The term *mica* is not likely to have been derived from the Latin *mica*, a crumb, or grain, but rather from the Latin *micare*, signifying, like the German *Glimmer*, to shine. In mediæval times, scaly mica was called *cat-silver*, or *cat-gold*—*Katzengold*, or *Katzensilber*; or *des chats*, or *argent des chats*. Thus, G. Agricola² spoke of *Ammochryson*, *Mica*, *Glimmer*, or *Katzensilber*. A. B. de Boott, and J. G. Wallerius described several varieties. A. G. Werner, and A. Estnor definitely adopted the term *Glimmer*, and described many varieties. No great progress could be made in the classification of the micas until they had been distinguished from one another by chemical analysis, and optical measurements.

The analyses of M. H. Klaproth³ distinguished the magnesian and the alkali micas, and the analyses of C. G. Gmelin established the lithia-micas. H. Rose showed that fluorine is sometimes present, and that the mineral contains chemically combined water. J. Peschier studied some titaniferous micas. C. F. Rammelsberg collected a number of analyses; calculated the ratios K : Al : Si; and showed that the hydrogen of the contained water must be regarded as a univalent metal. C. F. Rammelsberg, H. Rose, and J. Roth regarded the alkali and magnesian micas as orthosilicates, and this view is generally accepted at the present day. G. Tschermak in his paper, *Die Glimmergruppe* (Wien, 1877–8), explained the composition of the micas by regarding them as isomorphous mixtures of three fundamental silicates: (i) $H_2KAl_3Si_3O_{12}$, corresponding with ordinary mica; (ii) $Mg_3Si_3O_{12}$, a hypothetical polymer of chrysolite; and (iii) $H_4Si_5O_{12}$, a hypothetical silicon hydroxide which may take the form $Si_5F_4O_{12}$. C. F. Rammelsberg, also, in his paper, *Ueber die chemische Natur der Glimmer* (Berlin, 1889), assumed that the micas must be associated with three silicates: R_2SiO_3 , R_4SiO_4 , and R_6SiO_6 , associated in various proportions. Thus, muscovite was considered to be compounded of R_4SiO_4 and $Al_4Si_3O_{12}$. This mode of dealing with the problem cannot be considered a solution of the difficulty, for it can be applied to represent the composition of any conceivable silicate, however complex. W. and D. Asch apply their hexite hypothesis to the micas, postulating that they are compounded of three type micas. S. J. Thugutt, R. Brauns, J. W. Retgers, P. Groth, etc., have also discussed this subject. P. Erculisse, and J. Jakob applied the co-ordination theory to the micas, representing muscovite by $[Al(SiO_4)_3]_3[Al_2KH_2]$.

F. W. Clarke, in his *Theory of the Mica Group* (1889), argued that all the micas should be reducible to one general type formula; that the formulæ should express all known relations; and that hypothetical compounds should be as far as possible avoided. He used the normal salts $Al_4(SiO_4)_3$ and $Al_4(Si_3O_9)_3$ as theoretical starting points for the micas, vermiculites, chlorites, and margarite. Thus, in his memoir, *The Constitution of the Silicates* (Washington, 51, 1914), starting with normal aluminium orthosilicate, he obtains:

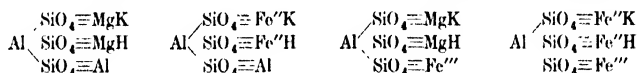

Aluminium orthosilicate	$\text{Al}_2(\text{SiO}_4)_2$
Muscovite	$\text{Al}_2(\text{SiO}_4)_3\text{KH}_2$
Normal biotite	$\text{Al}_2(\text{SiO}_4)_3\text{Mg}_2\text{KH}$
Normal phlogopite	$\text{Al}(\text{SiO}_4)_3\text{Mg}_3\text{KH}_2$

This makes the micas out to be *aluminotriorthosilicates*. Any further substitution of the same type would remove the linking atom of aluminium, and break up the fundamental nucleus $\text{Al}(\text{SiO}_4)_3$, as can be seen graphically :

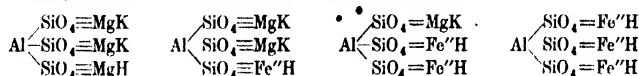

J. Uhlig suggested that *cryptotile*, $\text{H}_3\text{Al}_3(\text{SiO}_4)_3$, found by A. Sauer as an alteration product of prismatine, is the terminal member of the series of alkali micas, $(\text{AlSiO}_4)_2\text{Al}(\text{SiO}_4\text{H}_3)$. F. W. Clarke added that while typical muscovites agree sharply with the formula, the composition may vary within limits : (i) Sodium may replace potassium until it merges into paragonite which has the corresponding formula, $(\text{AlSiO}_4)_2\text{Al}(\text{SiO}_4\text{Na}_2\text{H})$; again, (ii) Some chromium may replace aluminium, furnishing the chromiferous mica called *fuchsite*. Usually, however, the proportion of chromium is small; (iii) Some ferric iron may replace the aluminium. This, too, is usually small but in a sericite mica analyzed by C. Senhofer, the formula approaches $\text{Al}_2\text{Fe}(\text{SiO}_4)_3\text{KH}_2$; (iv) The aluminium may be replaced by vanadium. In the idealized *roscoelite*, $\text{AlV}_2(\text{SiO}_4)_3\text{KH}_2$, there should be 33.6 per cent. V_2O_5 , but not more than about 24 per cent. has been actually observed; (v) The presence of magnesium or ferrous iron is usually attributed to the admixture of some biotitic mica; and (vi) While normal muscovite has 45.3 per cent. SiO_2 , the proportion may rise to about 59. G. Tschermak called these siliceous muscovites *phenigites*—from *φένιγος*, glitter—and explained them by assuming that they are mixtures of muscovite with an acid silicate, $\text{H}_4\text{Si}_5\text{O}_{12}$; and F. W. Clarke assumed they are mixtures of muscovite with the *aluminotrisilicates* $\text{Al}_3(\text{Si}_3\text{O}_8)_3\text{KH}_2$, built on the mica type of mol. Some of the lithia-micas are almost entirely the trisilicate, and other muscovite micas have from 0.50 per cent. of the trisilicate with ferric iron, chromium, or vanadium replacing more or less of the aluminium. The mica *euphyllite*, continued F. W. Clarke, has the univalent group $\text{Al}(\text{OH})_2$, making $\text{Al}_3(\text{SiO}_4)_3\text{KH}.\{\text{Al}(\text{OH})_2\}$. E. T. Wherry applied the at. vol. theory of isomorphism, and assumed that the passage from $\text{H}_4\text{K}_2(\text{Mg}, \text{Fe})\text{Al}_4\text{Si}_7\text{O}_{24}$ to $\text{H}_4\text{K}_2\text{Al}_6\text{Si}_6\text{O}_{24}$ involves the double isomorphous replacement of $(\text{Al} + \text{Mg})$ and $(\text{Al} + \text{Si})$.

The *biotite* and *phlogopite* micas exhibit greater variability in composition than the muscovite micas. F. W. Clarke refers the biotite micas to the four types :

which when mixed in various proportions, with the substitutions previously indicated, can be made to simulate the composition of this group of minerals. Thus, F. W. Clarke showed that the *siderophyllite* of H. C. Lewis can be represented by the second of these formulæ; while the *houghtonite* of M. F. Heddle is a mixture of the first, second, and third. The phlogopite micas were represented in a similar manner, by admixtures of two or more minerals of the type :

F. Grünling described a sodium phlogopite containing no potassium; F. von Kobell's *aspidolite* may belong to the same class; and the *manganophyllite* of L. J. Igelstrom, G. Flink, and A. Hamberg with its 9–17 per cent. of MnO, seems to

be mixed with $\text{Al}(\text{SiO}_4)_3\text{Mn}_3\text{KH}_2$. G. Tschermak, K. Dalmer, etc., have also discussed this subject.

In cases where the oxygen is in excess of that required to convert all the silicon into SiO_4 , and the excess is not due to defective analyses, it is assumed to be produced by alteration, or by replacement of univalent radicles by hydroxyl groups like $\text{Al}(\text{OH})_2$, $\text{R}'\text{OH}$, etc. The function of titanite oxide in the analyses of the mica is not known, since it may replace silica as TiO_2 ; it may replace alumina as Ti_2O_3 ; or it may be present as inclusions of rutile. Fluorine is contained in many micas. It may be present as a monad group like AlF_2 , or $\text{R}''\text{F}$. An average lepidolite, for instance, can be regarded as a 1 : 1 mixture of a trisilicate, $\text{Al}(\text{Si}_3\text{O}_8)_3\text{K}_3\text{Li}_3(\text{AlF}_2)_3$, and muscovite, $\text{Al}(\text{SiO}_4)_3\text{Al}_2\text{HKLi}$. H. Baumhauer, indeed, found inclusions of muscovite in lepidolite. Some potassium may be replaced by sodium; and some fluorine by the OH-radicle. Zinnwaldite is considered to be a mixture of the same trisilicate with ferrous biotite, $\text{Al}(\text{SiO}_4)_3(\text{FeK})_2\text{Al}$. Cryophyllite is related to zinnwaldite, and its composition, though more complex, can be represented in a similar manner. Analogous remarks apply to the *irvingite* of S. Weidman, while the *polyolithionite* of J. Lorenzen, and G. Flink and co-workers is considered by F. W. Clarke to be a trisilicate 1 : 5 mixture of $\text{Al}(\text{Si}_3\text{O}_8)_3(\text{Na}_2\text{K})_3$ and $\text{F}_2 : \text{Al}(\text{Si}_3\text{O}_8)_3 : \text{Li}_3$.

The biaxial potash-mica appears to have been designated *vitrum muscoviticum* by J. G. Wallerius,⁴ and, as previously stated, to have been found by A. B. de Boët in Moscovia. It was called *muscovite* by J. D. Dana in 1850. It has also been called common mica, *potash-mica*, white mica, *biaxial mica*, and *oblique mica*; it was formerly called *muscovy glass*. When clear and transparent, it is sometimes called, in commerce, *water mica*.

Several varieties have been assigned special names. A. Delessio gave the name *damourite*—after A. Damour—to a variety previously designated *hydromica* by T. Thomson. Damourite was discussed by A. Knop, A. des Cloizeaux, J. D. Dana, C. F. Rammelsberg, D. Lovisato, E. Dittler, G. Tschermak, J. L. Igelström, and M. Bauer. The *gibbertite* of T. Thomson was found in the tin mines of St. Austell, Cornwall, and it was named after D. Gilbert; A. Frenzel also found the same mineral in the tin mines of Saxony and Bohemia. V. Dürffeld described a sample from Fichtelgebirge, Bavaria. Gilbertite was also described by A. Breithaupt, A. Frenzel, F. Sandberger, C. Peters, and J. H. Collins. J. F. L. Hausmann, and C. Hintze considered it to be related to china clay. T. Thomson described *talcite* from Wicklow, Ireland; and what he called *nacrite* from Maine—*vide* kaolin. R. P. Greg and W. G. Lotson regarded gibbertite, talcite, and nacrite as varieties of *margarodite*. A. des Cloizeaux also discussed this mineral; and C. Hintze regarded it as an impure clay. The name talcite was applied by K. von Schaffnau to a talc-like mica from Mt. Grenier, Zillerthal. The name margarodite was suggested by the lustre—*μαργαρίτης*, a pearl. J. P. Cooke obtained a variety of damourite from Sterling, Mass.; and he called it *sterlingite*. A greenish-black variety from Dorby, Vermont, was called *adamite*. It was analyzed by G. J. Brush, and likened to muscovite by G. Tschermak. T. D. Rand described a micaceous mineral from Greenland, which he called *wightite*. Both G. Hagemann, and F. Johnstrup consider it to be a variety of gibbertite. F. Sandberger described a scaly mineral from Wittichen, Baden, which he called *lepidomorphite*—from *λεπίς*, a scale; and *μωφής*, form. P. Groth considered it to be a siliceous variety of muscovite. G. Starkl obtained a green mineral from the mica schist of Klein Pischingbachthal, Austria, and a sericite-like mass from Anna-Kapelle, Wiesmath, and Ofenbach, Frohsdorf, Austria. He called the former *pyenophyllite*, and the latter *leucophyllite*—from *πυκνός*, dense; *λευκός*, white; and *φύλλον*, a leaf.

C. List applied the term *sericite* to a talc-like mineral from Taunus—*σηρικός*, silky—because of its silky lustre. For a time, C. E. Stiff considered it to be a variety of talc; C. List, and A. Knop, a variety of damourite; and J. R. Blum, *nichts anderes als Kalkglimmer*. The relation of sericite to mica was emphasized by K. A. Lössen, F. Scharrf, A. von Lasaulx, A. Wichmann, and H. Rosenbusch. H. Laspeyres showed that it is essentially identical with muscovite, and is originally derived from feldspar. Occurrences and analyses of sericite were indicated by A. Pichler, A. E. Tornebohm, A. Rzehak, C. R. Credner, A. Wichmann, A. Hutchinson and W. C. Smith, C. W. von Gümbel, C. Schmidt, A. von Groddeck, B. Koto, A. F. Rogers, K. von Fritsch, etc. A greenish-white scaly mineral found by F. Sandberger as an alteration product of the oligoclase in the gneiss of Wildschapbachthal, Baden, was called *meta-sericite*.

F. von Kobell obtained a rounded, compact, light green mineral in the dolomite of Paasecken, Salzburg, and he called it *onocine*—from *ὄγκωσις*, a swelling up—in allusion

to its behaviour before the blowpipe. G. Piolti described a sample from Variney, Italy. A. des Cloizeaux classed oncosine with halloysite, agalmatolite, etc.; J. D. Dana, with pinite; and G. Tschermak, with the compact muscovites. E. Cohen reported a compact muscovite from South Africa; and F. Sandberger obtained a variety he called *oncophyllite* as an alteration product of feldspar. K. von Schafhäütl first designated a greenish mica containing calcium carbonate which he found in the chlorite schists of Zillerthal, *didymite*, but later corrected the name to *didymite*—from *δίδυμος*, a twin. C. Hartmann showed that the calcium carbonate, *ohne Fehler*, is an admixed impurity of the mica. K. von Schafhäütl applied the term *amphibolite* to a mineral similar to didymite—*from ἀμφίβολος*, doubt—in allusion to his uncertainty as to whether the contained calcium carbonate was a mixture or an essential component. K. von Schafhäütl named chromiferous mica from Schwarzenstein, Zillerthal, *fuchsite*—after J. N. von Fuchs. Other chromiferous micas have been examined by A. C. Gill, A. Damour, H. Gorceix, G. T. Prior, etc. S. M. Losanitsch found an earthy aggregate of crystalline scales in the quartzite of Monte Avala, Belgrade. He called it *avalite*. It contains almost 15 per cent. chromic oxide. A. von Groddeck regarded it as a chromiferous mica related to sericite. A kind of *baryta-mica*—with 5 per cent. BaO—occurring near Kemmat, Tyrol, was named *ollacherite* by J. D. Dana—after J. Ollacher. It was described by G. A. Kenngott, C. F. Rammelsberg, and G. Tschermak.

K. von Schafhäütl⁵ called the soda-mica which he found in the rock at Monte Campione, St. Gothard, **paragonite**—*from παράγων*, I mislead in allusion to its resemblance to talc. G. A. Kenngott called it *preggratite*—from Preggratten, Tyrol.

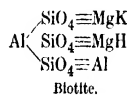

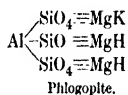

A compact variety of paragonite was identified in an antique ring or bracelet found in the neighbourhood of Turin. It was named *cosante* after A. Cossa. It has been found in a number of other places. A kind of soda-potash-mica intermediate between muscovite and paragonite was named *euphyllite* by B. Silliman—*from εὖ*, well; *φύλλον*, a leaf. Specimens have been described and analyzed by J. L. Smith, G. J. Brush, F. R. Mallot, J. D. Dana, J. J. Crooke, etc. G. Tschermak seems to regard the mineral as a mixture of muscovite with paragonite and margarite.

I. S. R. I. Eques a Born⁶ (1791) described what appeared to be a violet zeolite which occurred in white scales with a pearly lustre, and it was called *lilalite* in reference to its colour. A. Estner (1795) did not discuss it in connection with the micas. Soon afterwards, M. H. Klaproth analyzed the mineral, and named it **lepidolite**—*from λεπίς*, a scale—in allusion to the scaly structure. The same term was used by R. Kirwan. H. Credner showed that the mineral is related to mica. P. A. Wenz, and G. C. Gmelin showed that lithium is present; and G. C. Gmelin called it *Lithionglimmer*—*lithia mica*. W. Haidinger designated the lithium-iron mica from Zinnwald, **zinnwaldite**, and F. von Kobell included lepidolite and zinnwaldite as members of one class, *lithionite*.

A hydrated lithia-mica occurring in minute scales and in slender six-sided prisms, sometimes bent, was described by G. J. Brush. It was named *cookeite* after J. P. Cooke, and obtained at Hebron and Paris, Maine. T. D. la Touche found it at Padar, Kashmir. It was analyzed by G. J. Brush, G. C. Hoffmann, and S. L. Penfield. F. W. Clarke represents the composition of cookeite by the formula $\text{Al} \equiv \text{SiO}_4 \cdot (\text{AlOH}) \cdot \text{SiO}_4 \equiv \{\text{Al}(\text{OH})_2\} \cdot \text{HLi} + \text{H}_2\text{O}$; and S. L. Penfield by $\text{Li}\{\text{Al}(\text{OH})_2\}_2(\text{SiO}_3)_2$, *lithium trialuminium hercynohydrozymbecasilicate*. The sp. gr. is 2.675; the hardness 2.3; and the double refraction positive. J. P. Cooke found a variety of lithia-mica in the granite of Cape Ann; and he called it *eryophyllite*—*from ερύος*, ice; *φύλλον*, a leaf—in allusion to its easy fusibility and foliated structure. G. Tschermak classed it with zinnwaldite; P. Groth treated the two micas separately. J. Lorenzen applied the term *polyolithionite* to a variety of zinnwaldite from Kangerdluarsuk, Greenland. The *Rubenglimmer* of A. Breithaupt was shown by G. Tschermak, P. Groth, and M. Bauer to be a kind of ferruginous zinnwaldite. F. Sandberger described a lithium-iron-mica from Erzgebirge, Fichtelgebirge, and Eibenstock, and named it *protolithionite* because he considered it to be the source of zinnwaldite. G. Tschermak, and P. Groth regarded it as a variety of zinnwaldite.

R. J. Haüy⁷ allocated the crystals of mica first to the rhombic system, and later to the monoclinic system. Both J. B. Biot, and D. Brewster noticed that there are two kinds of mica—one being optically uniaxial, and the other biaxial. A. Breithaupt called the uniaxial micas *astrées*—*from ἀστήρ*, a star—and the biaxial micas *phengites*—*from φέγγος*, glitter. He designated the uniaxial biotite from

Vesuvius astriles merozenus—from μέρος, a part;¹ and ξένος, a guest—and the *magnesia mica* from Antwerp, New York, *phengites phlogopites*, or simply **phlogopite**—from φλόξ, flame; and φῶς, appearance. J. F. L. Hausmann called the uniaxial mica **biotite** in honour of J. B. Biot. He also called the black uniaxial mica from Wermland, Sweden, **lepidomelane**—from λεπίς, a scale; and μέλας, black. Numerous analyses⁸ of muscovite or potash-mica have been reported, and the inferences which have been drawn from these data as to the constitution of the muscovite have been indicated above. The idealized mineral can be regarded as **potassium dihydrotrialuminotriorthosilicate**, $\text{KH}_2\text{Al}_3(\text{SiO}_4)_3$. Analyses⁹ have likewise been made of *paragonite* or soda-mica, and the idealized mineral can be regarded as **sodium dihydrotrialuminotriorthosilicate**, $\text{NaH}_2\text{Al}_3(\text{SiO}_4)_3$. The analyses¹⁰ of lepidolite or lithia-mica show that it is more complex than muscovite or paragonite. As indicated above, the idealized mineral can be represented as a mixture of **potassium lithium hydrotrialuminotriorthosilicate**, $\text{KLiHAl}_3(\text{SiO}_4)_3$, and of **potassium lithium hexafluotetra-aluminotrimetasilicate**, $\text{K}_3\text{Li}_3(\text{AlF}_2)_3\text{Al}(\text{Si}_3\text{O}_9)_3$. The analyses¹¹ of zinnwaldite show that it is a complex lithium-iron-mica. It is considered to be a mixture of the trisilicate associated with lepidolite, and ferrous-biotite—*vide supra*. The analyses¹² of phlogopite or magnesia-mica, and of biotite or magnesium-iron-mica show that they are probably complex mixtures. Idealized biotite, on F. W. Clarke's system, is **potassium dimagnesium hydrodialuminotriorthosilicate**, and phlogopite, **potassium trimagnesium dihydroaluminotriorthosilicate**,

Similar remarks apply to lepidomelane. A. N. Winchell based a theory of the structure on the assumption that each crystal is an aggregate of a number of intergrown space-lattices which differ from each other in the sizes of their constituent atoms. P. Erculisse regards the micas as solid soln. of salts of two or three acids, HAlSi_2O_6 , H_3AlSiO_5 , and $\text{H}_2\text{Al}_2\text{SiO}_6$; and J. Jakob represented the magnesia-micas as complexes of

Several varieties of biotite, phlogopite, and lepidomelane have been reported. J. D. Dana¹³ called a black variety, almost free from magnesia, from Cape Ann, *annite*. J. P. Cooke showed that it is a lepidomelane. *Anonite*—*vide infra*—has been discussed by G. Tschermak, F. Becke, H. Rosenbusch, F. Malt, F. Eichstädt, etc. F. von Kobell applied the term *aspidolite*—from ἀσπίς, a shield—in allusion to the shape, to an olive-green mica from Zillerthal, Tyrol. P. Groth regarded it as an altered meroxene. A. Breithaupt applied the term *alurgite*—from ἀλουργός, purple—to a purple or red micaceous mineral occurring in the manganese ores of St. Marcel, Piedmont. It is also called *manganese-mica*. It may be the same as manganophyllite. W. T. Schaller considers that the *mariposite* of B. Sillman, and *alurgite* belong to a series of mixed crystals, and holds that the name *mariposite* should be abandoned. The minerals were analyzed by W. F. Hillebrand, and S. L. Penfield. *Alurgite* has the composition $6(\text{H}_2, \text{K}_2)0.2\text{MgO} \cdot 3\text{Al}_2\text{O}_3 \cdot 12\text{SiO}_2$; and *mariposite*, $\text{K}_20.4\text{Al}_2\text{O}_3 \cdot 12\text{SiO}_2 \cdot 3\text{H}_2\text{O}$. E. S. Larsen studied the optical properties of *alurgite*. A. Knop found the biotite from Schelingen, Kaiserstuhl, has over 7 per cent. of baryta, and he called it *baryto-biotite*. A. H. Dumont, and A. des Cloizeaux refer to a greenish-brown plicated mica occurring in the quartzite of Bastogne, Belgium, which was called *bastonite*. A. H. Chester described an alteration product of biotite from Franklin, New York, and called it *caswellite*. A. Renard considers it to be an altered phlogopite. J. P. Cooke refers to a mineral, *culsagecite*, from Culsagee, Franklin, North Carolina, which appears to be a hydrated alteration product of phlogopite. G. A. Koenig, and T. M. Chatard analyzed the mineral. F. W. Clarke also considers *dudleyite* from Dudleyville, Alabama, reported by F. A. Genth, to be a decomposition product of phlogopite; and also of margarite. He represents its composition by $\text{CaH} \equiv \text{SiO}_4 - \text{Al}(\text{OH}) - \text{SiO}_4 \equiv \{\text{AlOH}\} \{\text{Al}(\text{OH})_2\}$. The chlorite-like mineral *euchlorite*—from εὖ, well; χλωρίς, green—

obtained by C. U. Shepard from Chester, Mass., was shown by F. Pisani to be ordinary biotite. G. A. Kenngott described a *chloridähnliche Mineral* from Presburg, Hungary, which he named *eukampite*—from *εὐ*, easy; *κάμψις*, bending. C. von Hauer, J. D. Dana, and G. Tschermak consider it to be a hydrated biotite. A. Leeds called a mica from East Nottingham, Penn., *hallite* after J. Hall. It was described by J. P. Cooke, and F. W. Clarke and E. A. Schneider. G. Tschermak regards it as an altered meroxene. M. F. Huddle called a highly ferruginous biotite from various Scottish localities *haughtonite*—after S. Haughton. R. T. Simmler, and G. A. Kenngott called a micaceous mineral from the Swiss Alps *helvetan*—from *Helvetia*, Switzerland. G. Tschermak regards it as an altered biotite. H. C. Lewis and A. Schrauf refer to hydrated biotites as *hydrobiotite*. F. W. Clarke represents hydrobiotite by the formula $\text{Al}=\text{SiO}_4-\text{Al}=(\text{SiO}_4\equiv\text{MgH})_3+3\text{H}_2\text{O}$. He likewise gives for *hydrophlogopite*, $\text{Al}=(\text{SiO}_4\equiv\text{MgH})_3+3\text{H}_2\text{O}$. G. J. Brush found a vermiculitic mica at Westchester, Penn., and named it *jefferisite*—after W. Jefferis. F. W. Clarke and E. A. Schneider, F. A. Genth, T. M. Chatard, and G. A. Koenig analyzed the mineral. G. Tschermak considers it to be a more or less altered phlogopite; and F. W. Clarke says that its composition is near that of hydrobiotite. F. W. Clarke and E. A. Schneider described a mineral which they called *kerrite* from Franklin, North Carolina; it approximates to hydrophlogopite. They called a vermiculitic mineral from Lenni, Delaware, *lennite*—A. Schrauf regarded lennito as a *parachlorite*, J. Byroman analyzed lennito. T. M. Chatard called a vermiculitic mineral from Franklin, North Carolina, *lucasite*—after H. S. Lucas. A manganiferous biotite from Pajaberg, Sweden, was named *manganophyllite* by L. J. Igelström—from *φάλλον*, a leaf. F. W. Clarke and E. A. Schneider called a vermiculitic mineral from Middletown, Delaware, *painterite*. F. A. Genth described a micaceous mineral from Unionville; he called it *pattersonite*. H. C. Lewis applied the term *philadelphite* to a vermiculitic mineral occurring near Philadelphia; and G. A. Koenig, *protevermiculite* to a micaceous mineral from Magnet Cove, Arkansas. F. W. Clarke and E. A. Schneider consider it to be a hydrated biotite. G. A. Koenig, and F. A. Genth have also discussed the mineral. F. W. Clarke says that the formula

fits the analysis of protevermiculite very well. A. Knop applied the term *pseudobiotite* to an altered biotite from Kaiserstuhl, Baden. A. Breithaupt described an olive-green or liver-brown mica from Brevik, Norway, and called it *pterolite*—from *πτερόν*, a feather—in allusion to the fan-shaped forms in which it occurs. A. Lacroix showed that the mineral is heterogeneous, and W. C. Brogger, that it is an alteration product of amphibole. F. von Kobell reported a micaceous mineral from Elba, which he named *pyrosclerite*—from *πῦρ*, fire; and *σκληρόν*, hard (refractory). C. U. Shepard applied the term *rashtolyte*—from *ρᾶστος*, very easy; *λύω*, dissolve—to a hydrated biotite from Monroe, N.Y. G. Tschermak regards it as a decomposed product of biotite. A. Breithaupt called a reddish uniaxial mica from Laacher See, *rubellan*. M. U. Hollrung considers it to be an altered biotite. H. C. Lewis described a biotite very rich in iron and poor in magnesia from Piko's Peak, Colorado, and called it *aucrophyllite*—from *αἰδηρός*, iron; *φάλλον*, a leaf. N. S. Maskelyne and W. Flight described *vaalite* as a decomposition product of biotite at Du Toits Pan, South Africa. T. H. Webb applied the term *vermiculite*—*vermis*, a worm—to a micaceous mineral from Worcester, Mass., which was also described by T. Thomson, J. P. Cooke, A. Schrauf, and C. T. Jackson. F. W. Clarke and E. A. Schneider discussed the constitution of vermiculite. It is an altered phlogopite or biotite. E. E. Schmid applied the term *voigteite* to a kind of biotite from Ehrenberg near Ilmenau. G. Tschermak called it an altered biotite more or less hydrated. F. A. Genth described a micaceous mineral from North Carolina, as a decomposition product of biotite; and he named it *willcoxite*. F. W. Clarke regards this mineral as a kind of basic analogue of the mixed biotite—phlogopite type. H. Rosenbusch, and G. Lattemann have described a *titaniferous biotite* obtained from Katzenbuckel, and they called it *wodanite*—after the mythological Wodan.

Muscovite¹⁴ is a pyrogenetic mineral which occurs as a primary constituent in deep-seated igneous rocks rich in alumina and potash, and poor in iron and magnesia. It is common in granites, syenites, and pegmatites. From its water-content muscovite was probably formed in these rocks under press. It does not occur as a primary constituent in recent lavas and their glassy magmas. Muscovite is common as an alteration product of many minerals—andalusite, cyanite, topaz, feldspar, nephelite, spodumene, scapolite, etc. As a secondary mineral it is often called sericite. Paragonite is one of the rarer varieties; it occurs in crystalline schists, but does not occur as a pyrogenetic mineral. Lepidolite occurs in granite and pegmatite where it may form violet or lilac-coloured crystals

associated with muscovite. It sometimes occurs as a secondary product after muscovite, when it occurs as margins on the plates of muscovite. Cryophyllite similarly occurs on plates of lepidolite. Phlogopite occurs chiefly in metamorphosed limestones and dolomites and serpentine; W. Cross found it in an igneous rock, and it appears in some igneous rocks rich in magnesia and poor in iron. Biotite occurs in many igneous rocks—granite, syenite, diorite, trachyte, andesite, basalt, etc. It is rare in rocks containing a small proportion of magnesia or potash. It separated early in the crystallization of rock magmas, and followed the metallic ores, apatite, and zircon. It is a common constituent of gneiss and schists, and is developed in some zones on contact metamorphism. Lepidomelane occurs in felspathic rocks low in magnesia and high in iron—*e.g.* some granites, syenites, etc. It is also found in metamorphic rocks.

The alleged syntheses of mica are not altogether free from objection, because the micaceous appearance of a product is not proof that a mica has been formed. Further, although some phlogopites are almost anhydrous; in general, water is an essential constituent of true micas, and therefore pyrogenetic processes which yield anhydrous products may furnish mica-like products, but not true micas. F. Fouqué and A. Michel-Lévy¹⁶ heated powdered vitreous granite with water under pressure for a long time at red-heat, and obtained an artificial rock with scales of mica. C. Doelter reported the synthesis of scaly crystals of muscovite by heating andalusite with a solution of potassium carbonate and fluoride at 250°. In nature, also, andalusite readily alters into muscovite. J. Lemberg did not get mica by heating andalusite with sodium silicate. S. J. Thugutt obtained potash-mica by heating to 196°–233° a mixture of potash nepheline and water—G. Friedel studied the reverse reaction. E. Baur and F. Becke made muscovite by heating in steel cylinders mixtures of silica, alumina, and a solution of potassium hydroxide at 350°–450° for 12–16 hrs. C. Doelter also obtained micas by fusing various natural silicates—*e.g.* leucite—with potassium or sodium fluoride. When andalusite is fused with a mixture of potassium fluosilicate and aluminium fluoride, muscovite was formed; and when some lithium carbonate was present, a lithia-mica was produced. P. Hautefeuille and L. P. de St. Gilles found that biotite is formed by fusing a mixture of the constituents with potassium fluosilicate. K. Chrustschoff fused a mixture of the constituents of mica with the fluorides of sodium, aluminium, and magnesium, and also with potassium fluosilicate, and obtained crystals of biotite by slowly cooling the mass. J. Morozewicz mixed the constituents of rhyolite with one per cent. of tungstic oxide, and after prolonged fusion and slow cooling, obtained plates of biotite. C. Doelter obtained biotite (sodium) by fusing a mixture of hornblende, pyrope, augite, almandite, or grossularite with sodium and magnesium fluorides; by fusing leucite with magnesium fluoride; and by fusing a mixture corresponding with $KAlSi_3O_8$, Mg_2SiO_4 , and sodium and magnesium fluorides. Glaucofan treated similarly also gave phlogopite. E. Mitscherlich, J. F. L. Hausmann, and G. Forchhammer found mica-plates in slags, crucible walls, and furnace masonry. J. H. L. Vogt found that some slags from a copper works contained phlogopite with the hydroxyl replaced by a monad radicle. G. V. Wilson observed the formation of mica by the action of molten glass on bricks.

Micas vary greatly in colour. Muscovite may be colourless, white, grey, yellow, brown, pale green to olive-green, violet and rarely rose-red. Some Bengal muscovites are dark red, and the colour deepens into ruby-red when in thick sheets. Amber-coloured muscovite is found only in the Nellore district, Madras. Paragonite may be tinged with yellow, grey, or green; lepidolite is white, grey, lilac, or rose-red; and zinnwaldite is coloured like lepidolite, but in addition it may be brown. Phlogopite is often brown or brownish-red, but it may be colourless, white, yellow, or green; biotite is usually green or brown to black, often pale yellow, and rarely white. Lepidomelane is black. Fuchsite, or chromiferous muscovite, is emerald-green. When in thin sections, the lighter-coloured micas may appear colourless. The colour is modified by inclusions. In some cases there are aggre-

gates of wavy lines of a lighter colour than the mica itself; or a sheaf of such lines may spread in one direction from an inclusion. The lustre of mica is often different on the cleavage planes from what it is on the other planes. The lustre may be vitreous, or pearly; and in some cases glassy, and dull.

J. B. Biot showed some crystals of biotite are uniaxial; but G. Rose found that the greenish-black crystals from Vesuvius belong to the monoclinic system, and this was verified by the measurements of W. Phillips. On the other hand, J. C. G. de Marignac said that the Vesuvian mica is hexagonal, while mica from Binnenthal is monoclinic. The hexagonal character of the crystals was accepted by G. A. Kenngott, N. von Kokscharoff, and F. Hessenberg. B. Silliman, however, remarked that the crystals of biotite are often biaxial, and that uniaxial biotite is anomalous. This was confirmed by W. P. Blake, H. W. Dove, H. de Sénarmont, J. Grailich, etc. F. Leydolt, F. von Kobell, F. Hessenberg, G. vom Rath, M. Bauer, H. Baumhauer, and others supported the view that some micas belong to the rhombic system. T. L. Walker said that probably all the micas except muscovite have hexagonal symmetry, and belong to the triclinic system. M. Royer also inferred from the growth of crystals of ammonium iodide on fresh cleavage faces of muscovite, that the mineral is of triclinic symmetry, and is built up of laminations twinned at 180° to one another so as to make the crystals pseudomonoclinic. A. des Cloizeaux proposed assigning all the micas to the rhombic system, but he later showed that some belong to the hexagonal system. C. Hintze showed that the effect of temp. on the axial angles of the crystals of mica does not support the view that the crystals are hexagonal, or rhombic. N. von Kokscharoff then proved that the facts best fit the assumption that all the micas are monoclinic. This conclusion was confirmed by the work of G. Tschermak, and M. Bauer, who showed that no mica has a higher symmetry than corresponds with this system. The biotites which have the optic axis in the plane of symmetry have been called *microxenes*, and those with the optic axis perpendicular to the plane of symmetry have been called *anomites* from *ἀνομος*, contrary to law. These two optical varieties of biotite have not been found to be associated with any particular composition or magma, for both varieties may be associated with the same rock.

Isolated crystals may be scattered through masses of rock, or groups of crystals may be present in curved, spherical, or radiating fan-like clusters. Mica occasionally occurs massive and cryptocrystalline. The size of the crystals varies from the cryptocrystalline forms to the crystals of muscovite from Nellore, India, which have been known to measure 10 ft. across their basal planes. Phlogopite crystals weighing 3000 lbs., and measuring 5 ft. by 9 ft., have been taken from Canadian mines. Such hypertropes are exceptional. Crystals from

6-12 ins. in diameter are common. Geometrically perfect crystals, free from distortion, etc., of a size suitable for accurate measurement, are comparatively scarce. The prism face *m* of the crystal, Fig. 131, is the (221)-face; *c* is the (110)-face; *b*, the (010)-face; and μ , the (11 $\bar{1}$)-face. The edge *cm* is sometimes replaced by facets of *o*, the (112)-face, and the angle *co* is $73^\circ 1'$. Mica crystals—particularly those in the coarsely crystalline and softer rocks—

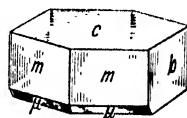

FIG. 131.—Muscovite.

may have been more or less distorted, crushed, and twisted. The so-called *step-crystals* are formed when the press. has acted across the crystals, so that the laminae have slipped in layers of varying thickness to form a series of steps which have generally been cemented in their new position by thin films of calcite or other mineral. The crystals may also have been subjected to some kind of chemical action, as is evidenced by pitted or roughened surfaces. The crystals of the different micas are isomorphous with one another. As indicated above, it is possible that the crystals belong to the monoclinic system, but, owing to the basal angles measuring approximately 120° , there is in many cases a close approach to the hexagonal or rhombic symmetry. N. von Kokscharoff¹⁶ gave for the

axial ratios of muscovite, $a:b:c=0.5774:1:1.6456$; G. Tschermak gave $0.5777:1:2.1932$, and $\beta=95^\circ 2'$; and A. des Cloizeaux, $0.5777:1:1.1583$, and $\beta=109^\circ 25'$. N. von Kokscharoff gave for biotite $0.57736:1:1.64518$ and $\beta=90^\circ$. The isomorphism of the micas is illustrated by the intergrowths of light-coloured muscovite with dark-coloured biotite, so that the latter encloses the former, and the cleavage of the one continues into that of the other. The symmetry planes often lie turned at an angle of 60° to one another. Lepidolite and muscovite behave similarly; and zonal intergrowths of biotite and pennine (a chloritic mineral) have been found. The frequent intergrowth of biotite and muscovite has suggested that the latter is an alteration product of the former. J. E. Pogue described the parallel growth of biotite and mica, and H. Baumhauer, of muscovite and lepidolite. Similar effects are produced simply by a crystal of dark-coloured muscovite enclosing a lighter crystal of muscovite; and in some cases the two crystals have a different shape. In more complex cases, the successive stages in the growth of the crystal conform more approximately to the symmetry of the central individual, for the growth of the crystal has proceeded nearly equally in different directions. This has produced a banded structure, forming the so-called *border mica*. These phenomena of *multiple crystallization* are probably produced by changes of pressure, and of the composition of the cooling magma, which have interrupted the processes of crystallization. When the normal conditions have been re-established, crystallization has begun anew, imparting a kind of *zonal structure* to the mica. R. Tronquoy discussed the zonal structure of mica. F. M. Jäger, and F. Rinne have studied the **X-radiogram** of muscovite, and biotite. The **twinning** of mica is shown in polarized light, when apparently well-formed crystals of mica are obviously composed of two or more individuals. The crystal forms, and the twinning of crystals of muscovite, lepidolite, and zinnwaldite were studied by G. Tschermak; those of muscovite by H. Baumhauer, P. I. Grishchinsky, and A. Johnsen; those of lepidolite, by W. T. Schaller; those of biotite and phlogopite, by N. von Kokscharoff, A. des Cloizeaux, G. Tschermak, G. vom Rath, H. Laspeyres, and S. Uroschewitsch. There is an irregular junction line, and the optic axial planes of the twins are inclined to one another at angles of about 60° . The common plane of twinning is in the prismatic zone (110) perpendicular to the basal plane c and parallel to the edge cm . This twinning plane may form the intergrowth face with both individuals in adjacent positions either with the front right prism edge or with the front left prism edge—Fig. 132. Twinning, however, does not usually proceed from twin faces—

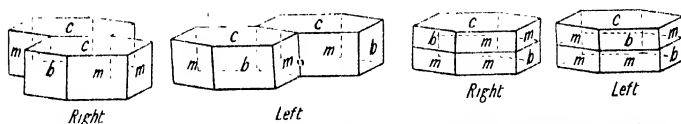

FIG. 132.—Juxtaposition Twins on the Front Prism Face—Right and Left.

FIG. 133.—Superposition Twins on the Basal Plane—Right and Left.

i.e. horizontally, but rather from the basal plane, so that the two individuals are superimposed and in contact along a plane almost parallel to (110). Right and left twins then appear as in Fig. 133. The re-entrant angles $mm=162^\circ 49'$ and $mb=179^\circ 19'$. This twinning is common with zinnwaldite and is often evidenced by the matte appearance of the m -faces. Owing to the twinning, large crystals of mica appear as rude tapering prisms with irregular sides. Usually the crystals are tabular owing to the preponderance of the basal plane c ; sometimes they have rounded edges; and rarely, the crystals are short and columnar in the direction of the vertical axes. In some cases, a number of small individuals of various shapes and sizes have intergrown symmetrically so as to form one large crystal. In some cases the large crystals are hollow as if the smaller crystals have grown about some mineral which has been subsequently removed. The **corrosion figures** have been studied by T. L. Walker, H. Baumhauer, etc.

The cleavage of mica parallel to the (001)-face or base of the prism is highly developed, and it causes the crystals to cleave readily into thin laminae. There seems no other limit to the possible thinness of the plates than the mechanical possibility of splitting them. Plates $\frac{1}{1000}$ in. thick are easily obtained, and C. W. Jefferson and A. H. Dyer obtained plates 0.00003 in. thick, but of no great size. This thickness is about one-thirtieth of that of ordinary tissue paper. These sections of mica parallel to the (001)-face do not usually show any cleavage lines or fracture cracks; but in all other positions, numerous sharply defined parallel cleavage cracks are noticeable in the direction of the trace of the (001)-face. Other lines of parting may be developed in mica by percussion with a sharp-pointed instrument, or by press. Pressure figures can be developed by natural processes—say, by the crystallization of some foreign mineral within the mica crystals, or by an external press.—or they may be produced by pressing normally to a cleavage plate with a dull pointed instrument. The planes of fracture with a naturally developed press. figure divide the mica crystal into trigonal pieces. If the press. has been equally distributed, the cleavage plates may show a close network of intercrossing fine lines; and plates are said to be *ruled mica*. When the press. lines form in two directions the so-called *feather mica* may be produced. If the press. has been sufficient, these cleavage plates may split along such lines, forming small fragments of regular shape. This splitting spoils the commercial value of the mica. In some cases, the press. lines are developed in one direction so that the cleavage plates can be split into narrow strips commercially called *ribbon mica*. The fragments possess pseudo-crystalline faces, some of which are inclined about 67° to the basal cleavage plane. These faces are called *gliding planes*. The gliding planes and cleavage planes are quite distinct and do not coincide, although the twinning planes of mica crystals coincide with the gliding planes. A. Johnsen, and W. Wetzel studied the press. figures of mica. The *percussion figure*, developed by striking a cleavage plate of mica with a sharp, pointed instrument, may appear as a six-rayed star, or, if imperfectly developed, as a three-rayed star. The percussion figures were studied by H. Reusch, D. Rotman, M. Bauer, T. H. Holland, W. Wetzel, G. Tschermak, and A. Johnsen. The most prominent crack in the three-rayed star is approximately parallel to the (010)-face, and the other two, in biotite, are parallel to the ($\bar{1}10$)-face. The angle κ of intersection of the rays is approximately 60° . T. L. Walker found that the inclination of the one crack to the principal one is $52^\circ 53' - 56^\circ$ for muscovite; 59° for lepidolite; 60° for biotite; and $61^\circ - 63^\circ 28'$ for phlogopite. The principal crack in the percussion figure, being parallel to the (010)-face, serves to orient the mica when the outward form of the crystal is wanting. As shown by J. Grailich, and H. Reusch, one of the rays of the percussion figure is perpendicular or parallel to the optic axial plane, and it must therefore be the trace of the plane of symmetry. G. Tschermak called the micas in which the optic axial plane is perpendicular to the plane of symmetry, *micras of the first class*, or *macrodiagonal micas*—e.g. the alkali micas, and the rare varieties of biotite called *anomile*. Those micas in which the axial plane is parallel to the (010)-face were called *micras of the second class* or *brachydiagonal micas*—e.g. the ferromagnesian micas, phlogopite, and zinnwaldite. T. H. Holland investigated the percussion figures and the natural press. figures due to the inclusion of crystals of a foreign substance. The angles of intersection of the rays approximate 30° , and one of the rays occupies the correct position of the principal ray of the artificially produced percussion figure. The natural figure, unlike the artificial, is formed by the intersection of rays at 60° . T. H. Holland also found that at 300° , the angle κ of the rays of the percussion figures is always larger than the corresponding angle on mica at ordinary temp. Thus, the angle κ at

Ordinary temp.	53°	53° 30'	54°	55°
300°	56°	56°	57°	57° 30'

This shows that muscovite possesses a higher degree of crystalline symmetry at

higher temp., and that the crystal, at the temp. at which natural figures are produced, might possess hexagonal rather than monoclinic symmetry. According to C. Hintze, the measurements of a Vesuvian biotite made the mineral appear hexagonal or rhombic, but in these systems the optic axis remains perpendicular to the base at all temp., whereas a change of over 30° was observed at 178° , he inferred that the mineral was monoclinic.

When cleavage plates of some varieties of mica are examined by reflected or transmitted light, in certain directions, peculiar star-like light-rays appear. The phenomenon is called **asterism**, and it is also exhibited by other minerals—*e.g.* the sapphire, quartz, chrysotile, satin spar, etc. G. H. Volger suggested that in the case of the sapphire the asterism is produced by repeated lamellary twinning, and G. Tschermak, by minute interstices arranged parallel to the sides of the hexagonal prism. With mica the asterism may be produced by inclusions between the laminae of numerous minute crystals whose axes are oriented at an angle approximately 60° to one another, and which were supposed by G. Rose to be mica, but were shown by G. Tschermak to be rutile. H. S. de Schmid found asterism was also produced in muscovite by regularly arranged hair-like tourmaline needles; he also said that the effect may be produced by very fine striations—*e.g.* polysynthetic twinning; minute fractures by a distortion of the crystals; inferior cohesion of laminae; interstices; or fibres which go to compose the mineral itself. In some cases there is double asterism.

Most varieties of mica are biaxial with a measurable angle between the optic axes, but in some biotites the angle is so small that the crystals appear uniaxial. The **optic axial angle**, $2E$, of muscovite is large and varies greatly usually ranging from 50° – 70° ; that of phlogopite and biotite is small, ranging from 10° – 17° . J. Grailich found the optic axial angle of muscovite increased as the sp. gr. increased. Thus:

Sp. gr.	.	.	.	2.602	2.714	2.755	2.782	2.790	2.796
$2E$.	.	.	65.2°	69.7°	70.5°	71.2°	72.3°	72.0°

The optic axial angle of muscovite was found by G. Tschermak to vary from 55° – $69^\circ 12'$ with red glass; from $60^\circ 12'$ – $68^\circ 54'$ with Na-light; from $60^\circ 6'$ – $68^\circ 30'$ for green glass; and $67^\circ 54'$ for blue glass. R. Scharizer gave for the red ray $2E=74^\circ 50'$, and for the Na-ray $2E=73^\circ 52'$; B. Silliman found for different varieties of muscovite, $2E=56^\circ 20'$ – 76° ; H. de Sénarmont, $2E=57^\circ$ – 73° ; J. Grailich, $2E=50^\circ 12'$ – $76^\circ 12'$; and M. Bauer, $2E=61^\circ$ – $74^\circ 36'$. For paragonite, G. Tschermak gave $2E=70^\circ$. For lepidolite, R. Scharizer gave $2E=57^\circ 13'$ – $83^\circ 16'$ for red glass, and $57^\circ 10'$ – 84° for Na-light; M. Bauer gave $2E=32^\circ$ – 36° , and $59^\circ 24'$; G. Tschermak, $2E=77^\circ 10'$ for red light, $76^\circ 51'$ for Na-light, and $76^\circ 34'$ for green light; G. Rose, $2E=51^\circ$ – 67° ; and J. Grailich, 74° – $76^\circ 40'$. For zinnwaldite, G. Tschermak gave $2E=50^\circ 36'$ for red light, $50^\circ 25'$ for Na-light, and $50^\circ 5'$ for Ti-light. J. Lorenzen gave $67^\circ 13'$ for Li-light, $67^\circ 19'$ for Na-light, and $67^\circ 51'$ for Ti-light. For biotite G. Tschermak gave $2E$ from $6^\circ 16'$ – $12^\circ 22'$ for red glass, $6^\circ 24'$ – $12^\circ 48'$ for Na-light, $9^\circ 24'$ – $13^\circ 18'$ for Ti-light, and $8^\circ 18'$ for green glass. For phlogopite, G. Tschermak gave $2E=14^\circ$ – $16^\circ 17'$; and for anomite, $2E=12^\circ 55'$ for red glass, $12^\circ 40'$ for Na-light, and $12^\circ 35'$ for green glass. B. Silliman gave $2E=7^\circ$ – 18° ; J. Grailich, 0° – $2^\circ 40'$; A. Lacroix, $2E=15^\circ$ – 35° . The optic axial angle of phlogopite appears to increase as the proportion of contained iron increases. F. Kohlrausch gave for muscovite, $2V=43^\circ 48.8'$ for Na-light; M. Bauer gave $40^\circ 21'$. A. des Cloizeaux measured the effect of temp. on the optic axial angle, and found for different samples $2E=70^\circ 4'$ at 6.6° , and $68^\circ 56'$ at 155.8° ; $69^\circ 44'$ at 6.6° , and $68^\circ 5'$ at 158.8° ; and

	8.8°	71.5°	105.6°	125°	146.5°	170.8°
$2E$	$76^\circ 50'$	$76^\circ 16'$	$75^\circ 58'$	$75^\circ 32'$	$75^\circ 30'$	$75^\circ 10'$

showing that the optic axial angle becomes smaller with rise of temp. He also

found with red light for biotite at 17° , $2E=12^\circ 3'$, and $11^\circ 5'$ at 171° , $14^\circ 3'$ at $21^\circ 5'$, and $13^\circ 28'$ at 181° ; etc. T. L. Walker, H. C. Lewis, and K. Toborffy measured the optic axial angles of a number of micas. H. Baumhauer called the variety of lepidolite with a large optical angle *macrolepidolite*, and the variety with a small angle *microlepidolite*. A. Johnsen discussed the axial angles of merxene. The corrosion figures of muscovite with hydrofluoric acid were studied by T. H. Holland, Z. Toborffy, H. Baumhauer, and F. J. Wiik; those of lepidolite, by F. J. Wiik; those of zinnwaldite, and biotite by H. Baumhauer, and F. J. Wiik. The crystallization of sodium chloride in definite positions on mica was studied by G. Kalb.

The **specific gravities** of most of the samples whose analyses have been indicated were also measured. In general, the sp. gr. of muscovite ranges from 2.76-3.00; paragonite, 2.8-2.9; lepidolite, 2.8-2.9; zinnwaldite, 2.82-3.20; phlogopite, 2.78-2.85; biotite, 2.7-3.1; and lepidomelane, 3.0-3.2. Micas are soft minerals; the **hardness** usually ranges from that of gypsum to that of calcite; they can be readily scratched by iron or steel, and, in some cases, by the finger-nail. The granitic micas are usually harder. The hardness ranges from 2-2½ with muscovite; 2½-4 with lepidolite; 2½-3 with paragonite, zinnwaldite, phlogopite, and biotite; and 3 with lepidomelane. A. Kosiwal made some observations on this subject. L. A. Coromilas found the maximum **elastic modulus** at 0° to be 22,133 kgms. per sq. mm.; and the minimum value at 45° to be 15,543 kgms. per sq. mm. L. H. Adams and co-workers found the **compressibility**, β , of phlogopite mica to be 2.34×10^{-6} at 0 megabar press., 2.27×10^{-6} at 2000 megabars, and 1.99×10^{-6} at 10,000 megabars; or $\beta = 0.05270 - 0.010348(p - p_0)$. Although mica is such a soft mineral, the basal cleavage into smooth tough laminae makes the grinding of mica to powder a difficult operation. The subject has been discussed by H. J. Hannover, J. Keeth, and A. Johnsen. E. Griffiths and G. W. C. Kaye gave 0.0010-0.0014 for the **thermal conductivity** of mica at 150° and under a press. of 120 lbs. per sq. in. H. C. Michell used scrap mica as a covering for steam pipes, boilers, etc. The effect is not due so much to the non-conductivity of the mica itself as to the numerous air-spaces in the lagging. F. Cirkel describes tests which show that with a bare steam-pipe, 75 per cent. of the loss of steam by condensation in the pipes can be saved by lagging the surfaces of the pipes, and 90 per cent. was saved by using a mica insulation; and also tests on the mica insulation of boilers which confirm these results. There is a saving of about 90 per cent. of the heat radiated from a bare boiler, and the efficiency is nearly twice as great as insulation by magnesia blocks. S. L. Brown measured the variation of the diathermancy of mica with temp.

P. Braesco found the expansion of mica to be regular up to 900° . J. Joly found the **specific heat** of muscovite to be 0.2049 between 12.4° and 100° ; lepidolite, 0.2097; and biotite, 0.2057. According to C. Doelter, when muscovite is fused, it breaks up into leucite glass and a substance resembling nephelite; lepidolite behaves in a similar manner. J. Morozewicz said that he found sillimanite and corundum among the products of the fusion of mica. The change may be symbolized: $\text{KH}_2\text{Al}_3\text{Si}_3\text{O}_{12} = \text{KAlSi}_2\text{O}_6 + \text{Al}_2\text{SiO}_5\text{H}_2\text{O}$. According to A. Brun, the dehydration of powdered mica commences in a vacuum at 98° and proceeds regularly; at 360° , one-quarter of the water is lost in the case of white micas, and four-ninths with black micas. Plates of mica were completely dehydrated when heated for half an hour at 830° , or for ten to twelve days at 510° - 540° . The material suffered no change in its optical properties, but, owing to the liberation of gas between the lamellae, the plates became opaque (this, however, could be avoided by heating in a vacuum under certain conditions). The quantity of hydrogen liberated depended on the rate of heating, less being obtained when the material is heated very slowly. The water was assumed to exist in the micas in a state of solid soln. According to C. Doelter, biotite does not yield leucite when fused, but breaks up into olivine and spinel. H. Bäckström obtained olivine, leucite, a little spinel, and a glass among the products obtained by fusing biotite. There is therefore no **melting**

point in the strict sense of the term. C. Doelter found samples of biotite which were molten between 1145° and 1240°; merxene was molten between 1355° and 1370°; anomite, 1325°–1395°; lepidomelane, 1150°–1170°; and phlogopite, 1270°–1330°. G. Tammann and C. F. Grevenmeyer found that mica forms a sparingly soluble potassium aluminosilicate when heated to 1000°. The fluxing of mica with clays and related materials has been examined by R. Rieke, R. T. Stull, and H. Ries. The **softening temperatures** of mixtures of muscovite and orthoclase were determined by A. S. Watts; and of mixtures of china clay and muscovite by R. Rieke.

The **index of refraction** varies considerably for each kind of mica. That of muscovite was found by M. Bauer, C. Viola, B. Hecht, R. Scharizer, etc. F. Kohlrausch gave for Na-light, $\alpha=1.5609$, $\beta=1.5941$, and $\gamma=1.5997$; A. Matthiessen, $\alpha=1.5692$, $\beta=1.6049$, and $\gamma=1.6117$; and C. Pulfrich, $\alpha=1.5601$, $\beta=1.5936$, and $\gamma=1.5997$. The last-named found for Li-light, $\alpha=1.5666$, $\beta=1.5899$, and $\gamma=1.5943$; and for Ti-light, $\alpha=1.5635$, $\beta=1.5967$, and $\gamma=1.6005$. R. Scharizer gave for lepidolite, $\beta=1.5975$ and $\gamma=1.6047$; but B. Hecht doubted if these values were accurate. A. Michel-Lévy and A. Lacroix gave for phlogopite, $\alpha=1.562$, $\beta=1.606$. H. Rosenbusch and E. A. Wulff found the index of refraction of biotite increased with the iron content. G. Linck found $\alpha=1.504$, $\beta=1.589$, and $\gamma=1.589$. F. Kohlrausch, and K. Zimanyi obtained values for α ranging from 1.5412–1.586, and for γ , from 1.5745–1.6032. The **birefringence** is strong for all kinds of mica; that of muscovite is $\gamma-\alpha=0.0392$, $\gamma-\beta=0.0061$, and $\beta-\alpha=0.0338$; that of lepidolite is large and negative; and that of biotite $\gamma-\beta$ is almost zero; and $\gamma-\alpha$, increasing with the percentage of iron, attains to 0.06. Mica in general is optically negative. The optical properties of mica were also described by S. Tsuboi, F. W. Clark and W. F. Hunt, H. Backlund, A. Laitakari, etc. J. Chaudier found the electric birefringence of mica particles suspended in water to be 0.40, and the optical birefringence, 0.04. P. N. Ghosh investigated the laminar diffraction of mica; and C. F. Meyer and D. W. Bronk, the ultra-red spectrum.

The **pleochroism** of biotite is very strong especially with the deeper coloured varieties. This has been studied by K. Toborffly,¹⁷ G. Tschermak, G. Flink, and A. Lacroix. Muscovite is not generally pleochroic, although M. Bauer found some varieties are pleochroic, and F. Cornu observed the phenomenon with the chromiferous muscovite, fuchsite. Brown micas, cordierite, and some other minerals have certain small circular spots when viewed in section. The spots are called **pleochroic haloes**. These haloes are invariably associated with a minute, centrally-placed crystal of zircon or apatite. The medium in which the halo occurs with biotite is pleochroic, but the pleochroic properties are intensified in the halo. The halo disappears when the mineral is heated, hence it was once thought to be produced by organic matter; but the haloes are really spherical, and it is doubtful if the diffusion of colouring matter would proceed at an equal rate across and along the cleavage of a mineral like mica. J. Joly showed that there is an exact correspondence between the radius of the halo and the distance which the α -particles of radium would penetrate before the ionizing properties would disappear. The maximum diameter of the haloes is 0.05 mm.; the average 0.04 mm. Hence, J. Joly infers that the halo is produced by the radioactivity of a central radioactive substance. This is confirmed by O. Mügge, and G. Hövermann. M. Weber examined the effect of the pleochroic haloes of mica and cordierite on zircon.

W. W. Coblenz found that the **ultra-red transmission spectrum** of the micas showed no deep wide absorption bands at 3μ , characteristic of hydroxyl groups. Muscovite gave a deep narrow band at 2.85μ , and smaller bands at 1.9, 3.6, 5.6, 5.9, 6.3, and 7.1μ ; while biotite has small bands at 2.8, 5.9, 6.2, and 6.7μ , and indications of bands at 5.6 and 7.8μ . It has also one in the visible spectrum. Both micas have an opaque region from 9–11 μ , a transparent region at 12 μ , and again complete opacity. The spectrum energy curves were studied by E. F. Nichols and W. W. Coblenz, and G. W. Stewart. Metallic reflection bands were found

by H. Rubens and E. F. Nichols at 8.32, 9.38, 18.40, and 21.25μ , so that the bands located by reflection and transmission do not coincide. W. W. Coblenz found reflection bands in the **ultra-red reflection spectrum** of muscovite at 9.2, 9.7, and 10.2μ . H. Rosenthal also failed to observe a reflection band at 8.32. W. W. Coblenz found maxima with biotite at 9.3, 9.6, and 9.85μ . The reflecting power of the micas is comparable with that of the silicates. The positions of the maxima are variable, presumably owing to variations in the composition of the mineral. P. Ites, and J. Königsberger studied the relation between the absorption of light and the colour of biotite. L. C. Martin, and S. L. Brown measured the transparency of biotite for the ultra-red rays. The **flame spectra** of micas were studied by W. Vernadsky and B. A. Lindener; and the grating spectrum by B. Davis and H. M. Terrill.

W. Vernadsky found muscovite and biotite to exhibit **triboluminescence**. C. Doelter found **radium radiations** have no action on muscovite, and they do not make biotite luminesce. C. Doelter also said that muscovite and biotite are not very transparent to **X-rays**, but thin layers 0.5 mm. thick are transparent; Singalese biotite was almost opaque; and a very ferruginous black biotite was opaque. The ratio of the transparency of phlogopite to that of tin-foil was as 1:20 when the ratio with the diamond is as 1:300 or as 1:425. Biotite is not radioactive when free from radioactive impurities.

J. Curie found the **electrical conductivity** increased with the temp. C. Doelter obtained a very small value for the conductivity at 1100° , but it increased in value beyond this temp. The conductivity at 1200° is small but measurable. Hence, mica is a good insulator at temp. below 1100° . W. H. Schultze found that sheets of mica split along the plane of cleavage resemble glass in improving in conductivity as the temp. rises, and also in a maximum conductivity being obtained at about 300° , after which further increase in the temp. causes a diminution in conductivity. Mica is a better insulator than glass. Measurements of the electrical conductivity were made by H. H. Poole, and E. Branly. A. E. Williams and J. C. McLennan, and K. R. Ramanathan measured the resistance of fused mixtures of mica and copper or iron. E. Wilson studied the magnetic susceptibility. E. and W. H. Wilson and T. Mitchell found the sp. resistance varied from $0.44\text{--}133.0 \times 10^{-12}$ ohms per cm. cube. The electrical resistance of mica has been studied by O. N. Rood. A. Klautzsch found the sp. resistance of a number of samples to vary from 700–1200 megohms—one sample had a sp. resistance of 380 megohms. The breakdown voltage of plates from 0.12–0.25 mm. in thickness varied from 10,000–18,000 volts.

E. Bouty found the **dielectric constant** to be 7.98–8.43; E. Mattenklodt, 7.1–7.7; H. Starke, 5.8–6.62; and A. Elsass, 5.66–5.97. The different micas have different values, particularly those with a varying proportion of water. E. Mattenklodt found the value to be independent of the field strength, and of the temp.—at least the temp. coeff. is less than 0.0000033. J. Curie obtained 8.0 for the dielectric constant of muscovite perpendicular to a cleavage surface. E. and W. H. Wilson and T. Mitchell measured the dielectric strength of different micas in terms of the difference of potential required to puncture a given specimen when surrounded by air; this constant is a function of the shape, relative size, distance apart, and nature of the electrodes. Some results for (1) Bengal ruby mica, (2) Canadian amber mica, and (3) Madras green spotted mica of different thicknesses, are shown in Fig. 134. They found that the specific inductive capacity of some samples of mica varied

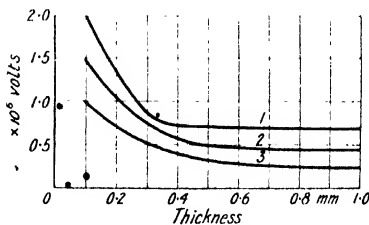

FIG. 134.—Dielectric Strength of Mica of Varying Thickness.

point in the strict sense of the term. C. Doelter found samples of biotite which were molten between 1145° and 1240°; meroxene was molten between 1355° and 1370°; anomite, 1325°–1395°; lepidomelane, 1150°–1170°; and phlogopite, 1270°–1330°. G. Tammann and C. F. Grevenmeyer found that mica forms a sparingly soluble potassium aluminosilicate when heated to 1000°. The fluxing of mica with clays and related materials has been examined by R. Rieke, R. T. Stull, and H. Ries. The **softening temperatures** of mixtures of muscovite and orthoclase were determined by A. S. Watts; and of mixtures of china clay and muscovite by R. Rieke.

The **index of refraction** varies considerably for each kind of mica. That of muscovite was found by M. Bauer, C. Viola, B. Hecht, R. Scharizer, etc. F. Kohlrausch gave for Na-light, $\alpha=1.5609$, $\beta=1.5941$, and $\gamma=1.5997$; A. Matthiessen, $\alpha=1.5692$, $\beta=1.6049$, and $\gamma=1.6117$; and C. Pulfrich, $\alpha=1.5601$, $\beta=1.5936$, and $\gamma=1.5997$. The last-named found for Li-light, $\alpha=1.5666$, $\beta=1.5899$, and $\gamma=1.5943$; and for Tl-light, $\alpha=1.5635$, $\beta=1.5967$, and $\gamma=1.6005$. R. Scharizer gave for lepidolite, $\beta=1.5975$ and $\gamma=1.6047$; but B. Hecht doubted if these values were accurate. A. Michel-Lévy and A. Lacroix gave for phlogopite, $\alpha=1.562$, $\beta=1.606$. H. Rosenbusch and E. A. Wülfing found the index of refraction of biotite increased with the iron content. G. Linck found $\alpha=1.504$, $\beta=1.589$, and $\gamma=1.589$. F. Kohlrausch, and K. Zimanyi obtained values for α ranging from 1.5412–1.586, and for γ , from 1.5745–1.6032. The **birefringence** is strong for all kinds of mica; that of muscovite is $\gamma-\alpha=0.0392$, $\gamma-\beta=0.0061$, and $\beta-\alpha=0.0338$; that of lepidolite is large and negative; and that of biotite $\gamma-\beta$ is almost zero; and $\gamma-\alpha$, increasing with the percentage of iron, attains to 0.06. Mica in general is optically negative. The optical properties of mica were also described by S. Tsuboi, F. W. Clark and W. F. Hunt, H. Backlund, A. Laitakari, etc. J. Chaudier found the electric birefringence of mica particles suspended in water to be 0.40, and the optical birefringence, 0.04. P. N. Ghosh investigated the laminar diffraction of mica; and C. F. Meyer and D. W. Bronk, the ultra-red spectrum.

The **pleochroism** of biotite is very strong especially with the deeper coloured varieties. This has been studied by K. Toborffy,¹⁷ G. Tschermak, G. Flink, and A. Lacroix. Muscovite is not generally pleochroic, although M. Bauer found some varieties are pleochroic, and F. Cornu observed the phenomenon with the chromiferous muscovite, fuchsite. Brown micas, cordierite, and some other minerals have certain small circular spots when viewed in section. The spots are called **pleochroic haloes**. These haloes are invariably associated with a minute, centrally-placed crystal of zircon or apatite. The medium in which the halo occurs with biotite is pleochroic, but the pleochroic properties are intensified in the halo. The halo disappears when the mineral is heated, hence it was once thought to be produced by organic matter; but the haloes are really spherical, and it is doubtful if the diffusion of colouring matter would proceed at an equal rate across and along the cleavage of a mineral like mica. J. Joly showed that there is an exact correspondence between the radius of the halo and the distance which the α -particles of radium would penetrate before the ionizing properties would disappear. The maximum diameter of the haloes is 0.05 mm.; the average 0.04 mm. Hence, J. Joly infers that the halo is produced by the radioactivity of a central radioactive substance. This is confirmed by O. Mügge, and G. Hövermann. M. Weber examined the effect of the pleochroic haloes of mica and cordierite on zircon.

W. W. Coblenz found that the **ultra-red transmission spectrum** of the micas showed no deep wide absorption bands at 3μ , characteristic of hydroxyl groups. Muscovite gave a deep narrow band at 2.85μ , and smaller bands at 1.9, 3.6, 5.6, 5.9, 6.3, and 7.1μ ; while biotite has small bands at 2.8, 5.9, 6.2, and 6.7μ , and indications of bands at 5.6 and 7.8μ . It has also one in the visible spectrum. Both micas have an opaque region from 9–11 μ , a transparent region at 12 μ , and again complete opacity. The spectrum energy curves were studied by E. F. Nichols and W. W. Coblenz, and G. W. Stewart. Metallic reflection bands were found

by H. Rubens and E. F. Nichols at 8.32 , 9.38 , 18.40 , and 21.25μ , so that the bands located by reflection and transmission do not coincide. W. W. Coblenz found reflection bands in the **ultra-red reflection spectrum** of muscovite at 9.2 , 9.7 , and 10.2μ . H. Rosenthal also failed to observe a reflection band at 8.32 . W. W. Coblenz found maxima with biotite at 9.3 , 9.6 , and 9.85μ . The reflecting power of the micas is comparable with that of the silicates. The positions of the maxima are variable, presumably owing to variations in the composition of the mineral. P. Iles, and J. Königsberger studied the relation between the absorption of light and the colour of biotite. L. C. Martin, and S. L. Brown measured the transparency of biotite for the ultra-red rays. The **flame spectra** of micas were studied by W. Vernadsky and B. A. Lindener; and the grating spectrum by B. Davis and H. M. Terrill.

W. Vernadsky found muscovite and biotite to exhibit **triboluminescence**. C. Doelter found **radium radiations** have no action on muscovite, and they do not make biotite luminesce. C. Doelter also said that muscovite and biotite are not very transparent to **X-rays**, but thin layers 0.5 mm. thick are transparent; Singalese biotite was almost opaque; and a very ferruginous black biotite was opaque. The ratio of the transparency of phlogopite to that of tinfoil was as $1:20$ when the ratio with the diamond is as $1:300$ or as $1:425$. Biotite is not radioactive when free from radioactive impurities.

J. Curie found the **electrical conductivity** increased with the temp. C. Doelter obtained a very small value for the conductivity at 1100° , but it increased in value beyond this temp. The conductivity at 1200° is small but measurable. Hence, mica is a good insulator at temp. below 1100° . W. H. Schultze found that sheets of mica split along the plane of cleavage resemble glass in improving in conductivity as the temp. rises, and also in a maximum conductivity being obtained at about 300° , after which further increase in the temp. causes a diminution in conductivity. Mica is a better insulator than glass. Measurements of the electrical conductivity were made by H. H. Poole, and E. Branly. A. L. Williams and J. C. McLennan, and K. R. Ramanathan measured the resistance of fused mixtures of mica and copper or iron. E. Wilson studied the magnetic susceptibility. E. and W. H. Wilson and T. Mitchell found the sp. resistance varied from $0.44\text{--}133.0 \times 10^{-12}$ ohms per cm. cube. The electrical resistance of mica has been studied by O. N. Rood. A. Klautzsch found the sp. resistance of a number of samples to vary from $700\text{--}1200$ megohms—one sample had a sp. resistance of 380 megohms. The breakdown voltage of plates from $0.12\text{--}0.25$ mm. in thickness varied from $10,000\text{--}18,000$ volts.

E. Bouty found the **dielectric constant** to be $7.98\text{--}8.43$; E. Mattenklodt, $7.1\text{--}7.7$; H. Starke, $5.8\text{--}6.62$, and A. Elsass, $5.66\text{--}5.97$. The different micas have different values, particularly those with a varying proportion of water. E. Mattenklodt found the value to be independent of the field strength, and of the temp.—at least the temp. coeff. is less than 0.0000033 . J. Curie obtained 8.0 for

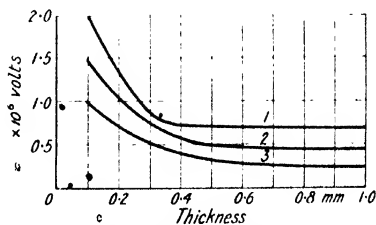

FIG. 134. - Dielectric Strength of Mica of Varying Thickness.

Some results for (1) Bengal ruby mica, (2) Canadian amber mica, and (3) Madras green spotted mica of different thicknesses, are shown in Fig. 134. They found that the specific inductive capacity of some samples of mica varied

from 2.5–5.9 for thickness ranging from 1.22–5.0 mm. This subject has been further studied by J. Hardén, E. Schott, W. S. Flight, J. R. Weeks, H. H. Poole, H. J. MacLeod, D. W. Dye and L. W. Hartshorn, F. Grunewald, and C. W. Jefferson and A. H. Dyer. The deleterious effects of oil on the insulating properties of mica have been discussed by F. Droui. T. O. Maloney found that a piece of mica which withstood 16,000 volts alternating current resisted but 9000 volts after the surface had been lightly coated with paraffin oil; under similar conditions, the breakdown voltage of another sample changed from 8000 to 4000 volts. Mica is accordingly used for interposing between the segments of the commutators of dynamos. The amber-mica of Canada, and the lepidolite of India are used for this purpose; muscovite, with its higher dielectric strength, is not considered so good for the purpose on account of its greater hardness.

A. Brun¹⁸ found that mica yields carbon dioxide, hydrocarbons, hydrogen, and nitrogen when heated—*vide supra*. I. Langmuir discussed the adsorption of gases on the surface of mica. According to A. Kennigott, moistened and powdered muscovite or biotite gives an alkaline reaction with litmus; after calcination, the reaction is feeble. With many biotites the reaction is very pronounced. E. W. Hoffmann made some faulty observations on the action of water on muscovite and biotite. A. Johnstone showed that the micas are hydrated by exposure to the action of pure carbonated waters for a year; muscovite appeared to be insoluble. T. Biéler-Chatelan found that 0.48 per cent. of potash was dissolved from muscovite by distilled water; 1.05 per cent. by peat water; 1.02 per cent. by a soln. of **calcium sulphate**; 1.55 per cent. by a soln. of **ammonium sulphate**; 1.76 per cent. by a soln. of **calcium hydroxide**; 2.24 per cent. by a soln. of **calcium monophosphate**; and 1.85 per cent. by a one per cent. soln. of **citric acid**. He also showed that the roots of some plants can assimilate the potassium from white mica in soils. E. C. Sullivan observed basic exchange occurs when muscovite and biotite are treated with a soln. of **cupric sulphate**. A. Johnstone found that biotite lost magnesia and iron when treated with **carbonic acid**. F. W. Clarke, and G. Steiger observed distinct evidence of dissolution when micas are treated with an aq. soln. of carbon dioxide; and C. Matignon and G. Marchal examined the corrosive action of water on mica in the presence of carbon dioxide under 10 atm. press. for 3 years. E. Raymond studied the action of **chlorine** and of **hydrogen chloride** on biotite and lepidolite. T. Biéler-Chatelan found that cold conc. **hydrochloric acid** contained 2.90 per cent. of potash after it had been allowed to stand in contact with muscovite. M. U. Hollrung, H. Lotz, and A. Breithaupt studied the action of hydrochloric acid on various types of biotite. F. Malt found that after a day's digestion with hydrochloric acid, doubly refracting plates of silicic acid were formed; and with 20 per cent. **hydrofluoric acid**, all the silica was removed and tabular crystals containing aluminium, ferric, and magnesium fluorides remained. W. B. Schmidt found that **sulphurous acid** dissolved some magnesia mica. J. W. Mellor found that an hour's treatment of fine- and coarse-grained mica of the respective average grain-size 0.087 and 0.040 mm., with **sulphuric acid** decomposed respectively 54.94 and 55.56 per cent. of muscovite; 67.94 and 70.02 per cent. of lepidolite; 71.07 and 92.50 per cent. of biotite; and 88.00 and 93.93 per cent. of phlogopite. H. Lotz studied the effect of air charged with **sulphur dioxide** on biotite and muscovite. C. and G. Friedel found that by treatment with aq. reagents—**potassium silicate**, **sodium hydroxide**, **sodium chloride**, and **sodium sulphate**—muscovite can be transformed into nephelite, sodalite, leucite, orthoclase, or anorthite. F. W. Clarke and G. Steiger studied the action of **ammonium chloride** on the magnesia micas.

Muscovite under ordinary conditions is not readily affected by atm. influences; witness, the felspar of granite may be completely kaolinized while the mica retains its pristine lustre. On the other hand, biotite, and phlogopite are readily transformed, the alkaline metals are replaced by hydrogen, and the products are hydrated, thus forming more or less indefinite substances called vermiculites and chlorites.

The weathering of biotite and phlogopite has been studied by G. Tschermak, J. D. Dana, C. F. Rammelsberg, G. A. Kenngott, E. Zschimmer, K. D. Glinka, F. Rinne, O. Dreibrod, H. Rosenbusch, J. R. Blum, W. Haidinger, C. R. van Hise, G. W. Leighton, etc.

Crystals of a mineral from the Pini mine, Aue, Schneeberg, were described by C. A. S. Hofmann,¹⁹ and M. H. Klaproth. It was named *pinitite* by D. L. G. Karsten. The alteration products of a number of aluminosilicates correspond more or less closely in composition to muscovite, and they have been grouped as *pinites*. The pinites are considered to be a massive compact muscovite mixed with more or less clay, etc. Massive amorphous pinitite with a compact texture is a part of the so-called *agalmatolite*—from *ἀγαλμα*, an image—from China. This name was applied by M. H. Klaproth;²⁰ and C. A. G. Napione called it *pagodite*—from *pagoda*. The Chinese carve the soft stone into miniature pagodas, images, etc. Part of the Chinese agalmatolite is a compact pyrophyllite, and part is a steatite. L. J. Igelstrom found at Langban, Sweden, pseudomorphs of a pinitite after iolite; he named the mineral *cataspinitite*—from *κατασπινδῆναι*, to spot or stain—in allusion to its mode of occurrence. C. U. Shepard found a mineral which he named *dysyntribite*—from *δύς*, bad; and *συντριβή*, to pulverize—at Diana, N.Y. T. S. Hunt made some observations on the minerals. J. L. Smith and G. J. Brush analyzed the mineral. Dysyntribite resembled the mineral *gieseckite*, brought by Giesecke from Akulliarssuk and Kangerluarsuk, Greenland; and named by T. Allan, who examined the crystals. It occurs associated with felspar. Observations on gieseckite were made by F. Strömeeyer, L. W. Gilbert, C. C. von Leonhard, H. Rosenbusch, G. J. Brush, A. Breithaupt, F. Mohr, E. F. Glocker, C. H. Pfaff, J. R. Blum, C. G. C. Bischof, A. des Cloizeaux, W. Phillips, etc. A. E. Nordenskjöld reported a related mineral, which he named *gigantolite*, from the size of the crystals. It occurred in the gneissoid granite of Tammela, Finland. It was discussed by W. Haidinger, M. F. Heddle, A. Wichmann, F. J. Wiik, F. Zirkel, J. C. G. de Marignac, A. E. Nordenskjöld, J. R. Blum, and A. Lacroix. Gigantolite is derived from cordierite and resembles the mineral *iberite* obtained by L. F. Svanberg from Montalvan, Spain. Observations on the mineral were made by J. R. Blum, W. Haidinger, F. Zirkel, A. Wichmann, A. Lacroix, M. F. Heddle, F. J. Wiik, etc. A. F. Thoreld described a mineral which was found in the talcose schist at Kimsamo, Finland. It was called *gongylite*—from *γογγύλος*, round—and it is a kind of pinitite. A. E. Nordenskjöld made some observations on this mineral. H. Laspeyres described a pinitite-like substance in the felspar at Halle a. d. Saale; he called it *hydriphylite*—from *ὕψος*, moist; *φύλος*, friend. F. Sandberger made some observations on a sample from Eaden. F. A. Genth's *kerrite*—named after H. L. Kerr—is a decomposition product of chlorite from Macon, North Carolina. T. Thomson reported a pseudomorph after spodumene at Killeny Bay, Ireland. He called it *killenite*. It has been described by R. P. Greg and W. G. Lettsom, A. Julien, W. Galbraith, C. F. Rammelsberg, C. Dewey, etc. J. C. G. de Marignac obtained a pinitite-like substance in the porphyritic feldspathic rock at Mt. Viesena, Fleinusthel; he called it *liebenite*—after L. Lieben. Observations were made by W. Haidinger, J. Oellacher, G. A. Kenngott, C. von Hauer, A. des Cloizeaux, J. Lemberg, J. R. Blum, F. Zirkel, H. Rosenbusch, F. von Richthofen, J. Heinemann, etc. D. L. G. Karsten found an altered nephelite in the syenite of Fredriksvärn and Laurvik; it was called *lythrodite*—from *λύθρον*, with blood and dust; and *εἶδος*, appearance—and analyzed by J. F. John. J. F. L. Hausmann called it *vernerite*. The *maconite* of F. A. Genth is regarded as a variety of joffersonite from Macon, North Carolina, and, like hermite, it is a decomposition product of chlorite. The *micarelle* of J. C. Froiselen is a pinitite found near Stolpen, Neustadt. A. Wichmann said that it is not a pseudomorph after iolite. Several different substances have been called *micarell* or *micarelle*—R. Kirwan, W. Haidinger, J. R. Blum, J. F. Hausmann, H. D. A. Ficinus, R. J. Haiy, A. Estner, A. des Cloizeaux, J. D. Dana, etc. A pinitite-like mineral was found by C. M. Marx in the Ode Valley, Baden, and named *oorite*. It was also described by J. R. Blum, F. Sandberger, and W. Haidinger. A mineral resembling dysyntribite was found by T. S. Hunt in several parts of Canada; he called it *paraphite*. Another mineral from Saxony resembling dysyntribite was called *pinitoid*, by A. Knop. It was further discussed by E. Cohen, C. W. von Gümbell, A. Hilger, and J. R. Blum. Reddish masses of a pinitite-like substance occurring at Tunaberg, Sweden, were called by L. F. Svanberg *polyargite*—from *πολύς*, much; *ἀργός*, sparkle. The mineral was investigated by L. Palmgren, A. des Cloizeaux, and A. Ertmann. According to A. des Cloizeaux, the name *pyrrholite* was applied to a mineral very similar to polyargite, and from the same locality. L. F. Svanberg also described a granular red mineral from Åker in Södermanland; it was called *raunte*. G. Rose regarded it as an altered anorthite. F. W. Clarke gave it the formula $H(MgOH) \cdot \frac{1}{3} SiO_4 - Al = (SiO_4)_4 = (AlOH)_1 + 2H_2O$. The mineral named *tererite* by E. Emmons is a pinitite-like substance which has been likened to scapolite. T. S. Hunt's *wilsonite* from Bathurst, Canada, was considered to be a variety of gieseckite; but E. J. Chapman found it closely resembled scapolite. Several alteration products of biotite are indicated in connection with the varieties of biotite.

The uses of mica.—H. A. Miers²¹ described the use of fuschsite as a decorative

stone by the ancients; and M. Bauer, its use in making prehistoric implements in Guatemala. The most important use of mica is in the electrical industry as an insulator. It is one of the best of insulators because of its resistance to puncture, pre-resisting qualities, impermeability to moisture, toughness, elasticity, and flexibility; and its cleavage into thin sheets. It is largely used for insulating the segments of commutators, armature wires and bars, etc. Scrap mica is made into sheets, plates, and boards by means of a suitable bonding agent—say, shellac—and under the commercial name *micanite*, is used for making washers, etc., for insulating lamp-sockets, fuse-blocks, cut-out boxes, etc. Sheet mica is used for lanterns and windows where glass does not withstand the shocks and vibrations; for spectacles to protect the eyes of metal and stone workers from chips, etc. It is also used in place of glass where abrupt changes of temp. would be liable to crack glass—e.g. fire-screens, stove windows, lamp-chimneys, and some miners' lamps. Special sparking plugs for aeroplanes, etc., are built up from sheet mica. It is employed as a heat insulator in the lagging of steam-pipes, boilers, etc. It is used as a sound-ing-diaphragm in telephones, gramophones, etc. It is used as an absorbent for nitroglycerol; and as a heavy lubricant. Mica is used in making wall-paper pigments; and various ornamental purposes—a mixture of gum arabic and ground white mica makes the so-called *silver ink*; and it is employed for inlaying buttons, in making lustrous hair-powder, and in making the bronze-like colours which bear the name *brocades*, *crystal colours*, *mica-bronzes*, etc.; and in making frosted effects in decoration.

K. C. Fielder²² described a mineral from the Urals as a *chlorite spar*, from its resemblance to chlorite; G. Rose, and A. Breithaupt called it **chloritoid**; E. F. Glocker, *barytophyllite*—from *βαρύς*, heavy; and *φύλλον*, a leaf; C. T. Jackson applied the term *masonite*—in honour of O. Mason—to a dark greyish-green mineral from Rhode Island, which M. R. Whitney, and G. A. Kenngott proved to be identical with chloritoid. A. E. Delesse named a mineral from St. Marcel, Zermatt, and Piedmont *sismondine*—in honour of A. Sismonda—and hence called *sismondite*. A. Brezina reported a mineral from St. Marcel which he called *strüverite*—named in honour of G. Strüver. G. Tschermak showed that *strüverite* and *sismondite* are identical; J. F. L. Hausmann, that *sismondite* is closely related to chloritoid; and F. von Kobell, that *sismondite*, *masonite*, and *chloritoid* are the same mineral species. T. Thomson described a mineral from Sterling, Mass., and called it *phyllite*; it had previously been called spangled mica slate by E. Hitchcock. A similar mineral from Newport, Rhode Island, was called *newportite* by C. U. Shepard. In 1821, C. C. von Leonhard mentioned a mineral brought from Ottreux, Ardennes; it was described by A. des Cloizeaux and A. Damour, and named *ottrelite*. This mineral was mentioned by R. J. Haüy. The resemblances between *phyllite*, *ottrelite*, and *chloritoid* were emphasized by T. S. Hunt, J. D. Dana, A. des Cloizeaux, G. Tschermak, and A. Lacroix. A manganiferous variety was called *salmite* by E. Prost; a variety from Venasque, Pyrenees, was called *venasquite*, by A. Damour; and a variety from Schmalenberg was called *brunsvigite*, by J. Fromme.

Attempts to devise formulæ from chemical analyses were made by C. F. Rammelsberg. C. Klement gave $H_2(Fe, Mn, Mg)(Al, Fe)_2Si_2O_9$; and P. Groth gave $H_2(Fe, Mg)Al_2SiO_7$ for chloritoid, and $H_2(Fe, Mn)(Al, Fe)_2Si_2O_9$ for ottrelite. The subject was discussed by E. Manasse, and P. Niggli. G. Tschermak regarded the minerals as isomorphous mixtures of two silicates. F. W. Clarke co-relates the constitution of chloritoid to xanthophyllite and seyberville through the formulæ:

This makes idealized chloritoid a **ferrous pentaluminoxy-aluminotriortho-**

silicate, and idealized ottrelite a **ferrous pentaluminoxy-aluminotrimetrasilicate**. The manganese oxide in ottrelite varies from 0.9 per cent. The colour of these minerals is dark grey, or greenish-black. The crystals of chloritoid occur in rosettes, or foliated masses. The tabular crystals of chloritoid rarely occur distinct; they are either monoclinic or triclinic; they have been investigated by G. Tschermak, F. Becke, H. von Foullon, A. Barrois, and A. des Cloizeaux. Ottrelite also furnishes either monoclinic or triclinic crystals, which have been studied by A. des Cloizeaux, A. Renard and C. L. J. X. de la Vallée-Poussin, H. Rosenbusch, and A. Lacroix. The basal cleavage is less perfect than is the case with the micas; the laminae are brittle. Twinning is as common as with the micas; the crystals are oriented as though rotated 120° to one another. A zonal structure is sometimes developed; and inclusions are common. The optic axial angle of chloritoid is $2V = 45^\circ - 55^\circ$, according to A. Barrois, and $2E = 65^\circ - 70^\circ$, according to A. von Lasaulx. A. des Cloizeaux found for different samples of sismondite, $2H = 64^\circ 31' - 74^\circ 6'$ for red glass, and $57^\circ - 65^\circ 38'$ for green glass; and $2E = 111^\circ 50' - 117^\circ 48'$ for red glass, and $103^\circ 40' - 108^\circ 44'$ for green glass. The values for ottrelite vary considerably from sample to sample. The sp. gr. is 3.53-3.55; and the hardness 5-6. H. Rosenbusch found the index of refraction is high, about 1.78—A. Lacroix gave 1.78; A. C. Lane, 1.75; and A. Duparc and L. Mrazec, 1.77. The birefringence is feeble. A. Lacroix gave $\gamma - \alpha = 0.015$. Chloritoid and ottrelite are optically positive. W. W. Coblenz found chloritoid to be rather opaque to the ultra-red rays; in the ultra-red transmission spectrum the water-bands 1.5μ and 3μ are absent; while there are small bands at 2.3μ , 2.6μ , 3.3μ , 5μ , 6μ , and 6.3μ . The pleochroism of chloritoid is strong, $a =$ yellowish green; b , indigo-blue; c , olive-green. The pleochroism of ottrelite, said A. des Cloizeaux, is not so marked as with chloritoid. Finely powdered chloritoid is decomposed by sulphuric, nitric, and hydrochloric acids with the separation of gelatinous silica.

The term **chlorite** is a family name for a group of minerals closely related to the micas; they are more basic and more hydrated than the micas, and virtually free from alkalies. If alkalies are present, the chlorite is assumed to be mixed with some mica. The name— from $\chi\lambda\omega\rho\acute{\iota}\varsigma$, green— emphasizes the green colour so common with these minerals. Pliny, in his *Historia naturalis* (37. 56), refers to the grass-green *chloritis*. A. G. Werner²³ applied the term *blattrüper chlorite*, or *chlorites lamellosus*, to a hexagonal mineral from St. Gothard. D. L. G. Karsten, L. A. Emmertling, and A. Estner described several different kinds of lamellar chlorites. The minerals were analyzed by J. G. A. Hopfner, L. N. Vauquelin, and W. A. Lampadius. The minerals were regarded by R. J. Haüy, C. C. von Leonhard, and A. Cronstedt as *variétés de l'espèce talc*; but F. von Kobell showed that chlorite contains too much water for a talc. He further found that the chlorites then known were varieties of two species—one, *chlorite*, contained 25-27 per cent. of silica, and was typified by that from St. Gothard; and the other, *ripidolite*—from $\rho\acute{\iota}\rho\acute{\iota}\varsigma$, a fan; and $\lambda\acute{\iota}\theta\omicron\varsigma$, a stone, in allusion to its occurrence in fan-like aggregates—contained 30-33 per cent. of silica, and was typified by that from Achmatovsk. G. Rose unfortunately reversed these terms, and introduced some confusion in the nomenclature. J. D. Dana suggested keeping the term *chlorite* for the whole family; calling the original chlorite *prochlorite*—from $\pi\rho\acute{o}$, before; dropping the equivocal term *ripidolite*, and using *clinocllore* in its place— $\kappa\lambda\acute{\iota}\nu\epsilon\iota\lambda\omicron$, to incline—in allusion to the unequal inclination of two of the optic axes to the principal axis. The latter term had been applied by W. P. Blake to a chloritic mineral from Westchester, Penn., which W. J. Crawford proved to be identical with the chlorite from Achmatovsk. This subject was discussed by N. von Kokscharoff, and F. Hessenberg. J. Orcl proposed to call the ferruginous prochlorites *ripidolites* when the ratio $MgO : FeO$ is 3 or less, and the birefringence is 0.0001-0.005; and the magnesian prochlorites *grochaultes* when the ratio $MgO : FeO$ is about 10, and the birefringence is about 0.01.

The chlorites are hydrated magnesium or ferrous aluminosilicates or ferrisilicates. They resemble the micas crystallographically, and in their scaly or foliated habit.

Each member of the series exhibits some variation in composition. Hence, like the ferromagnesian micas, they are often regarded as isomorphous mixtures. In his memoir: *Die Chloritgruppe* (Wien, 1891), G. Tschermak²⁴ called those chlorites which ordinarily occur in distinct crystals or plates, *orthochlorites*; and those which commonly occur in fine scales, or indistinctly fibrous forms, *leptochlorites*. According to K. Dalmer, the orthochlorites lose part of their water at 550°–570°, and part at bright redness; while the leptochlorites lose part at 440°–500°, and part at 580°–600°. Hence he argued that the intrinsic nature of the two series is different. The following lists include most of the chlorites which have received a name; but too much reliance must not be placed on the classification since too little is known about some of them. A list of unclassified chlorites is also appended. The summaries of the analyses represented by the formulæ are mainly due to G. Tschermak.

Orthochlorites.—The ordinary variety of *clinocllore*, $H_2(Mg,Fe)_2Al_2Si_2O_{10}$, is green or bluish-green, and it occurs in crystals, massive and foliated. Analyses were made by G. Tschermak,²⁵ V. Iskyul, and others. V. Iskyul examined the action of hydrochloric acid on the mineral. A. Hamberg obtained a sample from Pajsberg, Sweden, with 2.3 per cent. of MnO; he called it *manganochlorite*. P. von Jeffreynoff²⁶ named a variety of clinocllore from Zlatoust, Ural, *leuchtenbergit*—after N. von Leuchtenberg—which may be white, pale-green, or yellowish. Analyses were made by N. von Leuchtenberg, etc. The crystals were examined by G. A. Kenngott, F. C. Calkins, E. V. Shannon, and A. des Cloizeaux. V. Iskyul examined the action of hydrochloric acid on the mineral. N. von Kokscharoff²⁷ named a variety of clinocllore from Ufaleisk, Ural, *kotschubeite*—after P. A. von Kochubei. Analyses were made by N. von Leuchtenberg, etc. A chlorite from the Pennine Alps was called *pennine*—*penninite*—by J. Fröbel and E. Schweizer.²⁸ L. A. Necker called it *hydrotalc*. The crystals were described by J. C. G. de Marignac; the effect of temp. on the pleochroism, by O. Nagaoka; and the action of hydrochloric acid, by V. Iskyul. Analyses were made by G. Tschermak, etc. A reddish chromiferous variety of penninite occurring near Miask, Ural, was called by N. von Nordenskjöld,²⁹ *kammererite*—after A. Kämmerer. Analyses were made by R. Hermann, etc. F. Tucan represented the composition by $(Cr,Al)_2Si_4O_{22}Mg_4H_{10}$. A variety obtained by K. G. Fiedler, from Tenos, Greece, and by G. Rose from the Ural, was called *rhodochrome*—from *ῥόδον*, rose; and *χρῆμα*, colour. V. Iskyul found it to be related to the metasilicates. A variety from Texas, etc., was called *chromochlorite* by R. Hermann, and *rhodophyllite*—from *ῥόδον*, rose; and *φύλλον*, a leaf—by F. A. Genth. E. V. Shannon also described a chromiferous chlorite. F. Pearson found a green variety of *kämmererite* at Texas which he named *grasite*—from *γρᾶσις*, grass. H. Vogelsang proposed the general term *viridite* for all the intermediate green compounds of secondary origin observed in rocks, and it may include different chlorites and serpentine. The viridites were discussed by E. Dathe, and H. Rosenbusch. G. A. Kenngott³⁰ described a compact massive form of penninite from Berg Zdjär, Moravia, which he named *pseudopite*—*ψευδοίς*, false; *ophite*, serpentine—on account of its resemblance to serpentine. Analyses were made by G. A. Kenngott, L. van Werweke, H. Stadlinger, R. von Drasche, W. E. Gintl, E. Cohen, etc. Analogous substances were described by V. Wartha, and V. von Zepharovich. T. S. Hunt's *loganite* is very like pseudopite. A. G. Werner³¹ described a *blue talc* or *mica chlorite* which was shown by T. Scheerer to be a bluish-green or green penninite like that he obtained from Taberg, Sweden, and called *tabergite*. A. des Cloizeaux studied the crystals, and G. Tschermak analyzed the mineral which he regarded as a mixture of phlogopite and clinocllore. V. Iskyul studied the action of hydrochloric acid on the mineral.

The *prochlorite*, $H_2(Fe,Mg)_{2.5}Al_4Si_{1.5}O_{10}$, of J. D. Dana,³² and the chlorite of earlier observers was analyzed by A. J. Egger, etc. V. Iskyul studied the action of hydrochloric acid on prochlorite. G. H. O. Volger³³ described a prochlorite in slender vermiform crystals, hence the name *helminthe*—from *ἕλμιν*, a worm. M. Websky found crystals of a mineral which he called *grochauite* in cavities in the serpentine of Grochau, Silesia. It was studied by M. Bock; and shown by G. Tschermak to be prochlorite. C. U. Shepard's *lepidochlorite*—from *λεπίς*, a scale—is an impure chlorite from Mount Pisgah, Tennessee. A. Breithaupt's *lophoite*—from *λόφος*, a cook's comb—a name applied in allusion to the form of the crystal aggregates, is considered to be a chlorite; a similar remark applies to his *onkoite* or *ongite*—from *ὄγκω*, swollen. G. W. von Gümbel's *phylochlorite* is a ferruginous chlorite. Both *kerrite*, and *maconite* previously cited are sometimes classed with these chlorites. I. Lea described under the name *pattersonite* a micaceous chlorite from Unionville, Pennsylvania, which was analyzed by S. P. Sharples and F. A. Genth. According to M. F. Heddle, the *talc-chlorite* of J. C. G. de Marignac is a mixture of clinocllore and talc. The crystals were examined by A. des Cloizeaux.

E. V. Shannon and E. T. Wherry³⁴ class *coterainite* and *sherdanite* as *white chlorites*.

The former was reported by E. M. Pôitevin and R. P. D. Graham in minute hexagonal crystals with the composition $4\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 5\text{H}_2\text{O}$; the sp. gr. was 2.44–2.51; the hardness, 2½–3; the optical character was positive; and the refractive index 1.56. It occurs in the asbestos mines of Quebec. Sheridanite was found by J. E. Wolff in Sheridan Co., Wyoming, as a pale silvery-green talc-like mineral with a composition $\text{H}_2\text{Mg}_3\text{Al}_2\text{Si}_2\text{O}_{11}$. Very little water is expelled at 350°. The refractive indices are $\alpha=1.580$; $\beta=1.580$ –1.581; and $\gamma=1.589$; the optical axial angle $2E=26^\circ$ – 50° ; and the optical character is positive. The mineral is slowly decomposed by boiling sulphuric acid, and with difficulty by hydrochloric acid.

C. U. Shepard³⁵ applied the term *corundophilite*, $\text{H}_{10}(\text{Mg},\text{Fe})_{11}\text{Al}_2\text{Si}_2\text{O}_{48}$ —from *φλος*, a friend—to a chlorite occurring in the corundum of Asheville, North Carolina. J. P. Cooke showed it to be a variety of clinocllore. It was analyzed by F. Pisani, and E. V. Shannon. V. Iskyul studied the action of hydrochloric acid on the mineral. C. U. Shepard found a chlorite in the diasporite at Chester, Mass., which he called *amcelite*. It was analyzed by E. V. Shannon, F. Pisani, G. Ponte, and G. Tschermak; and shown by G. A. Kennigott to be a chlorite. G. Tschermak represented its composition by the formula: $\text{H}_4(\text{Mg},\text{Fe})_2\text{Al}_2\text{SiO}_4$; E. V. Shannon, by $2(\text{Fe},\text{Mg})\text{O} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2 \cdot 2\text{H}_2\text{O}$. The optical properties were studied by E. V. Shannon.

Leptochlorites.—G. Tschermak³⁶ found lamellar crystals of a chlorite associated with the arsenical pyrites and quartz of Penzance, Cornwall. He called it *daphnite*, $\text{H}_{16}\text{Fe}_2\text{Al}_{10}\text{Si}_4\text{O}_{111}$ —from *δαφνίς*, the bay-berry—in allusion to the aggregation of the crystals. The crystals are probably monoclinic. E. Gueymard³⁷ referred to *mine de fer oxydé en grains agglutinés*, and P. Berthier to *un minéral de fer grains*, which he named *chamosite* from the locality, Chamoson, Switzerland, where it occurred. B. Studer altered the name to *chamosite*. P. Berthier found that the iron ore at Hayanges, Moselle, contained calcium and ferrous carbonates and a silicate. The silicate was named *berthierine* by F. S. Beudant. J. J. N. Huot called the oolitic chlorites described by E. le Pouillon de Boblaye, *baralite*, or *baralutite*; and P. A. Dufrénoy proposed to designate all these related substances by the term *chamosite*. Analyses, etc., were made by E. Boricky, H. Loretz, C. Schmidt, J. Orcel, etc. These minerals were supposed to be mixed hydrogels of alumina, silica, and ferric oxide,³⁸ together with some impurities. G. Tschermak³⁹ described aggregates of lamellar crystals from Elbingerode, Harz, which he named *metachlorite*. Similar crystals had been previously noted by C. List, and G. Sillem. C. Klement described a chlorite from Vielsalm, Belgium, which G. Tschermak named *klementite*. A. von Lasaulx⁴⁰ reported a blue earthy mineral from the Pyrenees which he called *acerinite*. Its sp. gr. was 3.018, and hardness 3–4. A. des Cloizeaux showed it to be heterogeneous and not to be regarded as a definite mineral. Analyses were made by C. F. Rammelsberg, J. Macpherson, and J. Orcel. The last-named studied a mineral he also called *acerinite* from Casserras, Aragon; its composition was $1.5\text{CaO} \cdot (\text{Fe},\text{Mg})\text{O} \cdot 2(\text{Al},\text{Fe})\text{O}_2 \cdot 6\text{SiO}_2 \cdot 7\text{H}_2\text{O} + 3\text{H}_2\text{O}$; and he regarded it as a new type of leptochlorite. A. Breithaupt⁴¹ described a compact aggregate of minute scales of a chlorite from Saalfeld, Thuringia, which he named *thuringite*, $\text{H}_4\text{Fe}_3(\text{Al},\text{Fe})_2\text{Si}_2\text{O}_{11}$, and apparently the same mineral from Harper's Ferry, Virginia, was named by F. A. Genth *oculite*—after D. D. Owen. Analyses were reported by G. Tschermak, L. Slavikova and F. Slavik, J. L. Smith, P. Keyser, V. von Zepharovitch, S. L. Penfield and F. L. Sperry, H. Loretz, E. S. Larsen and G. Steiger, etc. The last-named found for the indices of refraction $\alpha=1.595$, $\beta=1.61$, and $\gamma=1.65$. C. Simmonds found that the reduction of thuringite is complete when heated to redness in hydrogen. F. Kretschmer⁴² obtained a chloritic mineral, resembling thuringite, from Gobitschau, Moravia, and he called it *moravite*. Its composition approximated $\text{H}_4\text{Fe}_3(\text{Al},\text{Fe})_2\text{Si}_2\text{O}_{11}$. Its sp. gr. was 2.38, and hardness 3.5. It was decomposed by hydrochloric acid with the separation of gelatinous silica. According to L. Slavikova and F. Slavik, the refractive index is 1.615. J. Steinman⁴³ described a chloritic mineral from Pribram, Bohemia, which was named *cronstedtite*, $\text{H}_4(\text{Fe},\text{Mg})_3\text{Fe}_2\text{Si}_2\text{O}_{11}$ —after A. Cronstedt. Crystals were examined by V. von Zepharovitch, N. S. Maskelyne, G. Tschermak, and A. des Cloizeaux; and analyses were made by J. Steinman, A. Damour, C. W. Hoadley, R. Kochlin, J. V. Janovsky, G. Tschermak, C. Vrba, F. Field, N. S. Maskelyne, etc. C. Simmonds found reduction is complete when the mineral is heated to redness in hydrogen. A. Breithaupt called a specimen *chloromelane*. The variety from Conghonas do Campo, Brazil, was called *sideronchisolite* by F. Wernicke—*from σίδηρος*, iron; *σχίζω*, to split; and *λίθος*, a stone. Analyses were made by J. F. L. Hausmann, and V. von Zepharovitch. J. F. L. Hausmann showed that it is a variety of cronstedtite.

A chloritic mineral from Eura, Finland, was called *euralite* by F. J. Wiik,⁴⁴ and he suggested that it is related to delossite. E. Becker,⁴⁵ and M. Websky found a chloritic mineral occurring as a coating in druses or cavities in the granite near Striegau, Silesia, and it was named *striegovite*, $\text{H}_4(\text{Fe},\text{Mn})_2(\text{Fe},\text{Al})_2\text{Si}_2\text{O}_{11}$. K. T. Liebe⁴⁶ applied the term *diabantachromyn*—*from χρώμιν*, to colour—to a chloritic mineral occurring in the diabase of Voigtland and Frankenwand, and to which it imparts a green colour. G. A. Kennigott showed that the mineral is a chlorite. G. W. Hawes found a sample at Farmington Hills, Connecticut, and he called it *diabantite*, $\text{H}_{14}(\text{Mg},\text{Fe})_{11}\text{Al}_2\text{Si}_2\text{O}_{48}$. F. Sandberger⁴⁷ found dark olive-green scaly crystals of a soft ferruginous chlorite in a

mine at Weilburg, Nassau. The mineral was called *aphrosiderite*, $H_{10}(Fe,Mg)_2Al_2Si_4O_{21}$ —from *ἀφρός*, foam; and *σίδηρος*, iron. The crystals were examined by G. A. Kenngott, H. Fischer, V. von Zepharovich, F. Slavik and V. Vesely, and E. A. Reuss. Analyses were made by F. Sandberger, F. Nies, M. Websky, G. Woitschache, L. Erlennmeyer, L. J. Igelström, etc. A. E. Delesse⁴⁸ found a fibrous chlorite with a scaly feathery texture as a coating or filling cavities of the porphyry at La Grève in the Vosges; he called it *chlorite ferrugineuse* or *iron-chlorite*, and C. F. Naumann called it *delessite*, $H_{10}(Mg,Fe)Al_2Si_4O_{21}$ —after A. E. Delesse. E. Weiss used the name *delessite* for the varieties—e.g. the La Grève chlorite—containing more ferric oxide and less ferrous oxide, and *subdelessite* for those—e.g. the Friedrichroda chlorite—containing more ferrous oxide and less ferric oxide. Analyses of delessite were made by A. E. Delesse, N. I. Bezborodko, E. Weiss, and M. F. Heddle. C. W. von Gümbel called *das grün färbende Princip der Diabase* of Fichtelgebirge *chloropit*. It was considered to be a variety of delessite or diabantite. P. A. Dufrénoy regarded the chloritic mineral of A. E. Delesse, named *dumasite*, as a variety of delessite. A. Schrauf designated the group of delessitic minerals, *protchlorites*. G. Fritsch⁴⁹ named a basic aluminium and magnesium silicate from St. Michael, Styria, *rumpfite*, $H_2Mg_2Al_2Si_6O_{25}$ —in honour of J. Rumpf. It is a chlorite rich in iron. Analyses were made by K. A. Redlich. G. Tschermak regards it as a relation of leuchtenbergite. The minerals *epiphanite*, *lennite*, and *vaalite*, alteration products of biotite, are considered by G. Tschermak to be chlorites. A. Schrauf groups them as *parachlorites*.

Unclassed chlorites.—There are a few chlorites which were not classed by G. Tschermak. C. F. Rammelsberg and C. Zincken⁵⁰ found a chlorite in the serpentine at Harzburg which they named *epichlorite*. A sample from Voigtland was analyzed by K. T. Liebe. A chloritic mineral from Grängesberg, Sweden, was called *grangéite* by W. Hisinger.⁵¹ The name is sometimes spelt *grengeite*. It was described by G. Suckow, A. Erdmann, A. Lacroix, and H. Heymann. E. T. Hardman found a black chlorite in cavities in the basalt of Carnmoney Hill, Belfast, and he called it *hullite*. M. F. Heddle found a similar mineral in the basalt of Kinkell, Fifeshire. H. Wurtz described a black chloritic mineral from a quarry near Charlestown, Mass. He called it *melanohite*—from *μέλας*, black; and *λίθος*, a stone. E. F. Glocker⁵² described a chloritic mineral from various parts of Silesia which was called *stilpnomelane*—from *στίλπνός*, shining; and *μέλας*, black. The colour is black, greenish-black, yellowish-bronze, or greenish-bronze. C. U. Shepard called a yellowish variety *chalcodite*—from *χαλκός*, brass or bronze. Stilpnomelane and chalcodite have been described by H. Fischer, F. Sandberger, F. Roemer, V. von Zepharovich, J. W. Mallet, G. Gurich, W. C. Brögger, etc. Analyses were made by C. F. Rammelsberg, E. V. Shannon, A. F. Hallimond, K. Sarkany, L. J. Igelström, G. J. Brush, and F. A. Genth. F. F. Grout and G. A. Thiel gave for the sp. gr. 2.882; and for the indices of refraction of stilpnomelane $\alpha=1.546$, $\gamma=1.615$. They found the optic axial angle $2V$ was very small; A. F. Hallimond found for the sp. gr. 2.85; hardness 3 to 3½; $\omega=1.685$, and $\epsilon=1.595$; and a negative optical character. He gave for the composition $K_2O.3(R_2O_3.RO)NiO_2+aq$. According to C. Simmonds, reduction is complete when stilpnomelane is heated to redness in hydrogen.

Some chloritic minerals have not been sufficiently investigated to decide if they really are chlorites. Thus, A. E. Reuss' earthy mineral⁵³ resembling glauconite, from Příbram, Bohemia, which was named *lillite*—named after M. von Lill—and examined by F. Babanek, J. A. Kronner, C. F. Rammelsberg, and A. H. Church. G. A. Koenig's *leidyte*—named after J. Leidy—was considered to be a zeolite; P. Groth classed it with the chlorites. The green *chrysoprass earth* of M. H. Klaproth was named *schuchardite* by A. Schrauf. D. L. G. Karsten called it *pinulite*—from *πινελή*, fatness. It was examined by G. Starkl, and W. Baer. L. J. Igelström described a foliated green to black chloritic mineral from Grythytt, Sweden, which he called *ekmanite*—after G. Ekman. H. Hamberg, and J. Jakob investigated the optical properties of ekmanite. F. Zambonini represented it as a *ferrous manganese trimetasilicate*, $4RO.3SiO_2.3H_2O$. E. E. Schmid described a pale green mineral from cavities in the porphyritic rocks of Höllekopf, etc. It was called *stetavargillite*. Its nature is doubtful. T. Thomson described a blue mineral from Baltimore, and called it *baltimoreite*. It was examined by C. von Hauer, and R. Hermann. A leek-green soft chlorite from Kilpatrick Hills was called *praseite*—from *πράσιος*, leek-green—by T. Thomson. An alteration product of serpentine from Krems, Bohemia, was described by A. Schrauf as *berlaude*. A chlorite occurring in small balls of irregularly arranged fibres was called *tolypite* by A. Uhlenmann. G. Flink obtained a chloritic mineral from Narasak, Greenland, which he called *epidiophyllite*; and A. Mallard, one from Noyant, France, which he called *bravaisite*. J. Samojloff found a lamellar variety of what looked like chlorite but whose chemical composition more nearly resembled clay or pyrophyllite. He called it *α-chlorite*. A. Lacroix obtained a chlorite from Segré, Maine-et-Loire, which he called *minguétite*, and which has a composition intermediate between lepidomelane and stilpnomelane.

The constitution of the chlorites.—C. F. Rammelsberg calculated a number of best representative formulæ from the analyses of various chlorites. The main diffi-

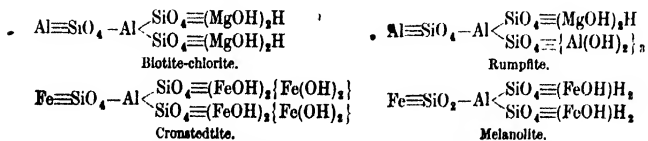

culties associated with work of this kind are due to the heterogeneous nature of the assumed mineral species; to the fact that some are isomorphous mixtures; and to the uncertainty as to the intrinsic or extrinsic nature of the water of hydration. Systems of formulation can therefore be easily carried beyond the range of known facts. The orthochlorites were supposed by G. Tschermak⁵⁴ to be isomorphous mixtures of different proportions of a magnesium silicate, $H_4Mg_3Si_2O_9$, having the same composition as serpentine, and magnesium aluminosilicate, $H_4Mg_2Al_2SiO_9$, which is represented by amesite. In order to explain the composition of the leptochlorites, G. Tschermak found it necessary to invent two other fundamental mols, $H_4Mg_2Al_2Si_2O_{11}$, represented by strigovite, and $H_2MgAl_2SiO_7$, represented by choritoid. By working in this manner, it would be possible to represent the composition of any aluminosilicate. Accordingly, the coincidence of calculated and observed results does not impart much confidence in the truth of the hypothesis; and the question might legitimately be raised whether the chlorites are of any interest to the chemist, however interesting they may be to the mineralogist. If serpentine be a component of the chlorites, and if serpentine on calcination breaks up into water, olivine, and enstatite (insoluble in acids), it follows that the calcination of the magnesium chlorites should furnish about 18 per cent. of enstatite. F. W. Clarke, and C. Doelter and E. Dittler found that actually no enstatite is formed; instead spinel is produced in quantities proportional to the excess of oxygen above that calculated for an orthosilicate. This, regarded as an *experimentum crucis*, makes it highly probable that serpentine mols. are not present in the chlorites, and, as F. W. Clarke puts it, G. Tschermak's hypothesis breaks down. V. Iskyul said that the existing theories as to the nature of the chlorites are based on too little experimental observations.

F. W. Clarke and E. A. Schneider based some formulæ representing the constitution of the chlorites on the action of hydrogen chloride on these silicates. R. Brauns, however, argued that the action was dependent on the degree of humidity of the gas employed, and he and A. Lindner questioned whether evidence on the constitution of the chlorites can be founded on these experiments. R. Brauns, V. Goldschmidt, P. Groth, and W. and D. Asch base formulæ for the chlorites on the assumption that the chlorites are isomorphous mixtures of idealized types or hypothetical components. P. Erculisse considered the chlorites to be solid soln. of the micas and spinel. B. Gossner represents clinocllore by

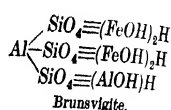

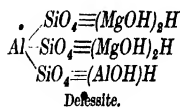

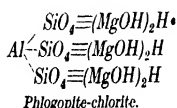

and by replacements between SiO_2 and $AlO(OH)$, and between $AlO(OH)$ and $Mg(OH)_2$ he accounted for the composition of all the members of the chlorite family. W. Vernadsky, and V. Iskyul considered the chlorites to be salts of, or complex compounds with, the acids $Al_2Si_{2+m}O_{7+2m-n}(OH)_{2n}$. The composition of the chlorites has been discussed by E. S. von Fedoroff. In his later work, F. W. Clarke represented the chlorites as orthosilicates, or trisilicates which formed a series of idealized compounds parallel with those which he employed for the micas, and in which basic groups like $MgOH'$, $FeOH'$, $AlOH''$, $Al(OH)_2'$, $Fe(OH)_2'$, and $Fe(OH)''$ appear. Thus, he based formulæ for the chlorites on three types:

I. *The biotitic chlorites* are built on the biotite-chlorite type and are illustrated by his formulæ for rumpfit, cronstedtite, and melanolite.

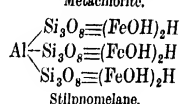

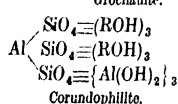

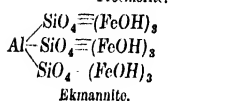

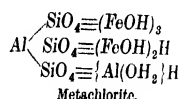

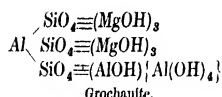

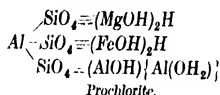

II. *The phlogopitic chlorites* are built on the phlogopite-chlorite type. The

composition of an average penninite agrees with an isomorphous mixture of the biotitic and phlogopitic chlorites in the proportion 1:1, and clinocllore and leuchtenbergite,

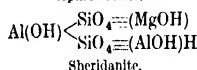

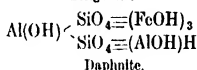

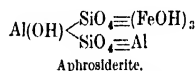

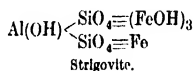

with the ratio 2:3 with one Al of the biotitic formula replaced by 3AlO. The formulae given by F. W. Clarke for brunsvigite, delessite, prochlorite, grochaulite, metachlorite, stilpnomelane, ekmannite, and corundophilite may be cited. In corundophilite the six R-atoms are made up from four Mg-atoms and two Fe-atoms.

Stilpnomelane has the chlorite formula, but is a trisilicate instead of an orthosilicate. The composition of diabantite and thuringite can be imitated by assuming they are binary mixtures; and epichlorite, a mixture of stilpnomelane and the orthosilicate, $\text{Al}(\text{SiO}_4)_3(\text{MgOH})_6\text{H}_3$.

III. The margaritic chlorites are illustrated by strigovite, aphrosiderite, daphnite, and sheridanite.

The hydrated character of the chlorites shows that they are not formed pyrogenetically. They are always of secondary origin, and almost all the ferromagnesian aluminosilicates may yield chlorites by hydrolytic reactions.⁵⁵ G. Friedel and F. Grandjean made chlorites artificially by the action of alkaline soln. on pyroxenes at 550°–570°.

The colour of the members of the chlorite group includes various shades of green, rarely brown; some are coloured violet, rose-red, and pink, particularly if chromium is present. Clinocllore occurs in tabular crystals flattened parallel to (001), and with a hexagonal outline; the crystals are sometimes prismatic. The crystals are monoclinic, and, according to G. Tschermak,⁵⁶ and N. von Kokscharoff, the axial ratios of crystals of clinocllore are $a:b:c=0.57735:1:2.2771$, and $\beta=89^\circ 40'$. Clinocllore also occurs scaly, granular, or earthy. Penninite is trigonal in habit, but, as G. Tschermak, and E. Mallard have shown, the crystals are pseudotrigonal, and belong to the monoclinic system with axial ratios like those of clinocllore. According to J. P. Cooke, the axial ratio of the pseudotrigonal crystals is $a:c=1:3.4951$. Penninite also occurs in scaly or compact cryptocrystalline masses. The crystals are thick and tabular rhombohedra, and also tapering six-sided pyramids; the X-radiogram was studied by H. Haga and F. M. Jäger. Prochlorite occurs in monoclinic six-sided plates or prisms with the planes strongly furrowed. The crystals are often joined at their sides, and occur in fan-shaped, vermicular, or spheroidal groups. They also occur in foliated or granular masses.

Corundophilite occurs in monoclinic 6-sided or 12-sided plates or prisms. The crystals of the orthochlorites were studied by G. Tschermak, E. Mallard, A. Schrauf, F. Naumann, P. Groth, A. des Cloizeaux, F. Hessenberg, J. D. Dana, N. von Kokscharoff, R. Prendel, L. V. Pirsson, H. Laspeyres, and J. Grailich and V. von Lang.

The **twinning** is usually similar to that of the micas with the twinning plane perpendicular to (001) and in the zone (001) (110). In some cases, the composition plane is (001) with the planes of the optic axes intersecting at 60° ; in other cases, (i) the twinned parts may lie in one plane adjacent to one another along two or three irregular planes, or (ii) they may form a trilling, or (iii) they may make one crystal with six sectors $\left\{ \begin{smallmatrix} \diagup \\ \diagdown \end{smallmatrix} \right\}$. The twinning may follow the so-called *penninite law*, with (001) for the twinning and composition plane. The two parts are in this case reversed, and corresponding faces differ in position 180° . Both modes of twinning may occur in one crystal. The apparent uniaxial character of penninite is explained by G. Tschermak and E. Mallard by assuming a highly developed multiple twinning of biaxial plates. The twinning was discussed by G. Tschermak, N. von Kokscharoff, G. A. Kenngott, and J. P. Cooke. The **cleavage** parallel to (001) is perfect furnishing flexible, tough, but not elastic laminae. The **percussion figures** and the **pressure figures** are oriented as with the micas. The **corrosion figures** were studied by G. Tschermak, and F. J. Wiik. Those at the (001)-face of clinocllore are in part monoclinic, and in part triclinic; those on penninite are hexagonal or triangular, rarely monoclinic or triclinic; and those on corundophilite are monoclinic. The **optic axial angles** are variable even in the same crystal; and in some cases the crystals appear uniaxial. G. Tschermak gave for $2E=2^\circ 30'-65^\circ$ for clinocllore, and $2V=20^\circ-51^\circ 31'$; for penninite, $2E=0^\circ-60^\circ$; for prochlorite, $2E=0^\circ-30^\circ$; for corundophilite, $2E=8^\circ 20'$, and $2V=46^\circ 40'$; for leuchtenbergite, $2E=0^\circ-29^\circ$; for kotschubeyite, $2E=0^\circ-36^\circ$; and for k  mmererite, $2E=0^\circ-20^\circ$. Observations have also been reported by A. des Cloizeaux, A. Michel-L  vy and A. Lacroix, and R. Prendel. According to A. des Cloizeaux, raising the temp. of clinocllore from $20^\circ-205^\circ$ raises $2E$ from $68^\circ-75^\circ$; no change occurred with leuchtenbergite and penninite.

The **specific gravity** of clinocllore ranges from 2.65-2.78; of penninite, from 2.60-2.85; of prochlorite, from 2.78-2.96; and that of corundophilite is 2.90. The **hardness** of prochlorite is 1-2; and that of other varieties ranges from 2-2½. R. Ulrich gave 0.2016 for the **specific heat** of chlorite between 20° and 98° . K. Dalmer found that orthochlorites lose their water at $550^\circ-570^\circ$; the leptochlorites commence to lose their water at $440^\circ-450^\circ$ and lose all at $580^\circ-600^\circ$. C. Doelter found that when penninite is melted with magnesium fluoride, magnesia mica, olivine, and enstatite are formed. He also found that when slowly cooled, olivine, augite, and spinel are formed. Observations were also made by C. Doelter and E. Dittler. F. W. Clarke and E. A. Schneider found that when clinocllore is strongly ignited it furnishes a soluble and an insoluble portion, and the latter has the composition of a spinel. The **indices of refraction** are nearly the same as for mica; for clinocllore, A. Michel-L  vy and A. Lacroix, K. Zimanyi, and J. K  nigsberger gave $\alpha=1.585-1.586$, $\beta=1.586-1.588$, $\gamma=1.5955-1.596$; for penninite, A. des Cloizeaux, C. Pulfrich, A. Michel-L  vy and A. Lacroix, W. Haidinger, and K. Zimanyi gave $\alpha=1.575-1.5821$, $\gamma=1.576-1.5832$. The corresponding **birefringence** is low, ranging from $\gamma-\alpha=0.001-0.0101$. The **optical character** is usually positive, sometimes negative, and sometimes both in adjacent laminae of the same crystal. E. S. Larsen studied this subject. The **pleochroism** of the crystals is well-marked; this subject was discussed by G. Tschermak, A. des Cloizeaux and J. C. G. de Marignac, G. A. Kenngott, J. P. Cooke, A. Bertin, and H. Rosenbusch. W. G. Hankel discussed the **pyroelectric properties** of the crystals.

G. A. Kenngott⁵⁷ observed that powdered and moistened chlorite has an alkaline reaction towards litmus. F. W. Clarke and G. Steiger found chlorites are partially decomposed by the vap. of ammonium chloride. C. Doelter and E. Dittler did not

obtain talc by the action of soln. of sodium carbonate and hydroxide. F. W. Clarke* and E. A. Schneider found chlorites are decomposed when heated in a stream of hydrogen chloride; R. Brauns doubted if the gas was adequately dried. A. Lindner also made observations on this subject. The transformations of the chlorites in nature have been discussed by G. Tschermak, A. Funaro and L. Brüssati, N. von Kokscharoff, etc. V. Iskyul studied solubility of the silica from the chlorites—prochlorite, corundophyllite, tabergite, rhodochrom, penninite, leuchtenbergite, and clinocllore. W. C. Smith and G. T. Prior described an ivy-green compact chlorite from Bernstein, Austria, which is sometimes erroneously called *precious serpentine*, and which is used for making vases and other small ornaments.

§ 42. Alkali Aluminium Silicates (continued)

M. F. R. d'Andrada¹ found a white or yellowish-white mineral at Utö, Södermanland, Sweden, and he named it **spodumene**—from σποδος, ashes—in allusion to its colour before the blowpipe flame. R. J. Haüy called it *triphane*—from τριφάνης, appearing three-fold—in allusion to his idea that the crystals can be divided by three planes with equal ease. J. A. Arfvedson first demonstrated the presence of lithium in the mineral, and other analyses were made by F. Stromeyer, R. Hagen, H. V. Regnault, and T. Thomson.

A variety of spodumene from Stoney Point, Connecticut, was described by J. L. Smith,² and W. E. Hidden, and called *hiddenite*—after W. E. Hidden. The colour is yellowish-green to emerald-green, and the latter is used as a gem-stone. It shows rather more variety of colour than the emerald because of its pleochroism. Another variety from Pala, California, is a clear rose or lilac-colour; it was called *kunzite*—after G. F. Kunz—and is also used as a gem-stone. It was described by G. F. Kunz, C. Baskerville, W. T. Schaller, and R. O. E. Davis. K. Przibram and co-workers found that a sample of kunzite which was pleochroic from rose-red to colourless gave colours varying from blue to yellowish-green after exposure to Becquerel's rays. T. Tanaka considered that the spectrum of the luminescence of kunzites indicated the presence of manganese, iron, thallium, samarium, and ytterbium.

Analyses of spodumene were made by C. F. Rammelsberg, A. Julien, etc. No elements of the cerium-yttrium group were present; and magnesium, barium, strontium, chromium, iron, titanium, zirconium, thorium, and phosphorus were absent from the kunzite analyzed by W. T. Schaller, and R. O. E. Davis. According to A. Piutti, spodumene of Mines Graës is not radioactive, although kunzite contains some helium. The proportion of lithia in the early analyses was shown by C. Doelter to be too low owing to imperfections in the analytical methods. The later analyses are best represented by the formula $\text{LiAl}(\text{SiO}_3)_2$, so that spodumene may be regarded as **lithium aluminium dimetasilicate**. F. W. Clarke gave a complicated graphic formula for spodumene involving a sextupling of the simple empirical formula. The synthesis of a spodumene like the natural mineral has not yet been effected—*vide leucite*. R. Ballo and E. Dittler melted together lithium metasilicate and aluminium metasilicate, and obtained what has been called *γ-spodumene*, which has a smaller sp. gr. and index of refraction than spodumene itself. G. Stein, and F. M. Jäger and A. Simek also failed to synthesize the mineral, but they obtained the *γ-spodumene*. R. Ballo and E. Dittler's f.p. curve of mixtures of lithium and

aluminium metasilicates is shown in Fig. 135. Starting from the lithium end, solid soln. are formed as far as 30 mol. $\text{Al}_2(\text{SiO}_3)_3$, and beyond the eutectic point a maximum occurs at 965° , corresponding with the compound **lithium dialuminium pentametasilicate**, $2\text{Li}_2\text{SiO}_3 \cdot \text{Al}_2(\text{SiO}_3)_3$. There is then a second eutectic point at 920° , and the curve rises steeply to a maximum at 1275° , corresponding with **lithium aluminium tetrametasilicate**, $\text{Li}_2\text{SiO}_3 \cdot \text{Al}_2(\text{SiO}_3)_3$. The third eutectic point is at 1200° . Natural spodumene furnishes a similar product to synthetic spodumene when it is fused and slowly cooled. In the system $\text{LiAlO}_2\text{-SiO}_2$, R. Ballo and E. Dittler found lithium aluminium dimetasilicate, m.p. 1275° ; lithium aluminium orthosilicate, m.p. 1330° ; **lithium aluminium mesotrisilicate**, $\text{LiAlSi}_3\text{O}_8$, m.p. 1180° ; and **lithium aluminium paratetrasilicate**, $\text{LiAlSi}_4\text{O}_{10}$, m.p. 1200° .

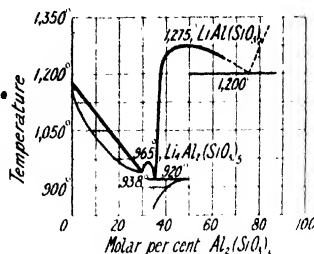

FIG. 135. Freezing point Curves of the Binary System: $\text{Li}_2\text{SiO}_3\text{-Al}_2(\text{SiO}_3)_3$.

Spodumene occurs in cleavable masses, and in prismatic crystals which are white and may be tinged green, grey, or yellow. There are also blue, rose, and lilac-coloured crystals—e.g. kunzite—and green crystals of hiddenite. F. A. Genth³ found 0.18 per cent. of chromic oxide in green hiddenite. The crystals of spodumene usually appear as flattened prisms, and very large crystals have been reported. W. P. Blake mentioned crystals from the Black Hills, South Dakota, 36 ft. in length and 1-3 ft. in thickness; F. L. Hess, one 42 ft. in length and approximately 3 ft. by 6 ft. in cross-section; V. Ziegler, one 12 ft. long and 5 ft. 4 ins. maximum diameter, and it weighed 90 tons; and W. T. Schaller, one 47 ft. long. R. J. Haüy said the crystals are rectangular octahedra; and observations were made by J. D. Dana, R. Hermann, and A. des Cloizeaux. According to G. vom Rath, the crystals belong to the monoclinic system, and have axial ratios $a:b:c = 1.1283:1:0.62345$, and $\beta = 69^\circ 32\frac{1}{2}'$; and E. S. Dana gave $1.1283:1:0.6355$, and $\beta = 69^\circ 40'$. K. Endell and R. Rieke say that the crystals become isotropic at about 950° . The (110)-cleavage is well marked. The crystals sometimes have a lamellar structure, and can be separated or parted into thin plates parallel to the (100)-face. Twinning occurs on the (100)-plane. Corrosion figures produced by a natural solvent have been found by E. S. Dana on some crystals of hiddenite; and G. Greim obtained similar figures by etching with hydrofluoric acid. G. Greim also gave for the optic axial angle $2H = 64^\circ 47'$ for red light; $64^\circ 58\frac{1}{2}'$ for Na-light; and $65^\circ 4\frac{1}{2}'$ for blue light.

The sp. gr. of many of the natural spodumenes analyzed ranged from 3.1-3.2; their hardness varied from 6-7. F. M. Jäger and A. Simek determined the sp. gr. of a number of natural kunzites, and found 2.411 at 25° for the sp. gr. of synthetic spodumene. K. Endell and R. Rieke stated that the sp. gr. of spodumene is not affected by heating it to 920° and cooling rapidly, but at 980° it is diminished from 3.147-2.370. R. Ballo and E. Dittler called the mineral α -spodumene, and found that at about 1000° there is an irreversible transition temp. into β -spodumene whereby the sp. gr. falls from 3.17-2.41. Natural α -spodumene is slowly transformed to β -spodumene at temp. as low as 690° , and the change progresses with an increasing velocity as the temp. is raised. The term β -spodumene is no longer applied to the natural mixture of albite and eucryptite (q.v.). Fused spodumene rapidly cooled furnishes a colourless glass of sp. gr. 2.362. Synthetic γ -spodumene has a sp. gr. 2.3127; and kunzite which has been transformed into γ -spodumene by melting and recrystallizing by slow cooling has virtually the same sp. gr. 2.3130. The curve, Fig. 136, represents the average results of K. Endell and R. Rieke, and R. Ballo and E. Dittler on the sp. gr. of spodumene, which has

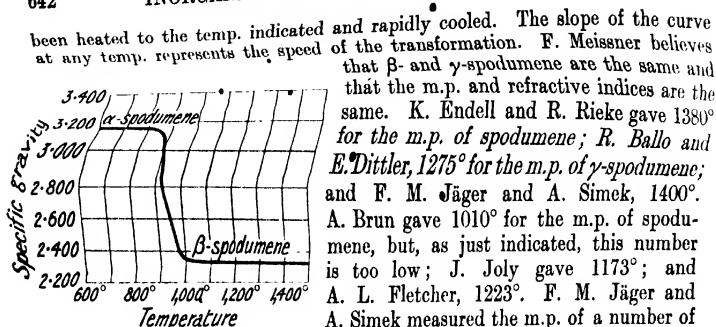

FIG. 136.—Effect of Temperature on the Specific Gravity of Spodumene.

been heated to the temp. indicated and rapidly cooled. The slope of the curve at any temp. represents the speed of the transformation. F. Meissner believes that β - and γ -spodumene are the same and that the m.p. and refractive indices are the same. K. Endell and R. Rieke gave 1380° for the m.p. of spodumene; R. Ballo and E. Dittler, 1275° for the m.p. of γ -spodumene; and F. M. Jäger and A. Simek, 1400°. A. Brun gave 1010° for the m.p. of spodumene, but, as just indicated, this number is too low; J. Joly gave 1173°; and A. L. Fletcher, 1223°. F. M. Jäger and A. Simek measured the m.p. of a number of natural kunzites and found them to be higher than synthetic spodumene. Hence they inferred that the m.p. decreased as the sp. gr. increased. The observed difference in the m.p. of β -spodumene (1380°) and γ -spodumene (1290°) is attributed by F. Meissner to the low fusion and crystallization velocities. From his experiments on the action of soln. of the alkali salts on spodumene before and after fusion, J. Lemberg assumed that the melting is accompanied by the decomposition: $2(\text{Li}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2) = \text{Li}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 + \text{Li}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$. K. Schulz gave 0.2161 for the sp. ht of spodumene. F. M. Jäger and A. Simek concluded that the natural kunzites, hiddenites, and spodumenes are metastable varieties (α -spodumenes) of the compound, and that γ -spodumene is the stable form at all temp. below 1400°. The natural spodumenes cannot therefore be produced from dry magmas, and it is probable that their formation is due to so-called hydrothermal synthesis. R. Lorenz and W. Herz studied the relation between the m.p. and the transition temp. G. Tammann gave 714 cal. for the heat of soln. per gram in a mixture of hydrofluoric and hydrochloric acids.

A. Michel-Lévy and A. Lacroix gave for the indices of refraction of the mineral $\alpha=1.660$, $\beta=1.666$, and $\gamma=1.676$ for red light; while A. des Cloizeaux gave $\alpha=1.651$, $\beta=1.669$, and $\gamma=1.677$ for yellow light. L. Duparc and co-workers obtained:

	White.			Green.			Rose-red.		
	α	β	γ	α	β	γ	α	β	γ
Li-ray	1.6567	1.6617	1.6719	1.6652	1.6682	1.6673	1.6567	1.6617	1.6722
Na ray	1.6604	1.6648	1.6755	1.6682	1.6712	1.6815	1.6603	1.6653	1.6758
Tl-ray	1.6634	1.6680	1.6791	1.6717	1.6742	1.6837	1.6634	1.6681	1.6694

K. Endell and R. Rieke found the birefringence disappears after heating the mineral to 980°, or the very finely powdered mineral to 950°. They found the mean refractive index of spodumene is 1.66; and that of the glass, 1.519. R. Ballo and E. Dittler gave for α -spodumene, 1.665; for β -spodumene, 1.527; for glassy spodumene, 1.519; for γ -spodumene (synthetic), 1.525; and for γ -spodumene from re-crystallized kunzite, 1.523. F. M. Jäger and A. Simek gave 1.521. The crystals are optically positive. E. S. Dana found the pleochroism to be strong particularly in the deep green varieties. As indicated above, A. Piutti⁴ said that the mineral is not radioactive. C. Doelter found that by exposing kunzite to radium rays, it is coloured green; spodumene does not change; and hiddenite becomes bluish-green. He found that kunzite becomes colourless at 400°, and rose at 240°. Calcined kunzite becomes green when exposed to radium rays. The green colour changes to lilac when the mineral is heated to 200° in a stream of oxygen. C. Baskerville and G. F. Kunz found that kunzite has a red phosphorescent glow when exposed to radium rays; according to S. Meyer, the light is polarized. Spodumene and hiddenite do not phosphoresce under these conditions. F. H. Glew,

K. Przibram, and E. Newbery and H. Lupton also investigated the action of radium rays on kunzite. C. Doelter found that green kunzite is thermoluminescent at 40° ; and kunzite is luminescent in X-rays, and in ultra-violet light. Thirty hours' exposure to X-rays produced a perceptible change in the colour of kunzite; hiddenite became greener. C. Doelter said that spodumene and hiddenite are almost transparent to the X-rays. Ultra-violet rays restore the original colour to green kunzite, but hiddenite is not changed. The subject was also studied by S. C. Lind and D. C. Bardwell.

G. A. Kenngott⁵ found that powdered and moistened spodumene has an alkaline reaction both before and after calcination; but the powdered glass does not give the reaction. Spodumene is not attacked by the ordinary acids, although, as indicated above, it is attacked by hydrofluoric acid. J. Lemberg investigated the prolonged action of soln. of potassium and sodium carbonates, and potassium and sodium chlorides at 100° – 230° , on both natural and glassy powdered spodumene. The lithium is displaced by potassium and sodium; and in some cases silica is removed as alkali silicate. The alteration of spodumene in nature was studied by A. A. Julien, C. R. van Hise, and G. J. Brush and E. S. Dana. Percolating soln. of sodium salts change it to eucryptite and albite. This mixture was once called *β -spodumene*—*vide* eucryptite. By the further action of potassium salts, the eucryptite is converted into muscovite. Thus, albite and muscovite appear as end-products of this reaction, and the mixture of albite and muscovite was called *cymatolite* by J. D. Dana; and *aglaite* by A. A. Julien. T. Thomson described an alteration product of spodumene from Killiney Bay, Ireland. This mineral is not unlike cymatolite. It was called *killinite*.

A. Damour⁶ applied the term *jadeite* to a jade-like mineral from Eastern Asia. The colour is nearly white with a green tinge, leek-green, emerald-green, apple-green, or bluish-green. He also applied the term *chloromelanite*—from *χλωρις*, green; *μέλας*, black—to a dark green, almost black, variety—*vide* jade and nephrite. The analyses have been discussed under the last-named minerals. The results show that jadeite can be regarded as a *soda-spodumene*, $\text{NaAl}(\text{SiO}_3)_2$, **sodium aluminium dimetasilicate**. It is known only in a massive form with a crystalline or granular structure, and it may be obscurely fibrous. The crystals are monoclinic (or triclinic) with optical characters like the pyroxenes. The crystalline structure has been discussed by A. des Cloizeaux, E. Cohen, A. J. Krenner, and A. Arzruni. For Na-light, A. Michel-Lévy and A. Lacroix gave for the optic axial angle $2V = 70^{\circ}$; and A. J. Krenner, $2H = 82^{\circ} 48'$. A. Michel-Lévy and A. Lacroix found the birefringence $\gamma - \alpha = 0.029$. The sp. gr. is 3.30–3.35, and the hardness, 6.7. S. Weidmann referred to a pyroxene related to jadeite which he called *percivalite*. It is from the pegmatite deposits of Wisconsin; its composition indicates that it is a mixture of jadeite and aemite. H. S. Washington found a pea-green jade ornament near San Andrés de Tuxtla, Mexico, of date about 96 B.C.; its composition corresponded with a mixture of equal parts of jadeite and diopside, $\text{NaMgCaAlSi}_4\text{O}_{12}$. He called the mineral *turtlite*. The sp. gr. was 3.270; the hardness, 6.5; $\alpha = 1.666$, $\beta = 1.674$, and $\gamma = 1.688$; the birefringence, $\gamma - \alpha = 0.022$; the optical axial angle, 75° ; and the optical character, negative. The minerals whose composition corresponded with solid soln. of turtlite and albite were called *mayaites*—from the Maya nation.

J. F. L. Hausmann⁷ described a green amphibole from Syra, one of the Cyclades Islands, but it has since been shown to be widely distributed. He called the mineral **glaucophane**—from *γλαυκός*, bluish-green; and *φαίνεσθαι*, to appear. G. Strüver called the mineral from Valle Grande di Lanzo, *gastaldite*—after B. Gastaldi. Analyses have been reported by C. Bodewig, O. Lucdecke, F. Berwerth, A. von Lasaulx, E. Schluttig, G. Strüver, F. Zambonini, L. Milch, W. C. Blasdale, A. Johnsen, B. Koto, A. Liversidge, C. Barrois and A. Offret, H. S. Washington, U. Grubenmann, and H. B. Foellon. C. F. Rammelsberg regarded glaucophane as a complex mixture of Na_2SiO_3 , RSiO_3 , and $\text{R}_2''(\text{SiO}_3)_3$; various other forms of

the mixture hypothesis were proposed by C. Doelter, L. Milch, U. Grubenmann, and C. W. Blasdale. Idealized glaucophane is represented as sodium aluminium dimetasilicate, $\text{NaAl}(\text{SiO}_3)_2$; and this is normally associated with ferromagnesian metasilicate, $(\text{Fe,Mg})\text{SiO}_3$, and calcium metasilicate. F. W. Clarke regarded it as a trisilicate, analogous to crocidolite,

A. Osann reported a *lithium-glaucophane* which was named *holmquistite*—after P. J. Holmquist—in the iron ores of Utö, Sweden. It contains 2.13 per cent. Li_2O , so that part of the soda of glaucophane is replaced by lithia. The mineral is optically negative, with $2E=68^\circ 56'$. Glaucophane is the amphibolic equivalent of the pyroxene, jadeite; and its composition was studied by B. Gossner.

Glaucophane occurs as the hornblende constituent of some crystalline schists, mica schists, amphibolytes, gneiss, eclogytes, etc. B. Koto regarded it as a secondary product of the alteration of diallage. The subject has been discussed by H. Rosenbusch, L. Milch, G. F. Becker, K. Oebbeke, H. S. Washington, and J. P. Smith. Glaucophane has not been synthesized artificially. C. Doelter found that like other amphiboles, it furnishes a pyroxene when fused and crystallized. When heated along with magnesium, calcium, and sodium chlorides in a current of steam, C. Doelter obtained a product like glaucophane in some respects. The colour of glaucophane is azure-blue, lavender-blue, bluish-black, and grey. It commonly occurs massive, fibrous, columnar, or granular. The crystals are prismatic and monoclinic, closely resembling the amphiboles in form. The axial ratios are $a:b:c=0.53:1:0.29$, and $\beta=105^\circ$. Observations were made by C. Bodewig, A. von Lasaulx, O. Luedecke, and G. Strüver. The cleavage parallel to (110) is complete. The optic axial angle for Na-light is $2E=85^\circ 35'$; and, according to G. Strüver, $2V=43^\circ 58'$. S. Kreutz gave $2E=72^\circ 55'$ and $2V=42^\circ 24'$ for red light, and $2E=72^\circ 36'$ for green light. The sp. gr. ranges from 3.0–3.1, and the hardness 6. C. Doelter gave $1040^\circ\text{--}1060^\circ$ for the m.p. The mineral becomes brown when calcined. E. T. Allen and J. K. Clement discussed the nature of the water which is present to the extent of 1.78–2.57 per cent. in samples dried at 100° . E. Wallerant gave for the indices of refraction $\alpha=1.6212$, $\beta=1.6381$, and $\gamma=1.6390$; and S. Kreutz, $\alpha=1.630$, $\beta=1.646$, and $\gamma=1.648$. For the birefringence, $\gamma-\alpha=0.0178$, $\beta-\alpha=0.0169$, and $\gamma-\beta=0.0009$. The optical character is positive. The pleochroism is strongly marked. Observations were made by C. Bodewig, G. Strüver, A. von Lasaulx, A. Michel-Lévy, A. Stelzner, C. Barrois, F. Becke, B. Koto, J. W. Retgers, A. Wichmann, F. Becke and E. Schluttig. In general, a is yellowish-green to colourless; b , reddish-violet; and c , sky-blue to ultramarine-blue. K. Oebbeke noted the change which occurs after the mineral has been calcined. O. Mügge noted the formation of pleochroic halos when glaucophane is exposed to radium radiations. The mineral is scarcely affected by acids. L. Colomba described the alteration of glaucophane into chlorite, feldspar, and hæmatite.

B. Faujas de St. Fond⁸ mentioned the occurrence of pellucid crystals of a *zeolithe dure* on the Cyclopean Islands, Sicily; L. A. Emmerling, D. G. J. Lenz, and J. C. Delaméthérie called it *zeolithe cubique*, and *zeolithe leucitique*; and R. J. Haüy called it *analcite*—from *ἀναλκίς*, weak—in allusion to its feeble electrification when rubbed. D. de Gallitzin altered the name to **analcite**.

J. G. Werner called analcite *kubizite*, and also *analzin*; and A. Breithaupt, *kuboid*. The *picranalcite*—from *πικρόν*, bitter—of G. Moneghini and E. Bechi, stated to contain about 10 per cent. of magnesia, proved, when analysed by E. Bamberger, to be ordinary analcite. J. Esmark obtained a compact analcite from a number of islands on the Langesund fiord, Norway, and it was named *euthallite*—from *εὖ*, well; and *θάλλος*, a green twig

—in allusion to the colour. P. C. Weibye found rhombic crystals of a mineral on islands in the Langesund fiord, Norway, and he called it *eudnophite*—from *eūdnōpos*, duskiness—in allusion to the cloudiness of the mineral. The crystals were examined by A. des Cloizeaux, E. Bertrand, and A. Lacroix. W. C. Brögger showed that the mineral is nothing but analcite with an unusually strong double refraction. T. Thomson found in the Kilpatrick Hills red vitreous crystals of a mineral approaching analcite in properties. It was named *chubaitite*—from Clutha, an old name for the Clyde Valley. It is considered to be an altered analcite. E. Bertrand examined its optical properties. F. Berwerth named a black-coloured rhombic mineral in a meteorite from Kodaikanal, Madras, *weinbergite*—after J. Weinberger—its composition corresponded with $9[(\text{Na}, \text{K})_2\text{Al}_2\text{Si}_4\text{O}_{14}] \cdot 51(\text{Mg}, \text{Ca}, \text{Fe})\text{SiO}_3$, or, more generalized, $\text{Na}_2\text{O} \cdot 6\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot 8\text{SiO}_2$; and it is assumed to be a mixture of $\text{NaAlSiO}_4 + 3\text{FeSiO}_3$. It is optically negative, has small axial angles, and a weak index of refraction and birefringence.

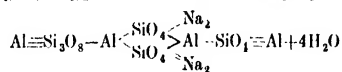

The first analyses of analcite were made by L. N. Vauquelin⁹ in 1807, and H. Rose made more accurate ones in 1822. Many analyses of analcite have since been made. C. F. Rammelsberg¹⁰ at first regarded the contained water as eq. to water of crystallization; later, he gave the formula $\text{H}_4\text{Na}_2\text{Al}_2\text{Si}_4\text{O}_{14}$. The formula usually accepted is $\text{Na}_2\text{Al}_2(\text{SiO}_3)_4 \cdot 2\text{H}_2\text{O}$, or, as P. Groth puts it, *sodium aluminium dimetasilicate*, $\text{NaAl}(\text{SiO}_3)_2 \cdot \text{H}_2\text{O}$; but H. W. Foote and W. M. Bradley showed that in the published analyses, the ratio $\text{Na}_2\text{O} : \text{Al}_2\text{O}_3$ is nearly 1 : 1, and the ratio $\text{H}_2\text{O} : \text{SiO}_2$ is very close to 1 : 2; but there is no simple ratio between the alumina or soda and silica or water. G. Tschermak represented analcite as constituted of four alumino-silicates. J. Jakob represented it by the co-ordination theory:

G. Friedel showed that over 100° there is a state of equilibrium between the vap. press. of the zeolites and the water vapour in the air; and for a given weight of mineral the vap. press. depends on the area of the exposed surface. He measured the dehydration curve of analcite *vide infra*. F. W. Clarke and G. Steiger found:

	100°	180°	200°	300°	350°	Low redness
Loss of water	0.13	0.75	2.44	1.28	1.76	2.03 per cent.

They regarded the water as extrinsic and, from their experiments on the action of ammonium chloride vap. resulting in the formation of *ammonium aluminium dimetasilicate*, $(\text{NH}_4)\text{Al}(\text{SiO}_3)_2$, wrote the formula $\text{Na}_1\text{Al}_4\text{Si}_8\text{O}_{24}$, or:

R. Brauns regarded the part of the water as intrinsic or constitutional, and wrote the formula $\text{Al} : \text{SiO}_3 \cdot \text{O} \cdot \text{Si}(\text{OH})_2(\text{ONa})$. C. Doelter, and E. T. Wherry consider that analcite is not a zeolite because it does not show the peculiar dehydration phenomena characteristic of zeolites. It is considered to be related with leucite. E. T. Wherry assumed that the mol. vol. of K and of $(\text{Na} + \text{H}_2\text{O} + x)$ are alike, and can replace one another isomorphously. From observations on the action of salt soln. on analcite, G. Tschermak, and C. Doelter regarded the mineral as a complex mixture or solid soln. of silicic acid and an anhydrous aluminosilicate, $\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_8 \cdot \text{H}_4\text{Si}_2\text{O}_6$. H. W. Foote and W. M. Bradley also explained the variation in composition of analcite by assuming that a solid soln. of some other compound is present—presumably silicic acid, $\text{H}_2\text{Si}_2\text{O}_5$; $\text{H}_4\text{Si}_2\text{O}_6$; etc. Water in analcite does not behave like ordinary water of crystallization, and the vap. press. at a given temp. is not constant. This is taken to support this hypothesis. J. Lemberg inferred that the formula should be at least doubled. G. Stoklossa assumed that the water of analcite is chemically bound in the mol. There is a break in the rehydration curve of analcite dehydrated at different temp., and this is taken to correspond with the existence of a definite hydrate.

Analcite has been synthesized by hydrothermal processes, working under press. C. Doelter said the sphere of existence of analcite at high press. is from about 180° – 500° . The reaction with nephelite is reversible; using simplified formulæ: $2\text{NaAlSiO}_4 + \text{H}_2\text{O} \rightleftharpoons \text{NaAlO}_2 + \text{NaAl}(\text{SiO}_3)_2 \cdot \text{H}_2\text{O}$; raising the temp. favours the system on the left, and conversely. Thus, he obtained analcite by heating nephelite with an aq. soln. of alkali carbonate in presence of free carbon dioxide at 200° ; and with water and analcite at 400° he obtained some nephelite. If C. R. van Hise¹¹ is right in saying that there is a 5.49 per cent. increase in vol. when nephelite passes into analcite, a high press. is not suited for the conversion of nephelite into analcite. J. Lemberg, and S. J. Thugutt showed that when leucite is heated to 180° – 195° along with a soln. of sodium chloride or carbonate, analcite is formed. The reaction is reversible. They also obtained analcite by the prolonged digestion of andesine or oligoclase with a soln. of sodium carbonate at 210° – 220° . S. J. Thugutt found the reaction with andesine is not reversible. E. A. Stephenson obtained analcite by the action of soln. of sodium carbonate or hydrocarbonate on adularia at temp. ranging from 183° – 233° . C. Doelter represents the conversion of albite into analcite as a reversible reaction: $\text{NaAl}(\text{SiO}_3)_2 \cdot \text{H}_2\text{O} + \text{SiO}_2 \rightleftharpoons \text{H}_2\text{O} + \text{NaAlSi}_3\text{O}_8$, when the left to right reaction requires a high temp.—over 420° , according to C. Doelter; over 520° , according to E. Baur. A. de Schulten made analcite by heating to 180° – 190° a mixture of sodium silicate and hydroxide, and water in contact with aluminous glass; and by heating to 180° for 18 hrs. mixed soln. of sodium silicate and aluminate in proper proportions. C. Friedel and E. Sarasin prepared analcite by heating precipitated aluminium silicate, sodium silicate, and water in a sealed tube at 500° . E. Banr likewise made analcite crystals from a mixture of silica, sodium aluminate, aluminium hydroxide, and water in a steel tube at 350° – 450° ; and C. Doelter also formed analcite from mixtures of soln. of silica, alumina, and soda, or of silicic acid, aluminium chloride, and sodium carbonate at 100° – 400° . J. Königsberger and W. J. Müller found that the formation of zeolites, in the absence of carbon dioxide in the system, $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2 - \text{H}_2\text{O}$, commences below 100° , and may increase up to 400° , but probably their limit of stability, with the exception of analcite, is below 300° .

Analcite is readily formed as a secondary mineral, the product of the so-called *zeolitization*; and when formed with other zeolites, it is one of the first to appear. Alterations of leucite into analcite have been observed by A. Sauer,¹² F. Zambonini, J. E. Hirsch, H. S. Washington, S. J. Thugutt, W. H. Weed and L. V. Pirsson, J. F. Williams, E. Scacchi, E. Hussak, etc.; and W. C. Brögger noted the formation of analcite from *elcolite* and *argirite*. Analcite may also be formed as a pyrogenic primary mineral in deep-seated rocks, where it was probably formed under press. Numerous observations have been reported in support of this statement.

Analcite may occur massive or granular; in composite groups of crystals, or in single crystals, usually in trapezohedra, or cubes, belonging to the cubic system. The cleavage is feebly cubic. Analcite may be colourless, white, or tinged grey, green, yellow, or red. The sp. gr. of many of the samples analyzed were determined, and the data range from about 2.15–2.35—thus, G. dal Piaz¹³ gave 2.195; B. Popoff, 2.2145; E. Billows, 2.28; and E. Vaccari, 2.35. J. Königsberger and W. J. Müller gave 2.2 for the sp. gr. of the artificial crystals. G. Friedel found that the expulsion of water from analcite is attended by a contraction, thus:

Water lost	0	3.60	6.29	8.02 per cent.
Sp. gr.	2.277	2.205	2.160	2.141
Contraction	0	0.5	0.88	2.15 per cent.

After a prolonged ignition, the sp. gr. rose to 2.437. The hardness of analcite is between 5 and 5½. G. Friedel found that when analcite is heated so that it loses water, it retains its original form and the refractive index is increased. At ordinary temp., the dehydrated mineral does not resorb water, but at about 100° ,

it will absorb water from the air and return to its original composition. C. Doelter found melted analcite gives no crystalline products on cooling. F. Pfaff found the mean coeff. of linear expansion between 0° and 100° to be 0.0009261; A. Bartoli gave for the sp. ht., 0.226 between 23° and 100° , and 0.246 between 29° and 492° . G. Tamman gave for the heat of the formation 85.22 Cals. per mol, or 0.215 Cal. per gram. O. Mulert found the heat of soln. in dil. acid to be 0.5688 Cal. per gram. According to G. Friedel, if the dehydrated mineral be mixed with a few drops of water, combination occurs with great energy; heat is evolved, and at the same time much air is liberated; the resorption of water by analcite is attended by the evolution of 740 cals. per gram. A. des Cloizeaux gave for the index of refraction 1.4874 for the red ray; C. S. Ross and E. V. Shannon gave 1.486; and K. Zimanyi, 1.4861–1.4881 for the yellow ray. J. Königsberger and W. J. Müller found the refractive indices of artificial analcite are perceptibly higher than that of the natural.

Although the crystals belong to the cubic system and are isotropic, D. Brewster noticed that they are sometimes optically anomalous, and exhibit a weak double refraction. The phenomenon was studied by J. B. Biot, A. des Cloizeaux, A. de Schulten, E. Bertrand, A. von Lasaulx, C. Stadtländer, G. Friedel, A. Merian, A. Arzruni and S. Koch, R. Brauns, etc. A. Schrauf regards the crystals as pseudocubic and describes them as complex twins belonging to the rhombic system; and E. Mallard proposed a similar explanation. A. Ben-Suade explained the phenomenon as a result of internal strains, and obtained similar effects from solidified gelatine cast in moulds. C. Klein showed that when heated in an atm. of water vap. or placed in hot water, the anomalous crystals became isotropic, while with a dry heat, the birefringence was increased. Hence, he attributed the anomalous effect to the change in mol. arrangement which results from the loss of a little water. F. Rinne found that analcite which has been ignited is trichinic, and he calls the product *soda-leucite*, which is analogous with potash- or ordinary leucite in the same sense that monoclinic potash-felspar is analogous with triclinic soda-felspar. T. Liebisch and H. Rubens found the reflection spectrum in the ultra-red had a maximum over 10μ , and a minimum at 80μ . K. Brieger found a maximum corresponding with that of water. W. W. Coblentz found the ultra-red transmission spectrum of analcite has the water bands at 1.5μ , 2μ , and 4.7μ quite obliterated. C. Doelter found that in a thin layer analcite is transparent to the X-rays, but in layers over 3 mm. it is almost opaque. J. Königsberger and W. J. Müller found 6.7 for the dielectric constant.

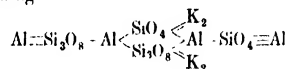

G. A. Kennigott,¹⁴ and E. W. Hoffmann found that analcite moistened with water has an alkaline reaction. G. Steiger found analcite to be markedly soluble in water. According to G. Friedel, the water in the zeolites is not in chemical combination in the common sense of the word, and it can be replaced by various gases, and even by solids such as silica, without alteration in the crystalline form or optical properties of the minerals. Dehydrated analcite absorbs ammonia in large quantity with great energy and development of heat, the quantity absorbed being independent of the nature of the zeolite and proportional to the quantity of water previously expelled. When exposed to moist air, the ammonia is gradually expelled; and its place is taken by water. In the case of analcite the analogy is very close; the ammonia, like water, is not absorbed by the mineral if dehydrated below 100° , and it is not displaced by atm. moisture at the ordinary temp. J. Königsberger and W. J. Müller found that analcite dissolves in hydrochloric acid often leaving a skeleton of gelatinous silica. C. G. C. Bischof found that a soln. of calcium sulphate displaces some sodium from analcite. J. Lemberg studied the action of soln. of sodium and potassium carbonates; ammonium, potassium, and sodium chlorides; potassium hydroxide; and calcium chloride. In general, there is an interchange of bases; with sodium silicate a substance like cancrinite is formed with SiO_3 in place of CO_3 . F. W. Clarke, and G. Steiger examined the action of ammonium chloride vap. in sealed tubes at about 350° , and, as indicated above, obtained ammonium-analcite. G. Steiger studied the action of soln. of

silver nitrate, and obtained *silver-analcite*, or *silver aluminium dimetasilicate*, $\text{AgAl}(\text{SiO}_3)_2 \cdot \text{H}_2\text{O}$. H. C. McNeil studied the action of barium chloride on the mineral and obtained a *barium-analcite*.

J. J. Ferber,¹⁵ I. S. R. I. Eques a Born, N. T. de Saussure, B. G. Sage, J. B. L. Romé de l'Isle and C. A. S. Hoffmann referred to *weisse Granaten*, *basaltes albus*, *grénats blancs*, or white garnet occurring at Vesuvius and Monte Somma. They said that it is a garnet which has been *altérés par une vapeur acide qui ayant dissout le fer a laissé les grénats dans un état de blancheur*. A. G. Werner distinguished the mineral from garnet, and called it **leucite**—from λευκός, white—in allusion to its colour. R. J. Haiiy proposed *amphigène*—from ἀμφι, both; and γένος, kind—in allusion to the supposed existence of cleavage in two directions. M. H. Klaproth analyzed the mineral, and said:

I was surprised in an unexpected manner by discovering a constituent part consisting of a substance whose existence, certainly, no one person would have conjectured within the limits of the mineral kingdom. . . . This constituent part of leucite is no other than potash, which, hitherto, has been thought exclusively to belong to the vegetable kingdom, and has, on this account, been called vegetable alkali.

M. H. Klaproth's analysis was quite good. A. von Awdejff found soda to be also present; T. Richter detected traces of lithia; and J. L. Smith, traces of caesia and rubidia. Many other analyses have been made.¹⁶ C. Matignon¹⁷ and others have described various deposits and the methods of working them as a source of potassium salts for agriculture, etc. C. F. Rammelsberg's summary¹⁸ of the analyses corresponded with the formula $\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, or KAlSi_2O_6 , *i.e.* **potassium aluminium dimetasilicate**. Up to about 6.5 per cent. of Na_2O may also be present. This is not likely to be present as albite, and it is assumed that a *soda-leucite* is associated with *potash-leucite*. Soda-leucite does not occur in nature, but sodium aluminium dimetasilicate, $\text{NaAl}(\text{SiO}_3)_2$, has been made by J. Lemberg. He also replaced the potassium in leucite by beryllium. S. J. Thugutt infers that leucite is really a polymer, and is the potassium salt of a complex acid, $\text{H}_2\text{Al}_2(\text{SiO}_3)_2 \cdot n\text{H}_2\text{O}$. F. W. Clarke also believes that the ordinary formula should be quadrupled, making

analogous to sodalite (*q.v.*). G. Tschermak studied the silicic acid liberated when leucite is treated with hydrochloric acid at room temp., and he called the product *leucitic acid*—*vide supra*. His formula for leucite is therefore $\text{KO} \cdot \text{SiO} \cdot \text{O} \cdot \text{SiO}_3 \cdot \text{Al}$. F. W. Clarke showed that although leucite and analcite are usually separated in mineralogical systems of classification, for one is placed with feldspars and the other with zeolites, yet they are so similar in form, composition, and properties, that they cannot be adequately studied apart.

Leucite is a comparatively rare mineral; it is common in recent lavas; but it is not found in the older deep-seated rocks. This may be due to its easy alteration into other species, more probably due to the instability below the temp. 1170° , when it passes into orthoclase if silica be present: $\text{KAl}(\text{SiO}_3)_2 + \text{SiO}_2 = \text{KAlSi}_3\text{O}_8$ —*vide* Fig. 154. It is formed in rock magmas only when the potassium is in excess of that required for the production of feldspar; and A. E. Lagorio¹⁹ found that in a leucite-tephrite magma, kept at red heat, leucite crystallizes out; and if the temp. be raised, the leucite dissolves, while, if lowered, the mass becomes so viscous that crystallization ceases. This emphasizes the narrow range of temp. in the formation of leucite in rock magmas. A. Himmelbauer found leucite is formed when analcite is digested with a mixed soln. of potassium hydroxide and chloride—*vide infra*. F. Fouqué and A. Michel-Lévy showed that leucite can be formed by simply fusing together its constituent oxides, and also, along with other minerals, by fusing various rock magmas—*e.g.* a mixture of biotite and microcline; C. Doelter

obtained it when muscovite, lepidolite, or zinnwaldite are fused alone; and G. W. Morey and N. L. Bowen, by heating orthoclase (*q.v.*) above 1170° . Similar observations were made by K. Petrasch, K. Schmutz, G. Medanich, J. Lenarcie, and K. Bauer. P. Hautefeuille also fused a mixture of potassium aluminate and vanadate, and silica at 800° – 900° for nearly a month, and obtained measurable crystals of leucite; similar crystals were obtained by fusing muscovite or a mixture of the constituent oxides along with potassium vanadate. S. Meunier made leucite by the action of silicon tetrachloride on aluminium turnings impregnated with alkali-lye; A. Duboin, by fusing a silicic acid or potassium fluosilicate and alumina in the presence of an excess of potassium fluoride; and C. and G. Friedel, hydrothermally, by heating a mixture of muscovite, silica, and potash-lye in a steel tube at 500° .

F. Fouqué and A. Michel-Lévy suppose that a *lithia-leucite* is obtained of sp. gr. 2.41, by fusing a mixture of silica, alumina, and an excess of lithium vanadate or tungstate. It is not clear if this product is not after all a spodumene. Spodumene itself is trimorphous. According to C. Doelter, when potash-lithia mica is melted there is an isomorphous mixture of $\text{KAl}(\text{SiO}_3)_2$ and $\text{LiAl}(\text{SiO}_3)_2$ formed; and it is therefore assumed that spodumene can also crystallize in the form of leucite. Jadeite and glaucophane are probably related to a *soda-leucite*; and C. Doelter made soda-leucite by melting a mixture of andalusite and sodium fluoride. P. Hautefeuille and A. Perrey made crystals of what they regarded as *beryllia-leucite*, $\text{KBe}(\text{SiO}_3)_2$; and P. Hautefeuille, crystals of *ferrie-leucite*, $\text{KFe}(\text{SiO}_3)_2$ vide silicates of beryllium and of iron.

Leucite occurs in pseudo-cubic crystals; in disseminated grains; and is rarely massive and granular. The colour is white, ash-grey, or smoke-grey. Leucite crystallizes in icositetrahedra which are so characteristic that this form has been called the *leucitohedron*, Fig. 137, by G. vom Rath.²⁰ In consequence, up to about 1870 the crystals were said to belong to the cubic system. About 50 years earlier, however, D. Brewster showed that the crystals are birefringent, and even biaxial in parts. These peculiarities were supposed to be the result of internal strains set up during crystallization as a result of cooling; and to be similar to the double refraction observed in chilled or compressed glass. J. B. Biot, A. des Cloizeaux, and F. Zirkel showed that the crystals are traversed by twin lamellæ parallel to the four faces, (011), (0 $\bar{1}$ 1), (101), and (1 $\bar{0}$ 1), of the dodecahedron; and the optical anomaly was accordingly attributed to the lamellar structure. If the dodecahedral face be a plane of symmetry, it cannot also be a twinning plane, and the crystals cannot therefore be cubic. G. vom Rath then showed that the angles between the faces are not those of the icositetrahedron which should be $48^{\circ} 11\frac{1}{2}'$; actually, the terminal faces, *o*, are inclined at an angle $49^{\circ} 57'$ and the lateral faces, *i*, $48^{\circ} 37'$. He therefore suggested that leucite belongs to the tetragonal system, and consists of a tetragonal bipyramid, *o*(112), and a ditetragonal bipyramid, *i*(211), twinned on the faces of the tetragonal bipyramid, (101). H. Baumhauer found the corrosion figures agreed with those of the tetragonal system. The subject was discussed by A. Scacchi, J. Hirschwald, A. des Cloizeaux, G. Tschermak, and P. Groth. If the crystals be tetragonal, they should be uniaxial; but although they are uniaxial in parts, they are biaxial in other parts. E. Mallard considered that the uniaxial parts are due to the overlapping of biaxial lamellæ; so that the crystals are really biaxial, and that their symmetry cannot be higher than that of the rhombic system. E. Mallard said that, optically, the crystals are monoclinic; and F. Fouqué and A. Michel-Lévy, triclinic. Later, A. Weisbach showed that the crystals are more probably rhombic (i) with twin lamellæ parallel to the dodecahedron faces (110) and ($\bar{1}$ 10); (ii) referable to their rectangular axes in which the lateral axes are so nearly equal that angular measurements do not distinguish between tetragonal and rhombic symmetry; and

FIG. 137. Icositetrahedral Leucite (the Leucitohedron).

(iii) traversed by so numerous and fine twin lamellæ that it is difficult to observe the biaxial figure of a homogeneous single crystal at any point in convergent light.

C. Klein showed that when the temp. of a section of leucite is heated to the beginning of redness, between crossed nicols, a dark shadow extends across the plate, and the leucite is then isotropic; H. Rosenbusch further showed that the twinning striations disappear on heating, and reappear in new positions on cooling. At the higher temp., therefore, leucite really belongs to the cubic system, and, on cooling, it probably breaks up into rhombic sections. S. L. Penfield, and O. Mügge gave 560° for the temp. of the enantiotropic change: α^2 -leucite \rightleftharpoons β -leucite. F. Rinne and R. Kolb said that at 684° the double refraction begins to diminish, and at 714° the crystals are isotropic. The transition is so sluggish that there appears an interval of 30° between the beginning and the end of the change. R. Lorenz and W. Herz studied the relation between the transition temp. and the m.p.

C. Doelter found the velocity of crystallization of leucite magma to be small, so that the velocity curve is flattened. L. Colomba investigated the influence of the cooling conditions on the transformation; and he found that a uniform press. of 6000 atm. has no appreciable influence. Skeleton forms of the crystals some-

FIG. 138.—Skeleton Crystals of Leucite.

times appear; and L. V. Pirsson has drawn a number of these representing various stages of growth. A selection is given in Fig. 138. The simplest forms have spurs attached to the four-fold cubic axes, A, Fig. 138; in B, these are thickened at the ends; and in C, the thickening has spread, and the icositetrahedron begins to appear. In the diagrams, the blackened areas represent the glassy base with inclusions. Spurs then appear along a two-fold axis as in D; and when these reach the margin, the form of the icositetrahedron is complete, E, and F, Fig. 138. Leucite may be free from inclusions, or inclusions of gas, glass, liquids, and minerals may occur. These minerals crystallized before the leucite, and they include augite, olivine, hædyne, nephelite, melanite, magnetite, picotite, and apatite. The inclusions may be arranged in clusters at the centre of the crystal; in one or more concentric zones; or in radial lines. The reason for the radial arrangement is indicated by L. V. Pirsson's study of the growth of the crystals. Some magma was first shut in, and afterwards separated into crystals. L. Colomba showed that crystals which have been formed in rapidly cooling rocks are apt to manifest anomalous characters, and a sectored structure. F. Zirkel, and H. Rosenbusch have made a special study of the inclusions.

The sp. gr. of leucite ranges from 2.45-2.50—J. A. Douglas²¹ gave 2.480 for the crystals, and 2.410 for the glass. V. Goldschmidt gave 2.464 for the crystals; C. F. Rammelsberg, 2.468-2.484; G. vom Rath, 2.479; L. Ricciardi, 2.480; and G. Tschermak, 2.469. The sp. gr. of many of the samples analyzed was also determined. The hardness is 5-6. J. Joly gave 0.1912 for the sp. ht., and G. Tammann, 0.178 for crystalline, and 0.175 for glassy leucite between 20° and 100° . The heat of soln. of crystalline leucite in 20 per cent. hydrofluoric acid is 507 cal. per gram, and of amorphous glassy leucite, 533 cal. per gram; hence the heat of crystallization is 26 cal. per gram. D. D. Jackson and J. J. Morgan found the vap. press. of the alkali vap. of leucite to be negligibly small below 1350° . According to O. Mulert, the heat of soln. in 20 per cent. hydrofluoric acid is 0.5187 Cal. per gram, or 226.8 Cals. per mol., and the heat of formation $K_2O + Al_2O_3 + 4SiO_2$ (amorphous) $\rightarrow K_2O \cdot Al_2O_3 \cdot 4SiO_2$ (crystalline) + 101.8 Cals. The mineral is said to be infusible in the ordinary blowpipe flame; G. Spezia fused it in a flame fed with oxygen. R. Cusack gave 1298° for the m.p.; A. L. Fletcher, 1348° ; A. Brun, 1270° ; and C. Doelter, 1275° - 1315° .

The indices of refraction, according to A. des Cloizeaux,²² are $\alpha=1.508$, and $\gamma=1.509$ for sodium light; K. Zimanyi obtained 1.5086. H. Rosenbusch, and

A. des Cloizeaux found very small crystals to be isotropic, and in thin sections, leucite is usually isotropic. F. Rinne and R. Kolb found the dispersion for α -leucite at 21° from A to G , 0.0142; and for β -leucite, at 750° , 0.0150. They gave for the indices of refraction of α -leucite at 21° , and β -leucite at 750° :

Line	A	B	C	D	F	G
α -leucite	1.5046	1.5054	1.5061	1.5088	1.5146	1.5188
β -leucite	1.4903	1.4912	1.4921	1.4947	1.5009	1.5063

The crystals are optically positive, but G. Tschermak found a specimen from Acquacetosa to be optically negative. J. Schincaglia investigated the phosphorescence of leucite; C. Doelter found that it is not luminescent with radium rays; and that it is equal to muscovite in transparency to X-rays. W. Vernadsky did not find leucite triboluminescent.

G. A. Kenngott²³ found that the moistened powder of leucite has a stronger alkaline reaction than potash-felspar. J. Lemberg found that soln. of sodium chloride or carbonate transformed leucite into analcite. He investigated the action of soln. of sodium silicate in an autoclave at 190° - 200° , and found the potassium was displaced by sodium, and analcite was formed. A. Himmelbauer showed that when analcite is digested with a mixed soln. of potassium hydroxide and chloride, leucite is formed. The reaction is reversible, $KAl(SiO_3)_2 + NaCl + H_2O \rightleftharpoons H_2O + KCl + NaAl(SiO_3)_2$. Similar results were obtained by S. J. Thugutt, who said that the reaction progresses from left to right as well at ordinary temp. as it does at 200° ; and in dil. soln. as in conc. soln. He also found that the complex is very stable; leucite is slightly soluble in a one per cent. soln. of potash-lye at about 200° ; and it is not decomposed, but with a 30 per cent. soln. of alkali-lye, the leucite is decomposed, forming a substance resembling nephelinite. H. Lotz found that a mixture of steam, air, carbon dioxide, and sulphur dioxide decomposes leucite. G. Tammann and C. F. Grevemeyer found that magnesia does not act on leucite at 1000° ; lime acts slowly at 500° ; and baryta acts strongly at 275° - 350° . Several methods have been proposed for the extraction of potash from leucite—e.g. by C. Montemartini, G. A. Blanc, G. Rozzi, and J. W. Hinchley—*vide* 2, 20, 4.

G. Steiger heated leucite with a soln. of thallium nitrate at 250° - 290° , and obtained a substitution product *thallium-leucite*. The natural transformation of leucite into analcite has been studied by A. Knop, C. F. Rammelsberg, A. Sauer, C. G. C. Bischof, and C. R. van Hise; into a zeolite, by E. Casoria, and J. Lemberg; into kaolinite, by E. Casorio, and C. R. van Hise; into orthoclase and muscovite, by J. F. Williams, E. Scacchi, G. F. Kunz, E. Hussak, C. R. van Hise, J. R. Blum, C. Bergemann, and A. Sauer; into calcium cancrinite, by G. Freda, F. Zambonini, A. Lacroix, C. Doelter, and J. Lemberg; into kaliophilite, by F. Zambonini, and G. vom Rath; and into a mixture of nephelinite and sanidine—the so-called *pseudo-leucite*—by A. Sauer, T. T. Read and C. W. Knight, and J. Shand. F. Zambonini found pseudomorphs of nephelinite after leucite and of leucite after nephelinite (*q.v.*). The action of sodium hydroxide and various salt soln. on leucite was studied by H. Schneiderholm.

O. B. Bögild²⁴ applied the term *ussingite*—after N. V. Ussing—to a reddish-violet-coloured, triclinic mineral from Kangerdluarsuk, Greenland. The analyses correspond with **sodium aluminium hydroxyltrimetasilicate**, $Na_2HAl(SiO_3)_3$. Its sp. gr. is 2.495; and hardness 6-7. The indices of refraction are $\alpha=1.5037$, $\beta=1.5082$, and $\gamma=1.5454$; the birefringence is feeble. The axial angles are $2V=39^\circ 4'$, and $2E=60^\circ 34'$. It is optically positive, and is decomposed by hydrochloric acid with the separation of gelatinous silica.

In 1800, M. F. R. d'Andrada²⁵ described a mineral which he found at Utö, Södermanland, Sweden, and named it **petalite**—presumably from *πέταλον*, a leaf, in allusion to the cleavage. A few years later, E. T. Svedenstierna, and R. J. Häuy gave more detailed descriptions, and A. Arfvedson found lithia in the mineral; E. T. Svedenstierna called it *lithite*; and E. D. Clarke called it *berzelite*.

A. Breithaupt described a mineral from Elba, and called it *castor*—after Castor in heathen mythology. G. Rose showed that castor and petalite are similar, and A. des Cloizeaux showed that they have the same optical properties and cleavage. Analyses were made by A. Arfvedson, C. G. Gmelin, R. Hagen, C. F. Rammelsberg, A. Breithaupt, W. S. von Waltershausen, K. Söndén, F. W. Clarke, J. L. Smith and G. J. Brush, and P. von Jeremejeff. A. des Cloizeaux showed that petalite is in some respects like spodumene, and C. F. Rammelsberg assumed that the two minerals contained different proportions of the two silicates, $\text{Li}_2\text{Si}_2\text{O}_6$ and $\text{Al}_2(\text{Si}_2\text{O}_5)_3$. C. Doelter discussed the relation of petalite to spodumene, and he considered that the idealized mineral was best represented by the formula $\text{Li}_2\text{Al}_2\text{Si}_{10}\text{O}_{24}$; and P. Groth represented it by $\text{LiAlSi}_4\text{O}_{10}$ or $\text{LiAl}(\text{Si}_2\text{O}_5)_2$, that is, **lithium aluminium dimesosilicate**. R. Ballo and E. Dittler synthesized petalite by fusing lithium metaluminate and silica; and they found that it corresponds with a maximum at 1200° in the f.p. curve of the binary system, $\text{LiAlO}_2\text{--SiO}_2$.

Petalite commonly occurs in foliated masses, colourless, white, grey, or tinged yellow or green. Crystals are rare, and commonly tabular. A. Breithaupt noted that the crystals are monoclinic, and A. des Cloizeaux gave the axial ratios $a : b : c = 1.1534 : 1 : 0.7436$, and $\beta = 67^\circ 34'$. The (001) cleavage is complete, the (201) good, and the (905) is imperfect. A. des Cloizeaux found the optic axial angle $2H = 86^\circ 24' - 86^\circ 27'$ for the red ray; $86^\circ 28' - 86^\circ 30\frac{1}{2}'$ for the yellow ray; and $86^\circ 42' - 86^\circ 43'$ for the blue ray. The sp. gr. of petalite ranges from 2.4–2.5. R. Ballo and R. Dittler gave 2.290 for the sp. gr. of the glass; the hardness is over 6. P. E. W. Oeberg gave 0.236 for the sp. ht. A. Brun found the m.p. to be 1270° ; and R. Ballo and E. Dittler gave 1370° for the m.p. of petalite from Elba. The last-named found that petalite between 1000° and 1100° becomes optically uniaxial; and at 1200° , optically isotropic. R. Lorenz and W. Herz studied the relation between the m.p. and the transition temp. A. des Cloizeaux found the refractive index $\beta = 1.5078, 1.5096$, and 1.5180 respectively for the red, yellow, and blue-rays. A. Michel-Lévy and A. Lacroix gave $\alpha = 1.504$, $\beta = 1.510$, and $\gamma = 1.516$; and the birefringence is strong, $\gamma - \alpha = 0.012$. A. des Cloizeaux found a rise of temp. up to $170^\circ 8'$ produced no appreciable change in the refractive index. R. Ballo and E. Dittler gave 1.4946 for the refractive index of glassy petalite. The optical character is positive. When gently heated, petalite exhibits a faint blue thermoluminescence. G. A. Kenngott found the moistened powdered mineral reacts alkaline, and if previously calcined, the alkalinity is less intense. Petalite is attacked by hydrofluoric acid, but not by other acids. The so-called *hydrocastorite* is a decomposition product of petalite or castor from Elba. It occurs in needle-like crystals of sp. gr. 2.16, and hardness 2. It was described and analyzed by G. Grattarola,²⁶ and F. Sansoni. The analyses agree roughly with F. W. Clarke's formula, $\text{H.Si}_2\text{O}_5.\text{Al}(\text{OH})_2$, **aluminium dihydroxy-hydromesosodisilicate**. Vide lepidolite for **lithium trialuminium hexahydroxydimetasilicate**.

Different varieties of the zeolite now called **natrolite**—from *natron*, soda—were at first designated by an adjectival prefix. Thus, A. Cronstedt;²⁷ I. S. R. I. Eques a Born, A. G. Werner, and J. B. L. Romé de l'Isle, spoke of the *zeolites crystallisatus, prismaticus, capillaris*, etc. C. J. Selb designated a variety from Högau, *högaunit*, and M. H. Klaproth, *natrolite*. Natrolite was at first confused with the related minerals mesotype or mesolite, and scolecite (*q.v.*), and natrolite was for a time called by J. N. von Fuchs, and others, *soda-mesotype* or *soda-mesolite*, to distinguish it from lime-mesotype or scolecite.

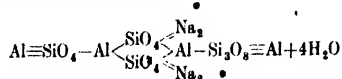

Colourless acicular crystals of natrolite with up to 4 per cent. of lime were referred to by G. A. Kenngott, and E. F. Glocker. The mineral from South Scotland was called *galacite*—from γλας, milk—in allusion to the colour. A red sample from Glen Farg was called *fargite* by M. F. Heddle. The natrolite from Langesund fiord, Norway, was called *radiolite* by J. Esmark, in allusion to its occurring in radiating masses; *bergmannite*, by F. Schumacher—after T. Bergman—or *Spruceite*, which T. Scheerer regarded as a *paraph* after an unknown mineral which he called *palao-natrolite*, but W. C. Brögger showed

that it is an impure natrolite derived from sodalite and cancrinite; and *brevicite*, by P. Ström. The last-named mineral was analyzed by K. Söndén. The *crocalite* of A. Estner is a red zeolite resembling bergmannite. The *savite* of G. Meneghini—named after P. Savi—found in the serpentine of Monte Caporciano, Italy, was shown by E. Mattiolo, A. des Cloizeaux, Q. Sella, and E. Artini to be identical with natrolite. The *iron-natrolite* of C. Bergemann, from the Brevik region, was supposed to have some alumina replaced by ferric oxide, but W. C. Brögger showed that the iron is derived from included ferruginous minerals. T. Thomson's *lehunitite*—named after C. Lehunit—is a natrolite from Antrim.

Numerous analyses of natrolite have been reported.²⁸ They can be summarized by the formula $\text{Na}_2\text{Al}_2\text{Si}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$, but a little lime is usually present—*vide* scolecite. The constitution of natrolite depends on what view is taken of the state of combination of the water—i.e. whether all or part is intrinsic or extrinsic. G. Friedel²⁹ investigated the dehydration curve, and found the loss very slow up to 250°, but at 280°, the water was rapidly given off, but no break was observed in the curve. F. Zambonini likewise found the curve at about 100° is almost horizontal, but at 300° almost vertical. The curve, however, continues without a break. His data are:

	110°	205°	210°	264°	278°	297°	324°
Water lost	0.12	0.16	0.25	0.46	0.81	1.57	9.41 per cent.

C. Hersch also made observations on this subject. A peculiarity is that, as first pointed out by A. Damour, the water is resorbed by dehydrated natrolite, but the crystal does not acquire its former transparency and firm texture. The resorbed water is lost at about 90°. F. Zambonini likened the water in the zeolites generally to that in hydrogels like silicic acid (*q.v.*). C. F. Rammelsberg assumed that the water is present as water of crystallization. G. Friedel, and F. Zambonini infer that the water is not an intrinsic part of the mol., and is eq. to neither the so-called constitutional water nor to the so-called water of crystallization. It is regarded as *zeolitic water*, which many consider to be either water in solid soln. (F. Rinne), or adsorbed water (C. Doelter). G. Friedel said that the zeolitic water is mechanically mixed occupying the space between the structural units of the crystal. The subject was investigated by A. Johnsen, and S. J. Thugutt. G. Stoklossa believed that the water is really combined in the mineral, and he considered that there are four hydrates represented by breaks in the rehydration curve of natrolite previously dehydrated at a temp. between 0° and 300°. Hence, he doubled the above formula, and wrote, $\text{Na}_4\text{Al}_4\text{Si}_6\text{O}_{20} \cdot 4\text{H}_2\text{O}$. S. J. Thugutt said that natrolite is to be regarded as a salt of aluminosilicic acid, $\text{H}_2\text{Al}_2\text{O}_{10} \cdot n\text{H}_2\text{O}$, represented in the free state by pyrophyllite and razumoffskyn. G. Tschermak assumed that natrolite is a complex containing an anhydrous silicate and silicic acid, $\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_8 \cdot \text{H}_2\text{SiO}_4$; and in general he supposes the zeolites to be acid salts with part of the hydrogen replaced by sodium, calcium, aluminium, etc. C. Doelter extended this hypothesis and showed that the zeolites have a feldspar or nephelite nucleus. E. Baschieri used a constitutional formula in harmony with G. Tschermak's views, $\text{Na}_2 : \text{SiO}_4 : (\text{Al} : \text{SiO}_4 : \text{H}_2)_2$. F. W. Clarke at first used a similar formula, but later when he found that natrolite is transformed into $\text{Al}_2(\text{NH}_4)_2\text{Si}_3\text{O}_{10}$ by the action of dry ammonium chloride in a sealed tube, and that the water is not intrinsic, he doubled the formula and wrote:

The investigators named above regard natrolite, as an orthosilicate. The formula $\text{Na}_2\text{Al}_2\text{Si}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$, used by C. F. Rammelsberg, and E. S. Dana, makes natrolite appear to be dihydrated *sodium dialuminium orthotrisilicate*. P. Groth considered natrolite to be a metasilicate, and wrote $\text{Na}_2\text{Al}(\text{AlO})(\text{SiO}_3)_3 \cdot 2\text{H}_2\text{O}$. G. F. H. Smith and co-workers gave $(\text{Na}, \text{K})_2\text{Q} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$.

C. Doelter³⁰ treated powdered natrolite with water sat. with carbon dioxide

in a sealed tube at 160°, and observed the re-crystallization of the mineral. S. J. Thugutt heated hydrated nephelite, sodium carbonate, and carbonated water in a sealed tube at 200°, and obtained prismatic crystals supposed to be natrolite; when potassium carbonate was used in place of sodium carbonate, *potash-natrolite* was formed. J. Lemberg also found that there is an exchange of potassium for sodium when a soln. of potassium carbonate is allowed to act on natrolite for a few months; the action is reversed by sodium carbonate. The formation of natrolite in nature has been investigated by J. E. Hibsich, A. Pelikan, A. Brun, C. N. Fenner, etc.

Natrolite is colourless, white, grey, yellow, or red. It is not commonly found massive, but it often occurs in masses of radiating fibres with a silky lustre, and also in slender prismatic crystals. J. N. von Fuchs and A. F. Gehlen⁸¹ regarded the crystals as rhombic; G. Rose, as monoclinic; and later, G. Rose and P. Riess found them to be rhombic. W. C. Brögger gave for the axial ratios of the rhombic crystals $a : b : c = 0.97852 : 1 : 0.35362$. Observations were also made by E. Artini, O. Luedecke, G. F. H. Smith and co-workers, S. Richarz, J. E. Hibsich, R. Görgey, G. Cesaro, A. Scheit, and G. B. Negri. S. J. Thugutt obtained what he regarded as a monoclinic form of natrolite which he called *epinatrolite* from Schömitz near Carlsbad. He found the action of silver nitrate (mixed with some potassium chromate) to be far more rapid than is the case with rhombic natrolite. It is also suggested that natrolite is derived from nephelite, and epinatrolite from hallyne. A. von Lasaulx, and W. C. Brögger also observed monoclinic forms with, according to the latter, the axial ratios $a : b : c = 1.0165 : 1 : 0.35991$, and $\beta = 89^\circ 54'$; and S. Kreutz, $0.97853 : 1 : 0.35362$, and $\beta = 90^\circ$. The monoclinic form is isomorphous with scolecite. The relationships have been discussed by S. Kreutz, and G. Tschermak. Some of the rhombic crystals can be regarded as monoclinic twins. The twinning has been discussed by C. Stadtländer, V. von Lang, and O. Luedecke. The cleavage parallel to the (110)-face is perfect; and that parallel to the (010)-face is imperfect, perhaps only a plane of parting. The plane of the optic axes is parallel to the (010)-face; the optic axial angle is large. W. C. Brögger gave $2H_0 = 61^\circ 29' - 62^\circ 25'$ for Li-light; $61^\circ 37' - 62^\circ 41'$ for Na-light; and $61^\circ 46' - 62^\circ 50\frac{1}{2}'$ for Ti-light; $2H_0 = 118^\circ 8' - 121^\circ 1'$ for Li-light; $118^\circ 2' - 120^\circ 47'$ for Na-light; and $117^\circ 53' - 120^\circ 24'$ for Ti-light; $2E = 98^\circ 7\frac{1}{2}'$ for Li-light, $98^\circ 58'$ for Na-light, and $99^\circ 34'$ for Ti-light; and for $2V$, $60^\circ 51' - 62^\circ 16\frac{1}{2}'$ for Li-light; $61^\circ \frac{1}{4}' - 62^\circ 29\frac{1}{2}'$ for Na-light; and $61^\circ 13\frac{1}{2}' - 62^\circ 39\frac{1}{2}'$ for Ti-light. B. Mauritz gave $2V = 60^\circ$. Observations were also made by K. Zimanyi, E. Artini, and E. Palla. For red light, A. des Cloizeaux found that $2E$ changed from $98^\circ 33'$ at 8.8° to $95^\circ 0'$ at 105.5° ; and with another sample, from $98^\circ 58'$ at 15° to $90^\circ 55'$ at 307.9° .

The sp. gr. of many of the samples analyzed were determined, and the results range from 2.2-2.5; the hardness is 5 or just about 5. J. Joly gave for the sp. ht., 0.23689-0.23819 between 11° and 100° . F. Rinne showed that when heated clear crystals of natrolite become turbid as the water is evolved, but they become clear again when dipped in oil. The optical properties of dehydrated natrolite correspond with that of a monoclinic substance which he called *metanatlolite*. No change in the geometrical form accompanies the mol. change. For the action of heat on the water-content of natrolite, *vide supra*. G. Tammann found that in an atm. with the vap. press. of water p mm., the percentage loss of water from a sample of natrolite with 10.4 per cent. of water was:

p	.	.	.	14.5	12.3	9.1	2.1	0.4	mm.
Loss	.	.	.	0.21	0.25	0.39	0.61	0.79	per cent.

O. Mulert found the heat of soln. in dil. hydrofluoric acid to be 0.5446 Cal. per gram; and the heat of formation, 95.76 Cals. The indices of refraction for Na-light by K. Zimanyi, A. des Cloizeaux, H. C. Backlund, B. Mauritz, W. C. Brögger, and A. Pelikan ranged from $\alpha = 1.47543 - 1.47813$; $\beta = 1.47897 - 1.48080$; and $\gamma = 1.48866 - 1.49047$. S. G. Gordon gave $\alpha = 1.480$, $\beta = 1.482$, and $\gamma = 1.493$, with

$\gamma-\alpha=0.013$ —*vide* thomsonite and scolecite. The corresponding birefringence is $\gamma-\alpha=0.0008$, $\gamma-\beta=0.0004$; $\beta-\alpha=0.0004$. O. B. Böggild found the double refraction of natrolite to be rather strong, almost 0.01; and the extinction parallel. J. Königsberger and W. J. Müller found the index of refraction and birefringence were not perceptibly changed by digesting natrolite in a 25 per cent. soln. of potassium chloride. The optical character of natrolite is positive. E. Engelhardt found the crystals exhibit a yellow fluorescence. W. W. Coblenz found the ultra-red transmission spectrum of natrolite showed the presence of water bands in their usual positions (1.9, 10); and in the ultra-red reflection spectrum, there are maxima at 9.05 μ , 9.5 μ , and 10.05 μ beyond which the reflecting power remains higher up to 12 μ . G. W. Hankel examined the pyroelectric qualities of natrolite; and O. Weigel, the electrical conductivity.

Natrolite adsorbs moisture from the atm., and this the more the finer the state of subdivision of the powdered mineral. S. J. Thugutt³² could find no relation between the newly adsorbed water and that already contained in the mineral. The amount adsorbed is a function of the grain-size or surface energy, the partial press. of the moisture in the atm., and the time of exposure. This subject was also investigated by W. F. Hillebrand. Powdered natrolite moistened with water was found by G. A. Kenngott to have an alkaline reaction; and A. Damour found that the soln. obtained by digesting dehydrated natrolite in water has an alkaline reaction. G. Steiger found that by digesting 0.5 gm. of natrolite in 50 c.c. of water at 21° for a month, 0.30 per cent. of alkali was dissolved by the water; 15.79 per cent. remained in the mineral. C. Doelter, and S. J. Thugutt made observations on this subject. J. Lemberg found that 8.37 per cent. of soda was removed from natrolite by 687 hrs.' digestion with water at 250°. C. H. A. Eichhorn found that a soln. of calcium chloride has but a slight action on natrolite. S. J. Thugutt studied the action of soln. of potassium and sodium carbonate, potassium and sodium chloride, and calcium chloride on natrolite, and found that part of one alkali is replaced by the other. A. Günther-Schulze found that 93 per cent. of the sodium can be replaced by silver when natrolite is immersed in a soln. of silver nitrate. The diffusion constant of the sodium is 1.48×10^{-10} sq. cm. per sec. K. Dalmier found that part of the sodium is replaced by ferrous iron when natrolite is digested with a soln. of ferrous sulphate. G. Steiger likewise found a replacement of sodium by silver or thallium occurs when natrolite is digested with a soln. of silver or thallium nitrate. F. W. Clarke and G. Steiger examined the effect of ammonium chloride on natrolite at 350°. When treated with acids, natrolite decomposes with the separation of gelatinous silica. V. P. Smirnov studied the action of humic and crenic acids on natrolite. The effect of natural agents on natrolite has been discussed by J. R. Blum, C. R. van Hise, G. Sillem, G. Tschermak, C. Doelter, and S. J. Thugutt.

§ 43: The Felspars

Felspar is a class name for a group of related minerals. They are the most important constituents of rocks; indeed, F. W. Clarke¹ estimated that nearly 60 per cent. of the material contained in igneous rocks is felspar. A system of classifying rocks has been based on the particular type of felspar they contain. This important mineral species does not appear to have been particularly noticed by the earlier writers. G. Agricola probably alluded to felspar in saying *silix ex exitu ferri facile ignis elicitur—ex cubis aliisque figuris intersectis constans*; J. G. Wallerius referred to it as white, grey, and red *felspat*, and *spatum pyrimachum*; and A. Cronstedt, as *fältspat*, and *spatum scintillans*. The scholars are not certain if the "feld" is derived from *Fels*, a rock, as R. Kirwan, and M. H. Klaproth apparently assume in respectively calling the mineral *felspar*, and *Felspath*, because

of its common occurrence in granite rocks; or from *Feld*, a field, in allusion to crystals being found scattered on the ground in some parts of the country. C. Hintze's view is that the *Feld* is the result of mutilating an old word in order to adapt it to the popular mind. The original word cannot now be traced. The term *Feldspar* is used in Germany, and *felspar* in England.

J. B. L. Romé de l'Isle mentioned seventeen varieties of felspar, but designated by special name only *pierre de Labrador*. G. Rose attempted a classification of the varieties known in 1823. The list has been extended and may now be taken to include the following idealized types. There are a number of varieties to some of these types. These may be arranged in two groups:—

I. *Trisilicates*.—The empirical composition of these felspars corresponds with $K_2O \cdot Al_2O_3 \cdot 6SiO_2$, or $KAlSi_3O_8$. It is, however, extremely rare to find a potash felspar without some accompanying soda, and conversely. Some lime is also usually present. These felspars include the artificially-prepared *lithia-felspar*, *rubidia-felspar*, and *cæsia-felspar*:

<i>Potash-felspar</i> , $KAlSi_3O_8$	Monoclinic	ORTHOCLASE (Or)
	Triclinic	MICROCLINE
<i>Soda-felspar</i> , $NaAlSi_3O_8$	Monoclinic	BARBIERITE
	Triclinic	ALBITE (Ab)
<i>Soda-potash-felspars</i> (Na, K) $AlSi_3O_8$	Triclinic	ANORTHOCLEASE
Or: Ab = 1:0–4:1	Monoclinic	ADULARIA
4:1–3:2	Monoclinic	AMAZONITE
3:2–1:1	Monoclinic	PERTHITE
1:1–1:4	Monoclinic	LOXOCLEASE

II. *Disilicates*.—These are typified by anorthite, $(CaO \cdot Al_2O_3 \cdot 2SiO_2)$, or $CaAl_2Si_2O_8$; and possibly the artificially-prepared soda-anorthite, $Na_2Al_2Si_2O_8$:

<i>Soda-anorthite</i> , $Na_2Al_2Si_2O_8$	Triclinic	CARNEGIEITE (Cg)
<i>Lime-felspar</i> , $CaAl_2Si_2O_8$	Triclinic	ANORTHITE (An)
<i>Baryta-felspar</i> , $BaAl_2Si_2O_8$	Monoclinic	CELSIAN

Mixed di- and trisilicates are typified by a whole series of isomorphous mixtures of the alkali trisilicates, and alkaline earth disilicates.

<i>Lime-soda-felspars</i> , Ab:An = 6:1–3:1	Triclinic	OLIGOCLEASE
3:1–1:1	Triclinic	ANDESINE
1:1–1:3	Triclinic	LABRADORITE
1:3–1:6	Triclinic	BYTOWNITE
<i>Mixed felspar</i> , Cg:Ab:An	Triclinic	ANEMOUSITE
<i>Baryta-potash-felspar</i> , (K, Ba) $Al_2Si_2O_8$	Monoclinic	HYALOPHANE

The classification here given for the soda-potash-felspars, and the soda-lime-felspars is due to G. Tschermak.² The subdivisions are quite arbitrary. Others for the soda-lime-felspars have been proposed by M. Schuster, and J. D. Dana. The artificial *lithia-felspar*, *rubidia-felspar*, *cæsia-felspar*, *strontia-felspar*, *magnesia-felspar*, *lead-felspar*, *zinc-felspar*, *potash-anorthite*, and *ferric-orthoclase*, which are mentioned below, are not included in the table.

Ordinary potash-felspar occurs in crystals or cleavable masses. The rectangular cleavage of some felspars suggested to R. J. Haüy³ the name *orthose*—from *ὀρθος*, straight. A. Breithaupt, for a somewhat similar reason, called it *orthoclase*—from *ὀρθος*, straight; and *κλάω*, to break. A cleavable *glassy felspar* from Drachenfels was described by C. W. Nöe, and called by J. J. Nöggerath *sanidine*—from *σάνις*, a tablet—in allusion to its usually occurring in tabular crystals. A. H. Klaproth showed that sanidine is chemically the same as orthoclase. The *ice-spar* of A. G. Werner belongs to the same mineral species. G. Rose found that the mineral from Monte Soma which he called *ryacolite* or *rhyncolite*—from *ρύαξ* (lava), stream; and *λίθος*, a stone—is glassy felspar mixed with some nephelite. E. Pini described a felspar from Adula which he called *adulaire*, and which is now called *adularia*, after A. G. Werner's suggestion. From L. A. Emmerling's and G. A. Kennigott's observations, Adula formerly included a more extensive area than it does to-day. Adularia is transparent, cleavable, and often has pearly opalescent reflections exhibiting a play of colours like labradorite. The so-called *moonstone*, *pierre de lune*, or

Mondstein is a variety of adularia, albite, or oligoclase. J. C. Delam  therie called it *hecatolite*—from *  κάρη*, the moon. A. Breithaupt found a mineral which he called *valencianite* in a silver mine at Valenciana, Mexico. It was adularia. Other names seem to have been given to orthoclase or microcline more or less at random—e.g. A. Breithaupt's *paradozite* from the tin mines at Marienberg is orthoclase with very little soda; according to the analyses of W. Sch  ler, the mineral *paradozite* from Euba, Saxony, is a potash-felspar. A. Breithaupt's *collait  *, from Carlsbad, Bohemia—named in honour of B. von Cotta—is greyish-white orthoclase; and his *muldan*, from Mulda, near Freiberg, was shown by C. F. Rammelsberg to be ordinary orthoclase.  An orthoclase found by F. V. Hayden near Baltimore was called *neoronite*—from *νεκρ  ς*, a corpse—in allusion to its fetid odour when struck. E. D. Clarke's *leelite* is a flesh-red orthoclase named after J. F. Lee; J. D. Dana's *chesterite* from Chester Co., Penn., is a microcline. Other orthoclases are G. Jenzsch's *weissigite* from Weissig, near Dresden; I. Lea's *lenzmita* from Lenzi, Penn., and his *delanantite* from Lenni, which have a pearly lustre; and T. Thomson's *erythrite*—from *  ρυθρ  ς*, red. W. Phillips called a flesh-red felspar resembling perthite, *murchisonite*—in honour of R. I. Murchison. It was obtained at Dawlish and Exeter. N. von Nordenskj  ld applied the term *lazur-felspar* to a felspar with the cleavage of orthoclase accompanying the lapis-lazuli of Lake Baikal. A. Breithaupt called the orthoclase from Hammond, New York, *laroclase*—from *λοφ  ς*, transverse; and *κλάσις*, fracture—in allusion to the peculiar cleavage parallel to the orthodiagonal section. J. L. Smith and G. J. Brush regarded it as a sanidine; and A. des Cloizeaux as a mixture of orthoclase and albite laminations. The so-called *sunstone*, *Pierre de soleil*, or *Sonnenstein*, was shown by T. Sch  erer, and A. des Cloizeaux to be an aventurine-orthoclase, associated with albite or oligoclase. J. C. Delam  therie called it *helv  lite*—from *  λ  ς*, the sun. I. Lea's *cassinite* is an aventurine-felspar from Lenni, Penn. T. Thomson's *perthite*, from Perth, Canada, was shown by T. S. Hunt to be a soda-potash felspar, and A. Breithaupt, G. A. Kenngott, and D. Gerhard showed that it consists of interlaminations of albite and orthoclase. Similar perthites were described by A. Streng, H. C  dner, G. Tschermak, P. Mann, J. H. Kloss, G. Woitschach, etc. When the laminations are visible only microscopically, F. B  ck called it *microperthite*; these minerals were examined by A. W. Stelzner. The name *microcline*—from *μικρ  ς*, a little; and *κλίνω*, to incline—was given by A. Breithaupt to felspars which have a slightly larger angle between the two cleavage planes than the 90   characteristic of orthoclase. G. Forchhammer applied the term *kr  b  te* to a mineral from Kr  bla, or Krafla, Iceland, and G. Flink called it *kraflite*. G. Forchhammer called a pearly mineral from Baula, *baulite*. P. Schirlitz, F. A. Genth, H. Buckstrom, etc., studied this mineral; and G. Flink regards it as a liparite rock containing orthoclase, quartz, etc. A. des Cloizeaux showed that while orthoclase is monoclinic, the microclines are triclinic. A. Breithaupt proposed the term *felsite* in place of felspar, and he suggested calling the non-microclincic felsite by the term *pegmatolite*. P. Mann, and C. T. Neubauer called perthite formed by the interlaminations of microcline and albite, *microcline-perthite*. W. C. Br  gger investigated the *orthoclase-microperthite*, the *microcline-microperthite*, and microperthites of other felspars. These are often characterized by a marked schlierenization. He assumes that the schlier is caused by laminations of the two felspars so extremely fine that they are not discernible by the microscope. He called these *cryptoperthites*. A. Breithaupt called the Amazon felsite *amazonite*. This is a bright, verdigris-green, microclincic felspar also called *amazon stone* or *Pierre des amazones*. It occurs in Ural, and South America. A. des Cloizeaux, and N. von Kokscharoff assumed the existence of two amazonites, one corresponding to orthoclase, the other to microcline.

The *schorl blanc* of J. B. L. Rom   de l'Isle   was probably soda-felspar, likewise also the *krumnbl  terigen Feldspath* of L. Hedenberg. It was called *albite*—from *albus*, white—by J. G. Gahn and J. J. Berzelius in 1815, and the mineral was analyzed by V. Eggertz in 1818. G. Rose regarded albite as an independent species; and A. Breithaupt proposed *tetartin* for the name of soda-felspar in allusion to the tetartohedral terminal faces. He also applied the term *percline* to a variety from the Alps—from *περικλιν  ς*, steep—in allusion to "the marked inclination of the terminal faces to the first lateral." Percline was analyzed by C. G. Gmelin. H. Thanlow, and W. Haidinger showed that percline and albite are the same. The subject was also discussed by F. Munz. A white lamellar albite from Chesterfield, Mass., was named *cleavelandite*—after P. Cleaveland—by H. J. Brooke. A blackish-green albite from Arendal was named by A. Breithaupt, *hyposcl  rite*—from *  ν  *, under; and *σκληρ  ς*, hard—in allusion to its softness. C. F. Rammelsberg said that 5 per cent. of pyroxene is present. T. Thomson applied the term *peristerite*—from *περιστέρη*, pigeon—to a white albite from Villeneuve, Canada. The name refers to the fanciful resemblance of its iridescent colours to those on the neck of a pigeon. T. Sch  erer called an albite from Snarum, Norway, *olafite*. The nature of this mineral was discussed by A. des Cloizeaux, A. Breithaupt, and C. H. Schneidhauer. O. L. Erdmann analyzed a Norwegian albite; C. F. Rammelsberg called it *sigteite* (not *syterite*) because it came from Sigtes   (not Sigterio) Island, Langesund fiord, and C. A. Tenne showed that it is a mixture of albite and eudialyte. H. S. Washington places sigteite in the plagioclase series between andesite and oligoclase, but with soda-anorthite (carnegieite) in place of anorthite. A. Breithaupt called a mineral from Andreasberg, Harz, *zyg  dite*—from *ζυγ  δην*, in pairs

M. E. Denaeher regarded microcline as being formed from three components in solid soln. B. Gossner writes for albite $\text{SiO}_3\text{Na}_2[\text{SiO}_2, \text{Al}_2\text{O}_3]4\text{SiO}_2$, and his hypothesis is also based on a kind of co-ordination plan which offers no particular advantages—*vide infra*. P. Niggli represented albite by

and E. T. Wherry by $\text{NaAl}(\text{Si}_3\text{O}_8)$. Many other suggestions have been made and are indicated by reference in the discussion on the general formulae for silicates. The impression obtained is that the arrangement of formulae consistent with the valencies of the atoms is rather a test of man's ingenuity than a representation of the orientation of the atoms. F. Rinne has obtained **X-radiograms** of sanidine and albite, and his interpretation of the results for orthoclase and albite is shown in Fig. 139, where R represents an atom of potassium or sodium. This result indicates that the formula of feldspar, $\text{RAl}(\text{Si}_3\text{O}_8)$, may have to be written $\text{RAlSi}(\text{Si}_2\text{O}_4)$ or $\text{RAlSi}(\text{SiO}_4)_2$.

A. Rivière said that the different kinds of feldspar cannot be sharply distinguished from one another, but pass gradually one into the other. C. F. Rammelsberg also considered that the feldspars should be regarded as an isomorphous family, and not as individual species. G. Rose expressed a similar view. He said that soda-feldspar passes into potash-feldspar by the simple substitution of potassium for sodium.

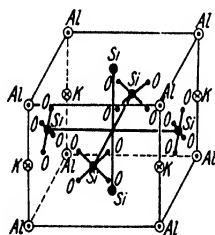

FIG. 139. — Stereochemical Scheme for the Molecules of Potash- and Soda-feldspars.

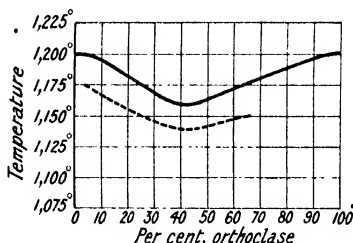

FIG. 140. — Fusion Curve of Binary Mixtures of Albite and Orthoclase.

H. Förstner described the native soda-orthoclases or anorthoclases, and their properties have been studied by F. Fouqué, C. Riva, and G. de Lorenzo and C. Riva. Homogeneous mixtures of the two feldspars are found only in volcanic rocks; in other cases, according to W. C. Brögger, the mixture appears as cryptoperthite, or, according to F. Becke, as microperthite. J. H. L. Vogt, and J. A. Douglas have made some observations on the m.p. of orthoclase and albite. E. Dittler obtained a curve approaching that indicated in Fig. 140. The dotted line represents the beginning of the melting, and the continuous line, the temp. when all is melted. There is a minimum in the curve corresponding with 56–60 per cent. of albite or 44–40 per cent. of orthoclase. There is no sign of the formation of a definite compound of the two feldspars.—*cf.* Fig. 157. J. H. L. Vogt assumed that the m.p. curve would represent type V (1. 10, 2), but E. Dittler's result, Fig. 140, corresponds with Type III. Feldspars between the limits $\text{Or}:\text{Ab}=72:28$ and $12:88$ give no evidence of the formation of mixed crystals.

The monoclinic alkali-feldspars are common in the more siliceous plutonic rocks—for example, orthoclase, muscovite, and quartz are the minerals most conspicuous in granites. There is also a tendency for the plagioclase to appear in the less siliceous rocks like the gabbros and basalts, and for the feldspars to approach anorthite as the proportion of silica in the rock decreases. W. Lindgren¹⁰ reported orthoclase as a gangue mineral in metalliferous mineral veins; and R. A. Daly found albite and

orthoclase in sedimentary limestones and dolomite. It is inferred that the feldspars are here of aq. origin, and in the calcareous muds, it is supposed to have been formed below 100° , probably below 70° . J. de Lapparent supposed that algae are responsible for the formation of some small crystals of albite which he found associated with the remains of algae and foraminifera. Orthoclase has not been reported in meteorites.

The synthesis of the alkali-feldspars.—Attempts to prepare crystals of alkali-feldspars by the simple fusion of a mixture of the constituents always furnish a glass. A. L. Day and E. T. Allen¹¹ suggested that the viscosity of the alkali-feldspars impedes their crystallization in a practicable time. L. Appert and J. Henrivaux heated glass for a long time in an annealing kiln near the softening temp., and claimed to have made microlites of feldspar. S. Meunier devitrified natural glasses, but, according to F. Fouqué and A. Michel-Lévy, no feldspar was produced. S. Meunier also reported orthoclase to be formed by the action of silicon tetrachloride on aluminium and potassium hydroxides, but F. Fouqué and A. Michel-Lévy regard this as non-proven. A. Brun claimed to have crystallized orthoclase glass by the action of fluoriferous vap. If an *agent minéralisateur* be present, crystallization may occur. For example, J. Leuarcie found that albite may be recrystallized when fused with half its weight of magnetite; a mobile liquid is thus formed within which crystallization can readily occur. P. Hautefeuille heated a mixture of an alkaline sodium aluminosilicate and tungstic oxide to 900° – 1000° , and obtained albite, and orthoclase was formed when potassium aluminosilicate was substituted for the sodium salt. A mixture of silica, alumina, and potassium tungstate also gave orthoclase; and a mixture of potassium aluminosilicate, and alkali phosphate and fluoride gave orthoclase and quartz. C. Doelter also obtained potassium-feldspar by fusing a mixture corresponding with KAlSiO_4 , and potassium fluoride and fluosilicate. A. L. Day and E. T. Allen heated a mixture of powdered albite glass and sodium tungstate. They found that the fragments of glass became crystalline without changing their form, indicating that the transformation occurred without dissolution of the material; on the other hand, R. C. Wallace observed that the crystallization at the zone of contact of the albite with the sodium tungstate is greatly accelerated, but the velocity of crystallization in the interior of the glass is not greatly affected. G. W. Morey and N. L. Bowen found that artificial crystals of orthoclase could be obtained by heating the glass and water vap. in a bomb. F. Fouqué and A. Michel-Lévy attempted to prepare artificial rocks containing orthoclase, but they succeeded only in producing plagioclase. K. Petrasch obtained albite in artificial rocks. K. Bauer obtained plagioclase by melting granite and Vesuvian lava; but both plagioclase and orthoclase were produced by melting a mixture of granite, sodium chloride, and potassium tungstate. J. Morozewicz heated various mixtures of the composition of trachyte rocks, and obtained no orthoclase, but he obtained an artificial liparite containing quartz, biotite, and sanidine when the liparite mixture and one per cent. of tungstic oxide was heated 14 days at 800° – 1000° . J. F. L. Hausmann, C. M. Kersten, A. Gurlt, A. Breithaupt, G. vom Rath, C. J. Heine, F. Zincken, J. T. Prechtel, H. Avich, and C. F. Rammelsberg observed orthoclase crystals in blast furnace slags. G. V. Wilson observed the formation of feldspar by the action of molten glass on bricks.

The alkali-feldspars seem to be produced more easily by hydrothermal processes. C. Friedel and E. Sarasin produced quartz and orthoclase by heating gelatinous silica, precipitated alumina, potassium hydroxide, and a little water in a steel tube at dull redness; and a mixture with the composition of albite with an excess of sodium silicate furnished albite when treated in a similar way. K. von Chrustschoff also obtained quartz and orthoclase by heating a mixture of dialyzed silicic acid, alumina, and potassium hydroxide at 300° for several months. W. J. Müller and J. Königsberger obtained orthoclase by heating aluminium hydroxide with potash water-glass in the presence of carbon dioxide. C. and G. Friedel obtained orthoclase by heating muscovite, potassium silicate, and water at 500° . The

critical temp. of water is near 366° , so that it is probable that steam acts as a gaseous agent *minéralisateur*, discussed by P. Niggli. E. Baur heated variable amounts of water, amorphous silicic acid, and potassium or sodium aluminate in steel tubes for several hours at 520° . Orthoclase and albite were obtained only from soln. containing an excess of base. The results are summarized in Figs. 141 and 142. In his study of the binary system, $\text{NaAlSi}_3\text{O}_8$ – KAlSi_3O_8 , N. L. Bowen found that the sodium compound occurs in two enantiomorphous forms, nephelite and carnegieite, with an inversion point at 1248° . The higher temp. form, carnegieite, melts at 1526° . The potassium compound also shows two forms: kaliophilite, isomorphous with nephelite, and a rhombic form with twinning, like that of aragonite. The rhombic form is apparently stable at temp. above 1540° , and melts at about 1800° . The potassium compound has a eutectic with carnegieite at 1404° . With nephelite, it forms an unbroken series of solid soln. It is concluded, therefore, that $\text{NaAlSi}_3\text{O}_8$ and KAlSi_3O_8 are the fundamental mols. of natural nephelite. The presence of calcium and of excess of silica in the natural mineral is explained by the solid soln. of the albite, $\text{NaAlSi}_3\text{O}_8$, and anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$, mols.

W. Vernadsky detected lithium, rubidium, and caesium in many feldspars, and

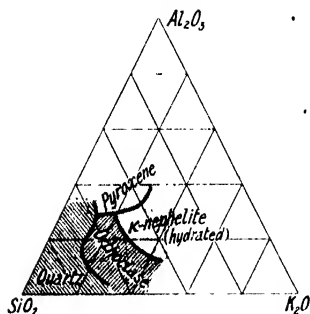

FIG. 141. — The Ternary System, K_2O – Al_2O_3 – SiO_2 , in the Hydrothermal Reaction at 520° .

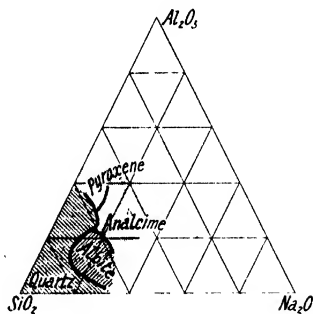

FIG. 142. — The Ternary System, Na_2O – Al_2O_3 – SiO_2 , in the Hydrothermal Reaction at 520° .

assumed that these elements were present as feldspars in solid soln. He synthesized *rubidia-feldspar*. P. Barbier found rubidium and lithium in 25 orthoclases and none in 19 microclines. Hence, he suggested the testing for the presence or absence of these elements as a chemical means of distinguishing microclines from orthoclases. W. Vernadsky and E. Revoutsky, however, showed that the test breaks down. Many microclines do contain these elements. H. Ramage confirmed this. W. H. Hillebrand found lithia in some microclines. A. de Gramont found rubidium, caesium, gallium, and thallium in the microclines from Madagascar; W. Vernadsky also found thallium in some orthoclases. E. Dittler made some feldspars which contained *lithia-feldspar*, *rubidia-feldspar*, and *caesia-feldspar*. The lithia-feldspar, $\text{LiAlSi}_3\text{O}_8$, obtained by R. Ballo and E. Dittler by fusing a mixture of lithium metaluminate and silica in the right proportions melts at about 1250° —*vide lithium aluminium mesotrisilicate*. P. Hautefeuille and A. Perry heated a mixture of silica, ferric oxide, potassium vanadate, and nitrate at 700° , and obtained iron leucite, and *ferric-orthoclase* whose composition corresponds with KFeSi_3O_8 .

The physical properties of the alkali-feldspars.—The purer feldspars are transparent and colourless. As T. Schøerer¹² indicated, the colour of many feldspars is due to the presence of various inclusions which act as pigments; these may be microscopic or submicroscopic. The opacity of feldspar crystals may arise from a multitude of inclusions. The yellowish, pink, and red tints usually come from iron oxides, although after calcination the red Swedish and Norwegian feldspars

often have a whiter colour than the white Canadian feldspars. The pinkish feldspars are usually potash-feldspars, though some albites have the same colour. Green colours are presumably derived from ferrous silicate inclusions, e.g. chlorite; but in some cases the cause of the colour is not known—*vide infra*, schillerization. The pearly bluish opalescence of Singalese moonstone may be due to the lamination of different feldspars; to inclusions; or to decomposition; it is most conspicuous when turned towards the observer. A. des Cloizeaux attributed the green coloration to copper compounds, but E. Erdmann said the colour is more likely to be organic matter since the green feldspar becomes white when calcined. Dark grey feldspars owe their colour to innumerable dark-coloured inclusions or minute particles. These are common in the lime-feldspars.

The crystals of the alkali-feldspars were examined by J. B. L. Romé de l'Isle,¹³ E. Pini, C. S. Weiss, G. Rose, A. T. Kupfer, J. D. Mackenzie, K. Schlossmacher, etc. The general results showed that the crystals belong to the monoclinic system; and N. von Kokscharoff gave for the axial ratios of orthoclase $a:b:c = 0.6585:1:1:0.5538$, and $\beta = 63^\circ 56' 46''$. The crystals of plagioclase and anorthite belong to the triclinic system, and since most of these contain appreciable quantities of potassium in solid soln., it must be assumed that monoclinic orthoclase can form isomorphous mixtures with triclinic plagioclase, or that potash-feldspar is dimorphous. In 1876, A. des Cloizeaux¹⁴ showed that many potash-feldspars are optically triclinic, and he grouped these under the name microcline. About the same time, on account of irregularities in angles and cleavages, E. Mallard, and A. Michel-Lévy suggested that if the cross-twinning and interpenetration of microcline be so minute as to be invisible under the microscope, the crystals would appear to be monoclinic and possess all the optical properties of orthoclase; otherwise expressed, ordinary orthoclase is extremely finely lamellated microcline. If this actually be the case, then orthoclase would be pseudo-monoclinic, but in reality it is triclinic; and the feldspars, as a class, are all triclinic. This question has given rise to much discussion by A. Michel-Lévy and A. Lacroix, W. C. Brögger, P. Groth, R. Brauns, H. Förstner, F. Klockmann, F. Rinne, A. Beutell, J. Lehmann, F. Becke, J. H. L. Vogt, etc. H. A. Miers, J. D. Dana, H. Rosenbusch, C. Doelter, F. Zirkel, and G. Tschermak regard potash-feldspar as dimorphous with monoclinic orthoclase and triclinic microcline. C. Hintze regards potash-feldspar as exclusively triclinic with orthoclase as a pseudo-monoclinic form. According to F. Klockmann, if orthoclase be really triclinic, the axial ratios are $a:b:c = 0.6495:1:0.5546$, and $\alpha = 90^\circ 7'$, $\beta = 115^\circ 50'$, and $\gamma = 89^\circ 55'$. According to E. Mackinen, alkali-feldspars with 0-30 per cent. of orthoclase crystallize triclinic at the highest temp., and those with 30-100 per cent., monoclinic.

The crystals of albite were examined by G. Rose, G. vom Rath, M. Schuster, B. Krebs, etc. A. des Cloizeaux gave for the axial ratios of the triclinic crystals, $a:b:c = 0.63347:1:0.55771$, and $\alpha = 94^\circ 3'$, $\beta = 116^\circ 28\frac{1}{2}'$ and $\gamma = 88^\circ 8\frac{1}{2}'$; S. von Glinka gave $0.6330:1:0.5573$, and $\alpha = 94^\circ 5'$, $\beta = 116^\circ 27'$, and $\gamma = 88^\circ 7'$; B. Krebs, $0.6352:1:0.5584$, and $\alpha = 94^\circ 14.6'$, $\beta = 116^\circ 35.7'$, and $\gamma = 87^\circ 46.0'$; C. Melzer, $0.635:1:0.5578$, and $\alpha = 94^\circ 6'$, $\beta = 116^\circ 36\frac{1}{2}'$, and $\gamma = 87^\circ 52'$; C. Dreyer and V. M. Goldschmidt, $0.6376:1:0.5592$, and $\alpha = 94^\circ 15'$, $\beta = 116^\circ 37'$, and $\gamma = 87^\circ 41'$; and C. Viola, $0.635:1:0.657$, and $\alpha = 94^\circ 15'$, $\beta = 116^\circ 32'$, and $\gamma = 88^\circ 5'$.

The monoclinic feldspars with notable amounts of soda can be called *soda-orthoclases*; here the molar proportion of soda is less than that of the potash. When the molar proportion of soda exceeds that of the potash, the crystals are generally triclinic, and are *soda-microclines*, or *anorthoclases*. P. Barbier and co-workers' analyses of some potash-soda-feldspars showed that although the soda was in excess of the potash, the crystals were monoclinic—in one case only 1.15 per cent. K_2O was present. F. Angel described a monoclinic soda-sanidine. The monoclinic soda-feldspar was called *barbierite* by W. T. Schaller. It therefore appears that soda-feldspar and potash-feldspar are dimorphous. The available evidence as to

whether the mixed alkali-felspars are simply isomorphous or isodimorphous is not conclusive. H. Baumhauer, and F. J. Wiik found the **corrosion figures** obtained by treating adularia with hydrofluoric acid are characteristic of the monoclinic system. H. Baumhauer also examined the effect with albite. J. Königsberger and W. J. Müller obtained corrosion figures with potash-felspar and water. A. E. Fersman found tourmaline and felspar grouped together at Mursinka, Ural.

As a rule, equidimensional crystals are found most frequently in potash-felspar in large prismatic crystals. The microscopic crystals of potash-felspar are usually tabular. In the idealized crystal, Fig. 143, the faces are $M(010)$, $P(001)$, $l(110)$, $x(101)$, $y(20\bar{1})$, $o(111)$, and $n(021)$; and the angles are lM , $59^\circ 24'$; ll , $61^\circ 13'$; Px , $50^\circ 17'$; Py , $80^\circ 18'$; and Pn , $44^\circ 57'$. These angles have been measured by N. von Kokscharoff, V. von Zepharovich, A. Hamberg, G. A. Kenngott, N. V. Ussing, A. Cathrein, A. des Cloizeaux, A. Lévy, M. von dem Borne, A. Becker, M. Websky, G. vom Rath, R. Brauns, M. Schuster, J. H. Kloos, F. A. Quenstedt, A. Beutell, F. Klockmann, G. Kalb, etc. F. Rinne, S. Kozu and K. Seto investigated the **X-radiogram** of sanidine; S. Kozu and co-workers, the X-radiograms of moonstone and adularia—*vide infra*, Fig. 146; E. Schiebold, that of albite; and A. Hadding, those of the adularia, sanidine, albite, microcline, microperthite, and anorthoclase. For deductions from the X-radiograms of the alkali felspars, *vide* Fig. 139. The crystals show three distinct **habits**, (i) the *Bavono habit*, in which the crystal is elongated along the faces PM , Fig. 144; (ii) the *sanidine habit*, in which the crystals are tabular along M , Fig. 145; and (iii) the *adularia habit*, in which the prismatic crystals have rear hemidomes, Fig. 146.

Adularia
Habit.

The crystals of felspar are usually twinned, but sometimes not twinned. The twinning may be in one, two, or three directions. Sixteen different modes of twinning have been observed. Some are extremely rare; some may be chance groupings. F. Scharff has discussed *Die Bauweise des Feldspaths*. The three most common modes of **twinning** are named after particular localities where the first specimens which attracted notice were found—Carlsbad, Bohemia; Bavono, North Italy; and Manebach, Thuringia. The first two were named by F. A. Quenstedt, and the last one by J. R. Blum. The second kind was described by J. B. L. Romé de l'Isle, and all three were described by R. J. Haüy. The twinning of potash-felspar was also discussed by F. Mohs, C. F. Naumann, J. D. Mackenzie, G. vom Rath, J. F. L. Hausmann, A. Breithaupt, G. Cesaro, G. Rose, N. von Kokscharoff, E. A. H. Laspeyres, G. Tschermak, J. Hirschwald, L. Calderon, F. Klockmann, W. Müller, K. Haushofer, O. Mügge. (i) In *Carlsbad twinning*, Fig. 145, the face $M(010)$ is the plane of the twinning so that it truncates the obtuse edge of the vertical crystal. In the diagram, analogous faces are indicated by a letter with and without a dash. J. W. Goethe thus alluded to the Carlsbad twinning:

The individuals in the doubled crystals are so interlocked that it is impossible to consider one without considering the other. A description of their form is not sufficient to bring it to the imagination, though they may be considered as two rhombic tables united to one another.

The crystals may be united as in Fig. 147, or that diagram reversed, thus forming right or left-handed twins. (ii) In *Baveno twinning* the crystals are attached to the rocks at one end, and at the free-end they show a very obtuse angle with a twin suture, Fig. 148. The two individuals are united by the $n(021)$ plane. (iii) In *Manebach twinning*, Fig. 149, two individuals are united by the $P(001)$ plane;

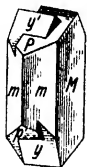

FIG. 147.—
Carlsbad Twin.

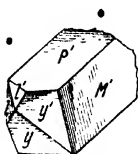

FIG. 148.—Baveno
Twin.

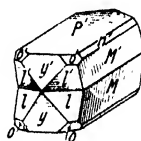

FIG. 149.—Mane-
bach Twin

and the base and the prism faces of the normal crystal form a prominent re-entrant angle. Sometimes Manebach and Baveno twinings are combined in a single group.

The faces of the idealized crystal of albite, Fig. 150, are illustrated by $M(010)$, $P(001)$, $L(110)$, $l(110)$, $x(101)$, and $o(11\bar{1})$, and the angle $MP = 86^\circ 21'$; $ML = 60^\circ 26'$; $IL = 59^\circ 14'$; $Pl = 65^\circ 17'$; $PL = 69^\circ 10'$; $Mo = 66^\circ 18'$; and $Pr = 52^\circ 16'$. Measurements were made by A. des Cloizeaux, F. Klockmann, S. von Glinka, etc. F. Scharff has written *Ueber die Baueise von Albite und Periklin*. The twinning of albite occurs according to the Carlsbad, Baveno, and Manebach plans, but less frequently than is the case with orthoclase. The so-called albite twinning is exceedingly common. (iv) In the *albite twinning*, Fig. 151, the two individuals are united by the $M(010)$ plane, and the faces PP' at the exposed end make an angle of $7^\circ 12'$. (v) In *pericline twinning*, Fig. 152, the contact plane of the individuals

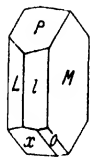

FIG. 150.—
Idealized Albite
Crystal.

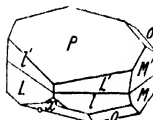

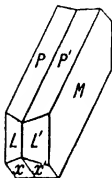

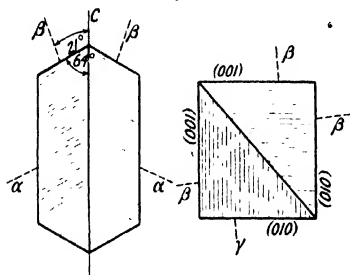

FIG. 152.—Pericline
Twin

is nearly along the plane P , not by reflection, but rather by rotation about the edge Px . The line of intersection of the faces MM' is not parallel to the edge PM , but makes an appreciable angle with it. This angle depends on the composition of the felspar. For instance,

Microcline.	Anorthite.	Labradorite.	Andesine.	Oligoclase.	Albite.
-80°	-18°	-9°	$\bullet \quad 0^\circ$	$\bullet \quad 1^\circ$	$13^\circ 27'$

The pericline lamellæ are less common than the albite lamellæ; but both are abundant and very thin in microcline. The polysynthetic twinning of microcline according to the albite and pericline types* is common. Fine striations by the albite twinning can often be observed on the basal face. The two kinds of twinning may give a double series of fine lamellæ nearly at right angles to one another, imparting a peculiar and characteristic grating structure when a basal section is examined in polarized light. Parallel growths of albite on orthoclase and orthoclase on albite are common; and the faces MIL are approximately parallel. This

parallel intergrowth is readily seen in perthite; finer parallel intergrowths pass into microperthite or cryptoperthite; and finer still, into anorthoclase. G. Cesaro, G. Rose, G. vom Rath, C. F. Naumann have discussed the twinning of albite. Felspars usually show distinct **cleavage** which may be interrupted without extending to the full length of the crystal. The cleavage parallel to the (001)-face

FIGS. 153 and 154.—Cleavages of Carlsbad and Baveno Twins of Orthoclase

is generally more distinct than that parallel to the (010)-face. Some laval felspars do not show cleavage cracks.° The cleavages of Carlsbad and Baveno twins are illustrated in Figs. 153 and 154. S. L. Penfield made some observations on the cleavage of albite; and J. Lehmann, on the contraction cracks in that mineral. Parting is sometimes distinct, and often parallel to the (100)-face, sometimes also parallel to a hemi-orthodome and inclined a little to the orthopinacoid producing a satin-like lustre or **schiller**. The pearly opalescence or schiller may be present when the parting is not distinct. The schiller has been discussed by F. E. Reusch, N. Fukuchi, Lord Rayleigh, A. des Cloizeaux, G. vom Rath, and W. Cross. W. C. Brögger assumes that schillerization is produced by extremely fine interlamination of albite and orthoclase not discernible microscopically as in cryptoperthite. Moonstone also receives its name from this property. S. Kozu and co-workers showed that the double arrangement of spots in the X-radiogram disappear at 790°, and schillerization also disappears at this temp. Hence, it is inferred that this property is caused by a special arrangement of the space-lattices of two different kinds of solid soln.—*vide infra*. In some cases the schiller is due to the interference phenomena and reflections from minute inclusions arranged in definite positions in felspar crystals—*e.g.* labradorite. The sunstone and aventurine effects are produced by inclusions—hematite, or hydrated ferric oxide—which may be quite large. The **fracture** is uneven or conchoidal in directions other than those of the cleavage.

In most cases, the plane of the optic axes of orthoclase is perpendicular to the (010)-face, and the normal is inclined 21° to the *c*-axis; in other cases, the plane of the optic axis is parallel to the (010)-face. With microcline, the plane of the optic axes is nearly perpendicular to the (010)-face. A. des Cloizeaux¹⁵ found the optic axes of albite proper are always normal to a plane which cuts the angle (001)(010), and makes with (001) an angle of 101°–102°. A. des Cloizeaux found the **optic axial angles** of adularia to be $2V=69^{\circ} 43'$, and $2E=121^{\circ} 6'$. The angles are very variable with different specimens; and in some cases $2V$ is so small that the crystal is nearly uniaxial. The values observed for different samples of orthoclase by A. des Cloizeaux, E. Goens, T. Wolf, G. vom Rath, A. Mühlheims, K. Zimanyi, and F. Kohlrausch range from $2V=11^{\circ} 51'$ – $84^{\circ} 26'$; and $2E=18^{\circ} 14'$ – $126^{\circ} 22'$. For microcline, and Na-light, N. V. Ussing obtained $2H_a=87^{\circ} 30'$; $2H_e=101^{\circ} 7'$; and $2V=83^{\circ} 41'$. For albite, A. des Cloizeaux's, and M. Schuster's values range from $2H_a=80^{\circ}$ – $88^{\circ} 50'$; and $2H_e=102^{\circ}$ – $109^{\circ} 26'$ for the red ray. C. Schmidt obtained $2H=83^{\circ} 45'$ for the Li-ray; 84° for the Na-ray; and $84^{\circ} 18'$ for the Tl-ray. K. Zimanyi gave $2V=80^{\circ} 58'$. H. Förstner made numerous observations on the values for anorthoclases, $2E$ ranged from $69^{\circ} 26'$ – $89^{\circ} 48'$ for Li-light; $68^{\circ} 27'$ – $88^{\circ} 27'$ for Na-light; and $67^{\circ} 18'$ – $86^{\circ} 33'$ for Tl-light. $2V$ ranged from $41^{\circ} 52'$ – $54^{\circ} 40'$ for Li-light; $41^{\circ} 0'$ – $53^{\circ} 32'$ for Na-light; and $40^{\circ} 12'$ – $52^{\circ} 22'$ for Tl-light. $2H_a$ ranged from $41^{\circ} 39'$ – $55^{\circ} 9'$ for Li-light; $40^{\circ} 52'$ – $54^{\circ} 19'$ for Na-light; and $40^{\circ} 12'$ – $53^{\circ} 3'$ for Tl-light. $2H_e$ ranged from $125^{\circ} 14'$ – $151^{\circ} 33'$

for Li-light; $126^{\circ} 12' - 152^{\circ} 33'$ for Na-light; and $127^{\circ} 21' - 154^{\circ} 15'$ for Ti-light. H. Fischer has made a special study of the optical properties of albite.

A. des Cloizeaux found that the effect of raising the temperature on the optic axes of microcline is insignificant, but the effect is very marked with orthoclase. The variability of the optic axial angle with temp. indicates an unstable mol. structure with respect to temp. The optic axial angle of sanidine from Laach, with red light, was found to be $2E = 13^{\circ}$ at 18° , and at 42° the crystals became uniaxial, at a higher temp., the optic axes separated out in the vertical plane, becoming parallel to the (010)-face instead of being perpendicular as at 18° . The different stages of this change are illustrated by the optic axial angles of crystals found in nature. In another sample

Temp.	43°	60°	100°	150°	190°	250°	302°	342.5°
$2E$	6°	18°	30°	40°	46°	53°	60°	64°

S. Kozu and co-workers represented the relation between the optic axial angle and temp. and wave-length of light constant, and the relation between the optical axial angle and wave-length and temp. constant, by a series of curves. With albite, A. des Cloizeaux found an increase of 2.5° when the temp. rose from $21.5^{\circ} - 170.8^{\circ}$. H. Förstner found that while in some cases, raising the temp. from $20^{\circ} - 250^{\circ}$ did not alter the value of $2E$, and on raising the temp. to 500° the value of $2E$ changed from $87^{\circ} 46' - 86^{\circ} 31'$, in other cases there was a change amounting to about 4° . There was usually a steady fall from $20^{\circ} - 250^{\circ}$, and subsequently a small increase. J. Beckenkamp made some observations on adularia; and F. Rinne, on albite. H. Bücking found that the effect of pressure was similar to that of temp.

The specific gravity has been determined of a large proportion of the samples of feldspar which have been analyzed. The numbers for orthoclase range from H. Abich's¹⁶ value 2.2467 for adularia to, for example, G. vom Rath's 2.619 for a sample of orthoclase from Bodenmais. L. Ahlers gave for theoretically pure orthoclase 2.536-2.438 at 4° . There is no appreciable difference in the values for the different varieties; and the best representative value for orthoclase is near 2.537. P. Hautefeuille's value for artificial orthoclase is 2.55 at 16° . Similarly for albite, the values range from G. vom Rath's 2.573 for a sample from Lagenburg, to F. L. Sperry's 2.633 for a sample from Haddam, Connecticut. L. Ahlers gave for theoretically pure albite 2.611-2.613 at 4° . The best representative value for albite is 2.613. P. Hautefeuille's value for artificial albite is 2.61 at 16° . The values for anorthoclase naturally depend on the relative proportions of Na : K, as well as on the composition generally. The observed values range from H. Förstner's 2.595 with a percentage (weight) ratio 7.99 : 2.53, to F. J. Wijk's 2.567 with the weight ratio 5.47 : 11.901; but comparable values for the Na : K ratio are not available since other variations in composition are involved. G. Tschermak, however, gave for adularia, approximately Or to Or_4Ab , 13-16 per cent. K_2O , the sp. gr. 2.56-2.57; amazonite, Or_4Ab_2 to Or_3Ab_2 , 10-13 per cent. K_2O , 2.57-2.58; perthite, Or_3Ab_2 to OrAb, 7-10 per cent. K_2O , 2.58-2.60; loxoclase, OrAb to $OrAb_4$, 4-7 per cent. K_2O , 2.60-2.61; and albite, Ab to Ab_4An , 10-12 per cent. Na_2O , 2.62-2.64. C. St. C. Deville found that adularia crystals had a sp. gr. 2.561, and after fusion, 2.351; J. A. Douglas obtained respectively 2.575 and 2.370. This corresponds with an expansion of 8.65 per cent. J. W. Mellor obtained with commercial feldspar respectively 2.611 and 2.467, or an expansion of about 6 per cent. The effect of the at. vol. of potassium and sodium on the limited isomorphism of albite and orthoclase was discussed by E. T. Wherry. The hardness of albite and of adularia on Moh's scale is about 6. F. Auerbach gave for the absolute hardness (2, 20, 7) of adularia, 253; or on a scale corundum 1000, 210; R. Frantz gave for the same scale, 392; F. Pfaff, 310; A. Rosiwal, 59; and T. A. Jagger, 25. P. J. Holmquist found that the abrasive hardness of adularia is 316 for the (001)-face; 478 for the (010)-face; and 493 perpendicular to

(010)(001); he also measured the cutting hardness of adularia, microcline, sanidine, soda-orthoclase, and albite, using carborundum of grain-size 0.006–0.012 mm. on different faces of the crystals. The results are illustrated by Fig. 155.

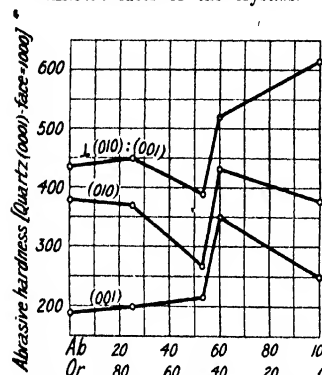

Fig. 155.—Cutting Hardness of the Albite-Orthoclase Felspars.

F. Auerbach gave for the **elastic modulus** of adularia, perpendicular to the base, 8460 kgms. per sq. mm., and of sanidine, 8030 kgms. per sq. mm. F. Rinne found 8120 kgms. per sq. mm. for adularia, and 7710 for sanidine; and for the crushing strength of orthoclase (Hirschfeld), 1700 kgms. per sq. cm. According to L. H. Adams and E. D. Williamson, the **compressibility**, β , of microcline, $\text{Or}_{91}\text{Ab}_9$, is 1.92×10^{-6} at 0 megabars, 1.88×10^{-6} at 2000 megabars, and 1.68×10^{-6} at 10,000 megabars, or $\beta = 0.051875 - 0.010242(p - p_0)$; orthoclase and micropertnite have nearly the same values for their compressibilities. E. Madelung and R. Fuchs gave $\beta = 1.74 \times 10^{-6}$ ($p = 125$ atm.) for orthoclase, and adularia. P. W. Bridgman

failed even at 30,000 kgms. press. per sq. cm. to make finely powdered felspar particles weld, owing possibly to films of air.

H. Kopp¹⁷ gave for the coeff. of **cubical expansion** of orthoclase between 13° and 47°, 0.000026; and between 15° and 99°, 0.000017. F. Pfaff found the mean **linear expansion** coeff. of adularia to be 0.000015687 in a direction perpendicular to the *a*- and *c*-axes; 0.00000059 in the direction of the *b*-axis, and 0.000002914 in the direction of the *c*-axis. The coeff. of cubical expansion is then 0.00001794. H. Fizeau found for the axes of greatest mean and least dilatation of adularia 0.000019052, 0.000001507, and 0.000002030 respectively. The mean linear expansion is -0.000002030 to -0.0000020039 ; and J. Beckenkamp gave for the coeff. of linear expansion of adularia in the three directions 0.00001758, 0.0000019, and 0.0000063. E. S. von Federoff, E. Offret, and J. Joly also made observations on the thermal expansion of felspar. H. de Sénarmont found the **thermal conductivity** to be greatest in the direction of the symmetrical axes. E. Jannetaz found the sq. root of the ratio of the thermal conductivity in the direction of the symmetry axis (100), to the (001) axis in the direction (001) to be 0.951. F. E. Neumann found the **specific heat** of adularia to be 0.1861; of felspar from Lomnitz, 0.1911; and of albite from Penig, 0.1961. H. Kopp gave 0.183 for orthoclase between 20° and 51°; and 0.190 for albite between 21° and 51°. P. E. W. Oeberg gave 0.1897 for orthoclase, and 0.1976 for albite between 15° and 100°. J. Joly gave for orthoclase 0.18865–0.18992 between 11° and 100°; between 0.18696 and 0.19219 for microcline; and between 0.19828 and 0.19846 for albite. R. Ulrich gave 0.1952 for orthoclase between 17° and 98°. K. Schulz found between 20° and 100° for amorphous (glass) adularia 0.1895, and crystalline, 0.1855; for amorphous microcline between 0.1881 and 0.1919, and crystalline, between 0.1845 and 0.1878. G. Tammann also gave for amorphous microcline 0.185 and for crystalline 0.197 between 20° and 100°. G. Lindner gave for adularia at 50°, 0.1835; at 100°, 0.1864; at 150°, 0.1956; and at 250°, 0.2140. A. Bartoli found the sp. ht. of orthoclase between 25° and 100° to be 0.204; between 28° and 309°, 0.226; and between 33° and 715°, 0.253. W. P. White gave for orthoclase crystals between 0° and 500°, 0.2247; and 0°–1100°, 0.2509; likewise for orthoclase glass 0.2297 at 0°–500°, and 0.2589 at 0°–1100°; for the true sp. ht. at 500° and 1100° he gave respectively 0.257 and 0.279 for orthoclase crystals, and 0.264 and 0.279 for the glass. A. Dannholm made measurements on this subject; and S. Kozu and

S. Saiki found abrupt changes in the linear expansion of adularia at 280°, 480°, 680°, 870°, and 950°.

Orthoclase has no sharp melting point. It melts slowly on a rising temp.; while its rate of fusion is small, its rate of crystallization must be extremely slow. A. L. Day and E. T. Allen¹⁸ were unable to crystallize the cooling mass by slow cooling, by mechanical vibration and shock during cooling; by circulating air, carbon dioxide, or water vap. about the cooling mass; or by the action of an alternating current on the cooling mass. The difficulty in crystallization was attributed to the great viscosity of the molten glass. According to A. L. Day and E. T. Allen, the dry crystalline powder was heated and prodded from time to time with a stout platinum wire. At about 1000°, traces of sintering were observed; at 1075°, it had formed a solid cake which resisted the wire, at 1150°, the cake had softened sufficiently to yield to a continuous press; and at 1300°, it had become a viscous liquid which would be drawn out into glassy opaque threads. Under the microscope, the opacity appeared to be due to fine included bubbles, the material being wholly vitreous. The term *melting point* thus appears somewhat of a misnomer, since the "point" is not a definite temp. but an interval of temp. - softening temperature is therefore a better term. This phenomenon is the normal kind of thing with complex aluminium silicates. S. Kozu and co-workers found that when examined by the X-radiogram method, a potash-felspar with about 23 per cent. of albite shows feeble indications of fusion at 1100°, and only at 1213° was fusion complete. The mineral was kept at the indicated temp. for 2 hrs. The liquidus therefore begins at 1213°, and the solidus at 1100° with a melting interval of 113°. In the particular case of orthoclase, G. W. Morey and N. L. Bowen showed that there is an incongruent m.p. at 1170°, incongruent

because the liquid has a different composition from the solid owing to the formation of a new crystalline compound, namely, leucite, KAlSi_2O_6 . Otherwise expressed, orthoclase decomposes at 1170°, forming leucite, KAlSi_2O_6 , and a liquid. Its behaviour is best described on an equilibrium diagram with leucite (Lc) and silica as components. Orthoclase then appears as a binary compound of these components. If orthoclase be kept at 1200° for a week, the glassy mass contains leucite crystals and crystallites. The resolution of molten orthoclase into leucite was previously discussed by H. Bäckström, A. Lacroix, and C. Doelter. The speed of fusion depends on the size of grain; and J. W. Mellor and co-workers showed that there is a probability that the actual fusion temp. is lower with a fine powder than it is with coarser grains.

This subject was discussed by W. Ostwald, F. W. Küster, R. C. Smith, P. Pawloff, M. T. Goldstein, P. P. von Weimarn, and C. Doelter. It is possible, as pointed out by G. Beilby, that the grinding renders the surfaces of the particles vitreous or amorphous—*vide* the sp. gr. of quartz. H. Leitmeier found that fine grains of adularia begin to melt at 1240°, coarse grains at 1300°; complete fusion occurred at 1350° with the fine grains and 1370° with the coarse grains. The high values here obtained were due to rapid heating; with slower heating, the m.p. appeared as 1145°. S. Kozu and co-workers also found evidence of a faster fusion with finely powdered felspar than is the case with the coarser-grained material. Accordingly, the reported values for the fusion temp. of orthoclase are somewhat discordant, and range from 1140° to 1300°. J. Joly obtained 1140° for the m.p. of sanidine; and 1175° for adular, microcline, and albite. R. Cusack gave

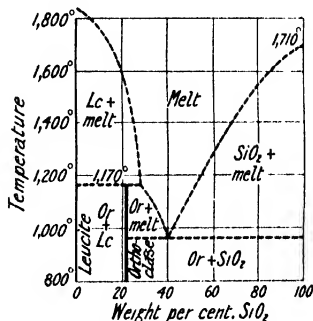

FIG. 156.—Equilibrium Curves of the Binary System: KAlSi_2O_6 - SiO_2 .

1169° for microcline, and 1172° for albite; A. L. Fletcher corrected these values to 1219° for microcline, 1214°–1218° for adularia, and 1222° for albite. J. H. L. Vogt gave 1300° for potash-felspar. H. A. Seger, and A. S. Watts made observations on the relation between the composition and fusibility of felspars. E. Dittler gave for soda-microcline, 1175°–1200°; soda-felspar, 1137°–1180°; crypto-perthite, 1130°–1140°; microcline, 1160°–1180°. C. Doelter gave for different samples of orthoclase, 1185°–1220°, and 1175°–1235°; for sanidine, 1145°–1175°; for microcline, 1150°–1160°, 1155°–1180°, and 1160°–1265°; and for albite, 1120°–1160°, 1130°–1170°, and 1135°–1215°. A. Brun found 1250° for albite, 1300° for orthoclase, and 1290° for microcline. Y. Yamashita and M. Majima gave 1250° for the m.p. of an albite orthoclase. A. L. Day and E. T. Allen gave 1175°–1235° for orthoclase; 1220° for natural albite, and 1225° for artificial albite.

A. L. Day and co-workers found the m.p. near the albite end of mixtures of soda- and potash-felspars are difficult to determine on account of the high viscosity of the melting solids. E. Dittler believed that albite and orthoclase form a completed series of mixed crystals with a minimum m.p.; J. H. L. Vogt estimated that there is a eutectic between 1150° and 1160° with between 56 and 60 per cent. of albite and between 40 and 43 per cent. of orthoclase. He assumed that the eutectic mixture consisted of two kinds of felspar with the respective compositions $\text{Or}_{72}\text{Ab}_{28}$ and $\text{Or}_{12}\text{Ab}_{88}$.

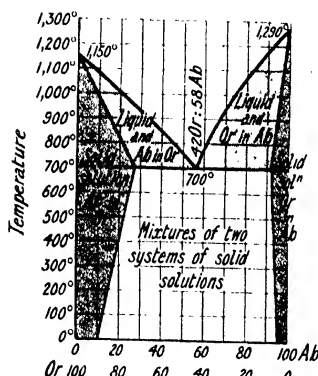

FIG. 157.—Freezing-point Curves of Mixtures of Albite and Orthoclase.

felspar carrying more than 8 per cent. of orthoclase. C. H. Warren also found evidence of an inversion point in potash-felspar above 575°; below this temp. α -potash-felspar is stable; above, β -potash-felspar. A. L. Day and co-workers found no signs of a break in the heating and cooling curves of felspar. This subject has been discussed by R. Herzenberg, and P. Tschirwinsky. H. Leitmeier observed a slight loss in weight which he attributed to the loss of alkali, when adularia (m.p. 1145°) or labradorite (m.p. 1245°) is kept about 10° below the m.p. for 500 hrs. The loss was of the order 0.2 per cent.

The **X-radiograms** of sanidine by F. Rinne, and of adularia, moonstone, etc., by S. Kozu and Y. Endo are normal and characteristic of one system of space-lattices, as L. Vegard and H. Schjeldrup found to be characteristic of a simple lattice in which corresponding atoms replace one another at random, forming a homogeneous solid soln. The case is different with the potash-felspar moonstone containing about 23 per cent. of albite. S. Kozu and Y. Endo found that X-radiogram furnishes two systems of space-lattices representing the co-existence of two kinds of solid soln. The X-radiogram of adularia suffers no change when the temp. is raised from 25° to 1060° and suddenly quenched in mercury at room temp. This indicates that the crystal structure is stable throughout this range. On the other

the eutectic mixture consisted of two kinds of felspar with the respective compositions $\text{Or}_{72}\text{Ab}_{28}$ and $\text{Or}_{12}\text{Ab}_{88}$. P. Tschirwinsky modified the equilibrium diagram to make it fit the facts a little better—cf. Fig. 140. The equilibrium is illustrated diagrammatically in Fig. 157. C. H. Warren estimated that orthoclase can carry up to about 10 per cent. of albite in solid soln., and that albite may take up similarly 8 per cent. of orthoclase. If a potash-felspar has more than about 10 per cent. of albite in solid soln., as the temp. falls, there will be a dissociation into two kinds of solid soln., and the so-called perthitic structure is considered to be a result of this dissociation. The perthitic structure thus occurs with potash-felspars carrying more than about 18 per cent. of albite. Similarly with soda-

hand, when the temp. of moonstone is raised, one of the two different systems of Laue-spots begins to decrease in intensity and to shift gradually towards the other, and the two systems merge into one. When the temp. is *slowly* reduced, the system of Laue-spots, stable at a high temp., begin to separate into two systems. Chillings in liquid air produce no appreciable difference to the results obtained by chilling in mercury at room temp. Fig. 158 shows portions of the X-radiograms of a potash-felspar heated to the temp. indicated above and rapidly chilled. Below 800° , the miscibility is incomplete, but at higher temp. albite and orthoclase are miscible in all proportions. If heated above 1115° , the spots gradually decrease in intensity, indicating that the space-lattices are gradually broken down into the disorderly arrangement of the amorphous state, and at 1190° the spots had almost all disappeared corresponding with almost complete fusion. A. Hadding did not find the differences in the X-radiograms to be sufficient for the identification of the different felspars.

The ceramic journals have an indefinitely large number of results of experiments on various mixtures of clay with felspar, feldspathic rocks, and other fluxes. Mixtures of orthoclase and quartz were found by M. Simonis to give glassy mixtures

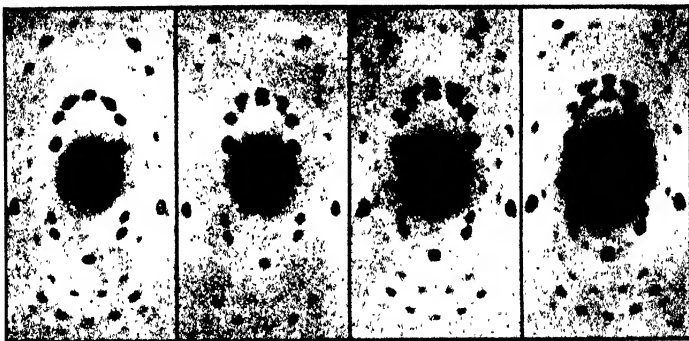

FIG. 158. - Effect of Heating and Chilling Or Ab felspar with about 24 per cent. of Albite.

with no sign of a eutectic; A. S. Watts made analogous observations and obtained indications of a eutectic with 5 per cent. of felspar; J. W. Mellor likewise obtained indications of a eutectic with 25 per cent. of quartz. In both cases, however, the results measure some other quality but not eutectism. Pegmatite with about 25 per cent. of quartz and 75 per cent. of felspar has been thought to represent the eutectic, but there is no proof of this. A. Zöllner estimated that at 1400° - 1450° , molten orthoclase can dissolve 60-70 per cent. of quartz. The fusion temp. of mixtures of china clay and felspar were measured by M. Simonis. A. Heath and J. W. Mellor made a rough estimate that at 1300° , molten orthoclase dissolves about 20 per cent. of clay to form a clear glass in a 3 days' heating, and A. Zöllner estimated that about 14 per cent. is dissolved at 1400° - 1460° to form a clear glass. E. Berdel and many others have determined the shrinkage and porosity of slabs made of mixtures of felspar and clay. M. Simonis measured the softening temp. of ternary mixtures of felspar, quartz, and china clay, and the results are summarized in Fig. 159. W. S. Howat found that with binary mixtures of steatite melting at 1380° , and microcline melting at 1232° , there was a eutectic in the vicinity of 1160° .

A. L. Day and E. T. Allen found that felspars could be readily sublimed in the electric arc furnace—about 3700° . D. D. Jackson and J. J. Morgan found the **vapour pressure** of the alkali to be negligibly small below 1350° . N. V. Kulaschaff computed for the latent **heat of fusion** of orthoclase, 109.4 cal., and for albite,

48.5 cal. J. H. I. Vogt gave 100 cal. for potash-felspar. O. Mulert found the **heat of solution** of crystalline adularia in hydrofluoric acid to be 0.4686 Cal. per

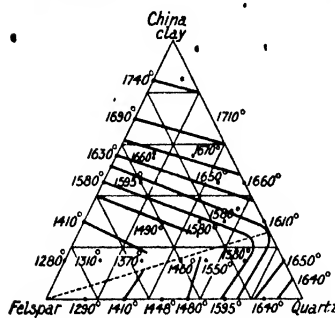

FIG. 159.—Softening Temperatures of Mixtures of Orthoclase, Quartz, and China Clay.

and hydrofluoric acids, 517 cal. per gram for the crystals, and 600 cal. per gram for the glass.

The **indices of refraction** of potash-felspar were measured by A. des Cloizeaux,¹⁹ F. Kohlrusch, K. Zimanyi, A. Mühlheims, S. Tauboi, H. Rosenbusch and E. A. Wulfing, N. V. Ussing, A. Michel-Lévy and A. Lacroix, E. Offret, H. Fischer, C. Viola, etc. A. des Cloizeaux obtained for sanidine $\alpha=1.5170$, $\beta=1.5239$, and $\gamma=1.5240$ for red light, and $\alpha=1.5265$, $\beta=1.5355$, and $\gamma=1.5356$ for blue light; and E. Offret, $\alpha=1.520278$, $\beta=1.524853$, and $\gamma=1.524972$ for yellow light. The values for adularia range from $\alpha=1.5181$ – 1.5195 , $\beta=1.5223$ – 1.5237 , and $\gamma=1.5243$ – 1.5260 for yellow light; and for microcline, $\alpha=1.5183$ – 1.5224 , $\beta=1.5220$ – 1.5250 , and $\gamma=1.5248$ – 1.5295 for yellow light. For soda-potash-felspars, the values range from $\alpha=1.5215$ – 1.5250 , $\beta=1.5266$ – 1.5306 , and $\gamma=1.5272$ – 1.5314 for yellow light. For albite, $\alpha=1.5282$ – 1.5320 , $\beta=1.5321$ – 1.5340 , and $\gamma=1.5386$ – 1.5400 . The best representative values are near $\alpha=1.519$, $\beta=1.524$, and $\gamma=1.526$ —mean 1.532—for orthoclase and microcline; and $\alpha=1.525$, $\beta=1.6306$, and $\gamma=1.5314$ —mean 1.529—for albite. W. T. Schaller found the index of refraction of barbierite to be lower than that of albite. A selection from E. Offret's observations on the effect of temp. and of light of different wave-length, λ , on the refractive index of sanidine, is given in

TABLE XXIII.—THE EFFECTS OF TEMPERATURE AND OF LIGHT OF DIFFERENT WAVE-LENGTH ON THE REFRACTIVE INDEX OF SANIDINE.

Table XXIII. A. des Cloiseaux' value for the **birefringence**, $\gamma - \alpha$, of sanidine is 0.0070 for red light, and 0.0091 for blue light; and E. Offret's for yellow light is 0.004469. The values for adularia range from 0.0054-0.0070 for yellow light; for microcline from 0.0060-0.0071; for albite, 0.0080-0.0102; and for soda-potash-felspars, from 0.0057-0.0071 for yellow light. The best representative values are $\gamma - \alpha = 0.007$ for microcline and orthoclase; and 0.0064 for albite. From E. Offret's observations, the indices of refraction of sanidine at 0° are $\gamma - \beta = 0.00005$, $\beta - \alpha = 0.00460$, and $\gamma - \alpha = 0.00462$, and the corresponding changes per 100° rise of temp. are respectively +0.00021, -0.00006, and +0.00016. A. Ehringhaus studied this subject. Orthoclase, microcline, and anorthoclase are optically negative; albite is optically positive.

W. W. Coblenz found the curve of the **ultra-red transmission spectrum** of adularia shows bands at 2.0μ , 3.2μ , 3.9μ , 4.8μ , 5.6μ , and 6.3μ , and the bands of albite at 2.9μ , 5.7μ , and 6.3μ coincide with those of adularia. Orthoclase has silicate bands at 2.85μ , 4.7μ , 5.7μ , and 6.28μ . As in the case of the transmission spectra, the curves of the **ultra-red reflection spectra** of adularia and albite are very much alike. The maxima with albite are at 8.7μ , 9.7μ , and 10μ , and those with adularia are at 8.8μ and 9.8μ —Fig. 160. With microcline, the reflection band from 9μ - 10μ is complex; there are sharp maxima at 8.85μ and 9.95μ , with a probable band at 11μ . W. W. Coblenz found the **reflecting power** of orthoclase for light of wave-length $\lambda = 0.69$ is 39.4 per cent.; for $\lambda = 0.95\mu$, 86.7 per cent.; for $\lambda = 4.4\mu$, 38.2 per cent.; for $\lambda = 8.8\mu$, 10.3-14.6 per cent.; and for $\lambda = 24\mu$, 9.7 per cent.

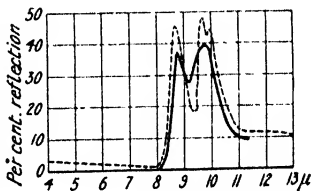

FIG. 160 — Ultra-red Reflection Spectra of Orthoclase, and Albite (dotted line).

K. Przibram studied the **phosphorescence** of orthoclase, and adularia when exposed to **radium rays**. D. Hofmann, G. de Razowinowsky, and W. Vernadsky noted the **tribo-luminescence** of felspar. K. Keilhack observed no luminescence with orthoclase. E. Engelhardt found orthoclase and microcline to have a feeble greyish-blue luminescence when exposed to **ultra-violet rays**. C. Doelter found that **radium radiations** gave a strong phosphorescence with orthoclase from Elba, but with other specimens the effect was feeble; no change in colour occurred. J. E. Burbank observed that **X-rays** make felspar phosphoresce; C. Doelter found adularia and albite are partially transparent to the X-rays.

C. Doelter²⁰ found the **electrical resistance** of adularia decreases with the rise of temp. The sp. electrical resistance, in ohms, on raising the temp. was :

Ohms	1000°	1070°	1200°	1260°	1300°	1320°
	13706	317.5	55.6	10.2	7.5	7.1

and on cooling the mineral :

Ohms	1300°	1260°	1200°	1100°	1100°	1060°
	7.4	8.1	9.4	10.9	13.3	15.0

There is no sign of a break in the curves at the softening temp. The sp. **electrical conductivity** of crystalline orthoclase is less than that of glassy orthoclase. The conductivity for glassy orthoclase has a break at 850°, and above 1000°, it gives a curve almost continuous.

Sp. elect. cond.	1100°	1200°	1240°	1260°	1300°	1320°
	0.04537	0.00411	0.01460	0.02182	0.02961	0.031133

Similarly, for albite :

R	1523°	1473°	1418°	1373°	1318°	1273°	1218°
	21.25	22.71	28.41	32.2	43.1	46.8	69.3

If the reciprocal of the temp. be plotted against $\log R$, an approximately straight line is obtained, so that $\log R = \theta^{-1} + C$, where C is constant. For the **electrical conductivity** of orthoclase C , Doelter gave 0.0000537 mho at 1100°; 0.00411 mho at 1200°; and 0.02961 mho at 1300°. J. Königsberger and K. Schilling gave 8500 ohms for the sp. resistance of orthoclase at 800°; and 800 ohms at 1000°. G. Tammann measured the electrode potential of orthoclase against the normal hydrogen electrode in soln. of various salts—zinc and silver sulphates, lead chloride, etc. G. W. Hankel found that orthoclase is **pyroelectric**; the face (010) is positively electrified, and the face (110) negatively electrified. He also found albite to be pyroelectric.

The chemical properties of the alkali-felspars.—According to A. des Cloizeaux,²¹ when adularia is fused, it loses only about a thousandth part of its weight. E. Wolff examined the loss on ignition of felspars. A. L. Day and E. T. Allen found that when powdered felspars are exposed to the atm., moisture is adsorbed in quantities of the same order of magnitude as that usually quoted in mineral analyses; and that it requires a dull red heat—600°–800°—to expel all the moisture. M. W. Travers heated a felspar which contained about one per cent. of water, and obtained 0.214 per cent. of a mixture of hydrogen and carbon monoxide, and 1.201 per cent. of carbon dioxide. The two former gases are presumably formed by a reaction with the ferrous oxide, steam, and carbon dioxide: $2\text{FeO} + \text{H}_2\text{O} = \text{Fe}_2\text{O}_3 + \text{H}_2$ and $2\text{FeO} + \text{CO}_2 = \text{Fe}_2\text{O}_3 + \text{CO}$. No hydrogen or carbon monoxide is produced when the mineral is treated with sulphuric acid.

G. A. Kenngott²² found that when sanidine, adularia, or albite is moistened with **water** coloured with red litmus, the test-liquid is coloured blue. If felspar be ground in water for some hours the water becomes viscid, owing to the dissolution and hydrolysis of alkali silicate. In 1835, G. Forchhammer heated felspar with water in closed copper tubes to 150° and 222° (21 atm. press.), and found that much soluble potassium silicate (water-glass) was formed. Water hydrolyzes the mineral. S. J. Thugutt found that when 3.3153 grms. of a sample of typical orthoclase were exposed for 100 hrs. in contact with 500 c.c. of distilled water at 200°, the water on evaporation furnished a dry residue with 66.76 per cent. of silica; 11.53 per cent. of potash; and 3.56 per cent. of soda. He also treated albite and obtained similar results. A. Daubrée also obtained 12.6 grms. of potash from 5 kgrms. of felspar. Confirmatory experiments were made by C. G. C. Bischof, W. P. Headen, K. Haushofer, A. Beyer, A. Pfaff, J. Königsberger and W. J. Müller, G. Steiger, D. Prianschnikoff, L. Splichal, J. W. Mellor, and M. Biéler-Chatelain. A. Pfaff worked with water at 8° under a press. of 160 atm. The effect of water on albite was examined by F. W. Clarke, G. Steiger, A. Bygden, etc. According to A. S. Cushman and P. Hubbard, and V. Lenher, the attack by water is more rapid when the mineral is finely ground. According to A. E. Tucker,²³ when powdered felspar is digested for 10 days at ordinary temp. with carbonated water, it is converted into a white powder resembling clay, and some micaceous-looking substance is simultaneously formed. Finely powdered felspar colours phenolphthalein almost immediately when wetted with water. A certain amount of the potassium of felspars is dissolved by water when the mineral is finely ground, and the amount dissolved is increased by addition of substances such as ammonium salts, lime, and gypsum. Complete dissolution of the potassium can be effected by means of an electrolytic method, both with and without addition of hydrofluoric acid. C. G. C. Bischof, W. B. and R. E. Rogers, E. C. Sullivan, C. Matignon and M. Marchal, A. Johnstone, F. Cornu, E. W. Hofmann, L. Splichal, and J. R. Müller have investigated the action of carbonated water, or **carbonic acid**. The last-named found:

	SiO_2	Al_2O_3	CaO	K_2O
Original felspar	65.24	18.15	1.28	14.96
Extracted matter	1.1552	1.1368	—	1.3527

The high proportion of potash which is extracted shows that the action is rather

a chemical process than one of mere dissolution. The attack by water was found by A. Brongniart and J. Malaguti, and by A. S. Cushman to be accelerated by passing an electric current through the water holding pulverulent felspar in suspension—*vide* kaolinite.

In general, the effect of acids on albite is less marked than is the case with orthoclase. G. Tschermak²⁴ obtained silicic acid, $H_2Si_3O_7$, by the action of hydrochloric acid on albite. The ordinary acids attack felspar rather slowly; the action is more rapid if the mineral be finely ground. The powdered mineral is rapidly decomposed by **hydrofluoric acid**; the action was studied by H. Baumhauer, and F. J. Wiik. J. H. Collins passed the vap. of hydrofluoric acid over felspar heated in a lead tube, and found the mineral to be rapidly converted into a hydrated aluminium silicate, soluble potassium fluoride, and silica. Dil. hydrofluoric acid acts in a similar manner. Orthoclase is more readily attacked than albite or oligoclase; and labradorite is attacked only in spots. The hydrated aluminium silicate had the same composition and appearance as china clay. E. Reymond studied the action of **chlorine** and of **hydrogen chloride** on adularia, and amazon stone. A. E. Tucker found that very dil. hydrofluoric, **hydrochloric**, **nitric**, or **sulphuric acid** decomposes powdered felspar in ten days, forming a white powder resembling china clay, and a scaly product micaceous in character. The solvent action of hot sulphuric acid on felspar was indicated by H. Rose. H. A. Seger, A. Sabeck, and W. Jackson and E. M. Rich found that about 2.24 per cent. of felspar was decomposed after an hour's treatment with conc. sulphuric acid; K. Langenbeck found 17.3 per cent. dissolved. J. W. Mellor showed that the amount dissolved depends on the grain-size of the felspar; with felspar of average diameter, 0.165, 0.082, and 0.032 mm., respectively, 0.31, 0.64, and 15.64 per cent. was decomposed by the acid treatment in a given time. If the felspar be weathered, a greater proportion is broken down. L. Spilchal also treated orthoclase with **formic acid**, as well as with hydrochloric and sulphuric acid. W. B. Schmidt found aq. **sulphurous acid** extracted nearly three per cent. of soluble matters; and H. Lotz examined the effect of air charged with **sulphur dioxide** on sanidine and orthoclase. H. St. C. Deville found that boiling conc. soln. of **potassium hydroxide** decomposes felspar, forming a soluble alkali silicate, and an insoluble potassium aluminosilicate. The latter dissolves readily in acids. C. Doelter found that 15 per cent. soln. of **sodium hydroxide** removed 0.24 per cent. of K_2O from adularia, and 2.20 per cent. from microcline at 200°. W. Flight found that after digesting adularia for 25 hrs. with soda-lye, the portion dissolved contained less alumina than the portion not dissolved; he also treated albite in a similar way. E. A. Stephenson studied the action of alkaline soln. on the felspars. G. Tammann and C. F. Grevenmeyer found that **magnesia** does not act on orthoclase at 1000°; **lime** acts slowly at 500°; and **baryta** acts strongly at 275°–350°. A soln. of **sodium carbonate** dissolved some felspar after about 24½ hrs.' action at 100°. J. Lemberg treated orthoclase with soln. of the strong alkalies and transformed the mineral into zeolitic substances with an exchange of the basic element—thus andesine with sodium carbonate soln. forms analcite, and with **potassium chloride** soln., leucite. F. A. Gentz also noted the alteration of potash- into soda-felspar by the substitution of bases. J. Spilchal examined the effect of soln. of **barium and magnesium chlorides** on felspar; and F. W. Clarke and G. Steiger, the effect of **ammonium chloride** soln. on orthoclase, and on albite. J. Lemberg digested albite with a soln. of sodium silicate, and obtained a substance resembling cancrinite with SiO_2 in place of CO_2 . H. Schneiderhölz studied the action of various salt soln. on felspars. G. André has investigated the action of soln. of different salts, and found that after grinding 10–20 grms. of felspar with 100 grms. of water and a gram of the given salt for 100 hrs. in an agate mortar, the amounts of potash indicated in Table XXIV were dissolved. The marked attack by ammonium sulphate is noteworthy. H. Streme, and E. C. Sullivan also examined the influence of a number of different substances on felspar. H. Leitmeier and M. Hellwig showed that felspar can slowly take up

TABLE XXIV.—ACTION OF SALT SOLUTIONS ON POTASH-FELSPAR.

Solvent.	Grams of potash, K_2O , dissolved per	
	100 grms. felspar.	100 parts of K_2O in the felspar.
Water alone	0.139	0.22
Sodium chloride	0.37	3.25

Sodium nitrate	0.36	3.21
Ammonium sulphate	0.84	7.38
Calcium sulphate	0.36	3.23

phosphoric acid from soln. of **ammonium phosphate**. H. Briegleb studied the action of **sodium phosphate** on felspar at a red heat.

F. A. Genth, J. de Lapparent, F. Grandjean, and H. Rosenbusch and E. A. Wülfing have shown that one felspar may pass into another, as when microcline or orthoclase changes into albite by the substitution of sodium for potassium. According to E. C. Sullivan, Table XXV represents the **metals** precipitated

TABLE XXV.—EFFECT OF SALT SOLUTIONS ON ORTHOCLASE.

Solution.	Metal precipitated.		Original content (Mgram.-atoms).	Bases dissolved (Millimols).
	Grams.	Mgram.-atoms.		
Magnesium sulphate	0.0099	0.40	1.98	0.47
Calcium chloride	0.0207	0.51	2.44	0.54
Manganous sulphate	0.0355	0.62	2.54	0.53
Ferrous sulphate	0.0365	0.65	2.10	—
Ferric sulphate	0.0648	1.16	1.21	1.41

Lead nitrate	0.2970	1.43	2.00	1.14

and bases dissolved when 25 grms. of orthoclase were treated with 50 c.c. of soln. The bases dissolved are usually in excess of the metal precipitated on account of the slight solvent action of water on the orthoclase. The acidic nature of the aq. soln. of auric chloride gave an excess of bases dissolved over metal precipitated. If the precipitate contains a basic salt the bases passing into the soln. throw out more than their eq. of metal. He also tried the effect of soln. of cupric sulphate on microcline and albite. V. P. Smirnoff studied the solvent action of **humic and crenic acids** on albite, and orthoclase.

The felspars are all highly susceptible to natural influences, and when exposed, they are readily attacked by the reagents which are so common in Nature's laboratory—water, water charged with carbon dioxide, acid waters formed by the oxidation of sulphides or issuing from volcanic vents, peat waters, alkaline waters, etc. The felspars are therefore highly alterable minerals, and they furnish numerous other minerals. The commonest end-products of the reaction between felspar and

natural agents are quartz and kaolinite—*vide supra*, clays—but other hydrated aluminium silicates are produced. Many zeolites, scapolites, epidote, zoisite, etc., may have been formed from felspar. According to A. Johnsen,²⁵ at ordinary temp. on the earth's surface, microcline is the most stable form of potash-felspar. The transformation of potash-felspar into muscovite has been discussed by H. Rössler, G. vom Rath, F. W. Clarke, C. G. C. Bischof, J. de Lapparent, etc.; into pinitoid, by A. Knop, E. Cohen, C. G. C. Bischof, A. Streng, C. W. von Gümbel, K. Dalmer, etc.; into analcime, by A. Phillips, T. Scheerer, etc.; and into kaolinite, by H. Stremme, G. L. Crasso, F. von Höchster, etc. Pseudomorphs after orthoclase have been described by A. Breithaupt, J. R. Blum, G. Tschermak, J. Roth, L. Hezner, etc. The alteration of albite into sericite and zoisite was discussed by A. Cathrein, C. Benedicks, etc. Some general observations on the transformation of potash- and soda-felspars were made by C. R. van Hise, C. G. C. Bischof, H. Rössler, M. Lublin, J. Roth, etc.

The use of felspar.—Felspar²⁶ is used in making some special types of pottery; but felspathic rocks like pegmatite and Cornish stone are perhaps as frequently employed as sources of felspar. These bring quartz and sometimes clay into the body along with the felspar. Felspar is also used in making certain types of pottery glazes, enamels for metals, opalescent glass, and artificial teeth. The higher grade potash felspars have been investigated with the idea of extracting their contained potash for making fertilizers, etc.—*vide* 2, 20, 4.

P. G. Silber²⁷ obtained a canary-yellow silver aluminium silicate, $\text{Ag}_3\text{Al}_2\text{Si}_2\text{O}_8$, by heating the corresponding sodium aluminium silicate with silver nitrate. A number of silver derivatives has been obtained by the more or less complete displacement of the alkali or alkaline earth metal by silver. Thus, F. W. Clarke, and G. Steiger reported a *silver-chabasite*, $\text{Ag}_3\text{Al}_2(\text{SiO}_4)(\text{Si}_2\text{O}_5) \cdot 4\text{H}_2\text{O}$, to be formed by the action of silver nitrate on chabasite; G. Steiger similarly obtained *silver-analcite*, $\text{AgAlSi}_2\text{O}_6 \cdot \text{H}_2\text{O}$; *silver-nadolite*, *silver-thomsonite*, etc.—*vide index*. There are also the *silver-ultramarines* (q.v.) studied by K. Houmann,²⁸ R. de Forcrand and M. Ballin, J. Szlasi, C. Chabré and F. Levallois.

§ 44. The Alkaline Earth Aluminium Silicates

The calcium aluminium silicates have attracted much attention owing to the part they play in the formation of slags in metallurgical operations, in the manufacture of glasses and glazes, and in the formation of portland cement (*q.v.*). The calcium aluminium silicates in slags were studied by W. A. Lampadius,¹ P. Berthier, R. Kirwan, H. Abich, M. W. Iles, N. G. Sefström, J. Percy, and W. H. Miller, J. F. L. Hausmann, C. W. C. Fuchs, R. Akerman, P. Gredt, M. Theusner, etc. P. Berthier made some observations on slags containing $\text{CaO}:\text{Al}_2\text{O}_3:\text{SiO}_2 = 6:2:3$; $3:1:3$; $3:1:9$; $1:1:22$; and $1:1:6$; both P. Berthier and N. G. Sefström made observations on $3:1:6$; $6:4:9$; and $3:2:6$; N. G. Sefström, on $3:2:9$; and C. Schnabel, on $9:1:10$. A. Gorgeu reported the $2:1:1$ silicate to be formed as a by-product when kaolinite is melted with 13-14 times its weight of calcium bromide. The anisotropic prisms, $\text{Ca}_2\text{Al}_2\text{SiO}_7$, may be calcium dialuminometasilicate, $(\text{AlO.O.Ca})_2\text{SiO}_3$. O. Boudouard prepared the same compound. L. Bourgeois obtained $12:2:9$; $3:1:2$; $3:1:3$; and $6:4:9$; and W. Heldt, $8:2:15$, by fusion or sintering mixtures of the constituent oxides. C. F. Rammelsberg found crystals corresponding with $6\text{Ca}_3\text{SiO}_5\cdot\text{Al}_2\text{SiO}_3$ mixed with calcium sulphide in the masonry of a soda-potash furnace. The greenish-yellow tetragonal bipyramids had the axial ratio $a:c=1:0.5832$, and sp. gr. 3.05. R. Akerman, O. Boudouard, and P. Gredt measured the heats of solidification and the temp. of formation of a number of calcium aluminium silicates, and L. Babu, H. E. Ashley, and H. M. Howe plotted the results on triangular diagrams.

R. Kirwan found that silica mixed with alumina and baryta or strontia fuses more readily than is the case with lime as the alkaline earth. P. Berthier also fused mixtures of $\text{BaO}:\text{Al}_2\text{O}_3:\text{SiO}_2$ in the proportions $3:6:14$ and $3:4:12$. R. Riecke, and G. Flach studied the effect of the three alkaline earths on the fusibility of clay. E. Frémy and C. Feil obtained a product with the composition $4:5:10$ by the action of barium fluoride on a mixture of alumina and silica. F. Fouqué and A. Michel-Lévy obtained $\text{BaO}\cdot\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$, $\text{SrO}\cdot\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$, and $\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2$ by the method indicated below for the synthesis of anorthite. Z. Weyberg obtained $4\text{BaO}\cdot 4\text{Al}_2\text{O}_3\cdot 7\text{SiO}_2$ in isotropic crystals by fusing a mixture of kaolinite and barium chloride.

T. J. Pelouze added calcium chloride to a soln. of alum and alkali silicate in an excess of alkali hydroxide, and obtained a mixed precipitate of lime, silica, and alumina. W. Heldt found that a mixture of precipitated calcium aluminate and water-glass soln. does not harden, but a similar mixture with the aluminate prepared by calcination does harden. C. and G. E. Tischler found crystals of $\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot 6\text{SiO}_2\cdot 6\text{H}_2\text{O}$ in sandlime bricks; the composition of stilbite is given as $\text{CaAl}_2\text{Si}_6\text{O}_{16}\cdot 5\text{H}_2\text{O}$. J. Lemberg heated aluminium hydroxide with calcium silicate and water to 180° and obtained six-sided plates of a calcium aluminium silicate. C. and G. Friedel heated mica with a soln. of calcium chloride and lime-water, and obtained crystals of anorthite (*q.v.*). J. Lemberg made a barium aluminium silicate by heating a mixture of kaolinite and barium silicate in water for 75 hrs. at 190° .

S. J. Thugutt prepared a product with the composition $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 2\text{CaCl}_2 \cdot 20\text{H}_2\text{O}$, by the action of a soln. of calcium chloride on sodalite. A. Gorgeu melted garnet with calcium chloride and oxychloride, and also melted calcium chloride with kaolinite or a mixture of silica and alumina, and obtained a singly-refracting, crystalline product with the composition $\text{Ca}_6\text{Al}_6\text{Si}_3\text{O}_{21} \cdot 2\text{CaCl}_2$. Z. Weyberg obtained

a similar product by the latter process; and prepared $\text{Ca}_{12}\text{Al}_{10}\text{Si}_5\text{O}_{38} \cdot 4\text{CaBr}_2$, by melting calcium bromide and kaolinite.

Nature has provided an extraordinary number of calcium aluminium silicates—both hydrated and anhydrous. E. Selch² observed the effect of lime on clays; and R. Rieke, the softening temp. of mixtures of lime and china clay. Very few of these complex compounds are indicated on the diagram of the ternary system, Fig. 161, explored by G. A. Rankin and F. E. Wright for dry melts of the three oxides, $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$. This diagram shows well the strength

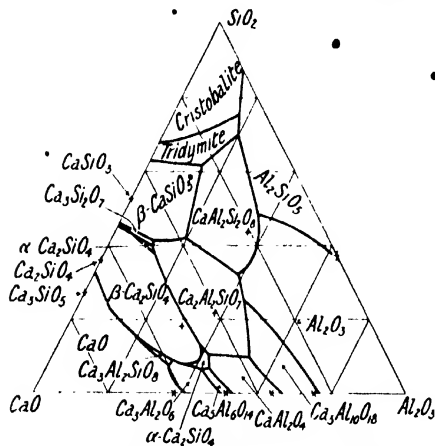

Fig. 161. Equilibrium Diagram of the Ternary System: $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$.

and weakness of P. Berthier's rule: *Il paraît même que la fusibilité des silicates multiples est plus grande que la fusibilité moyenne des silicates composants*. The system was discussed by B. Neumann, and P. Niggli. A. L. Field and P. H. Royster discussed the viscosity of the molten ternary mixtures. Indeed, only three ternary compounds are indicated on this diagram, *anorthite*,

$\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$; *velardevite*, $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$; and **calcium dialuminatorthosilicate**, $\text{Ca}_3\text{Al}_2\text{SiO}_8$. The first two of these compounds are discussed later; the last one does not appear on the ternary diagram because it dissociates at its m.p. The absence of numerous anhydrous alumino-silicates from this diagram does not mean that such compounds do not exist. It is true that many break down at their m.p., but others, stable at this temp., are not formed under the conditions represented by Fig. 161. Other conditions, other diagrams. The

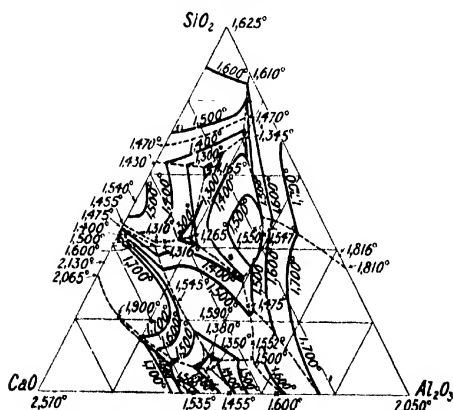

Fig. 162. Melting-point Curves for the Ternary System: $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$.

isothermal m.p. of the ternary mixtures are indicated in Fig. 162. The binary compounds have been previously discussed. The compound calcium dialuminatorthosilicate,

dissociates at its mp., $1335^{\circ} \pm 5^{\circ}$, into calcium orthosilicate, Ca_2SiO_4 , and calcium aluminate, $\text{Ca}(\text{AlO}_2)_2$; and hence it is best formed by crystallization from a glass of its own composition at a temp. below 1335° . According to G. A. Rankin and F. E. Wright, the preparation appears under the microscope dusty and so unsatisfactory that it is not possible to state definitely that it is homogeneous. The crystalline mass is usually crypto- to micro-crystalline and consists of overlapping fibres and grains. The larger grains show under high powers the ribbed structure common to crystal skeletons. The crystal system is possibly rhombic. The refractive indices are $\alpha_{\text{Na}} = 1.675 \pm 0.005$, $\gamma_{\text{Na}} = 1.685 \pm 0.005$. The birefringence is medium, $\gamma - \alpha$ being about 0.01. The optic axial angle is medium to fairly large. The optical character positive. The plane of the optic axes is apparently parallel with the positive elongation of the fibres. P. Niggli studied the ternary systems albite-anorthite-diopside; and anorthite-forsterite-silica.

The matrix of corundum from Carnatic, India, described in some detail by J. L. Bournon,³ and afterwards called *indianite*, was recognized by A. Breithaupt to be a lime-felspar. Some crystals of lime felspar from Monte Somma, Vesuvius, were called by G. Rose *anorthite* from *ἀνορθος*, oblique in reference to the crystalline form.

T. Monticelli and N. Covelli called some crystals of lime-felspar from the same locality *christianite*—after Christian Frederick, Prince of Denmark; and others, *biotina*—after J. B. Biot. A. Breithaupt showed that the former, and H. J. Brooke that the latter, are simple anorthite. The *thorsauite* of F. A. Genth, from Thorsauite, Iceland, is also anorthite. N. von Nordenskjöld's *amphodelite*—from *ἀμφί*, double; and *δελός*, spear, in allusion to the form of the crystals—is a reddish or peach-coloured variety from Lojo, Finland, and Tunaberg, Sweden. A. Breithaupt's *lepidite*—from *λέπος*, crust—is also an anorthite from Lojo and Orijarvi, Finland; it was studied by N. von Kokscharoff, who found the crystals were complex, but possessed angles like anorthite. H. J. Brooke's *latrobit*—after C. F. Latrobe—is a rose-red anorthite from Amittok Island, Labrador. N. von Nordenskjöld's *lundeayite* from Orijarvi, Finland, is an altered variety of lepidolite; it was investigated by R. Hermann, and F. J. Wijk. A. E. Nordenskjöld's *sundevikite*, from Nordsundvikite, Iceland, is also an altered anorthite. W. S. von Waltershausen named some glassy crystals from Trezza, Etna, and the Cyclopean Islands, *cyclopite*. A. Lacroix showed that they are anorthite. According to A. des Cloizeaux, some pinkish crystals from Arendal were called *tankite*, they were probably anorthite. T. Thomson's *huronite*, from Lake Huron, is an impure anorthite. B. J. Harrington confirmed this assumption, but T. L. Walker's analysis made the mineral resemble scapolite. Its index of refraction was 1.57159. G. Tschermak proposed the term *microtine*—*μικροτίνη*, littleness—for the glassy plagioclase felspars analogous to the sanidine forms of orthoclase.

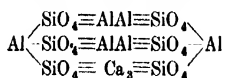

The *barsowite* of G. Rose, from Barsowsky, Ural, has the composition of anorthite when an allowance is made in the analyses of F. Varrentrapp, and K. M. Friederici for the corundum present as an impurity. The sp. gr. is 2.796. According to M. Bauer, the crystals are rhombic, and G. Rose, and P. Groth said that barsowite is dimorphous. J. Morozewicz doubted the existence of this mineral as a definite species; W. C. Brögger believed it to be a *selbständiges Mineral*, and he represented it and danburite by the formula $\text{Ca}_2\text{R}_2(\text{SiO}_4)_2$, where R represents an atom of boron in the case of danburite, and an atom of aluminium in the case of barsowite. F. L. Ransome and C. Palache regard barsowite, Al_2SiO_5 , $\text{Al} : \text{SiO}_4 : \text{Ca}$, as a product of the dehydration of lawsonite. J. Lemberg found that when barsowite is digested with a soln. of sodium silicate at 100° for 7 months, 50-70 per cent. of the calcium is displaced by sodium.

In 1824, J. J. Berzelius⁴ recognized a new mineral in some specimens from Danviks-Zoll, and he called it *soda-spodumene*; and A. Breithaupt also found a variety of soda-lime-felspar which he named *oligoclase*; and afterwards showed its identity with J. J. Berzelius' mineral. Some *arenurine felspars*, and *sunstone* (q.v.) are oligoclase. H. Abich found a soda-lime-felspar at Marmato, Andes, and named it *andesine*. E. F. Glocker referred to a variety in the serpentine of Frankenstein as *saccharite* in allusion to its granular appearance, but A. Lasaulx showed that it is a mixture. A. G. Werner referred to the chatoyant *Labradorstein* brought by a Moravian missionary from St. Paul's Island, the coast of Labrador, about 1775. It was called *Pierre de Labrador* by J. B. L. Koenig de l'Isle; and *Labrador felspar* and *labrador* by G. Rose.

G. vom Rath showed that the lime-oligoclase or the *hafnesfordite* G. Forchhammer obtained from Hafnesfjord, Iceland, is *labradorite*. The *silicite* and *normite* of T. Thomson are from Antrim, Ireland, and are varieties of labradorite. The felspar from Carnatic, India, and named *caradite* by A. des Cloizeaux, described by F. S. Beudant, is regarded by A. Breithaupt as labradorite. The term *saussurite*—from H. B. de Saussure—has been

given to some varieties of compact labradorite, although A. Cathrein showed that saussurite is a jade-like mineral containing zoisite and several feldspars. This mineral was called *jade* by H. B. de Saussure; *Swiss jade*, by A. Höpfner; *lehmanite*, from Lake Lehman by J. C. Delamétherie; and *jade tenace* and *jade de Saussure*, by R. J. Haiiy. It was discussed by T. S. Hunt, H. Traube, G. H. Williams, etc. A. Breithaupt's *radauite*, from Radau Valley, Harz, is a compact variety of labradorite. G. Tschermak applied the term *maskelynite*—in honour of N. S. Maskelyne—to an isotropic feldspar found in some meteorites, and he suggested that it is a fused feldspar. P. Groth considers it a particular species allied to leucite. The original *bytownite* by T. Thomson⁶ was a greenish-white feldspathic mineral from Bytown, Ottawa, Canada. It was analyzed by S. Tennant, and T. S. Hunt. F. Zirkel showed that this mineral is a mixture. G. Tschermak applied the term to feldspars with a composition lying between that of labradorite and that of anorthite as indicated in the preceding table.

Numerous analyses of anorthite,⁶ oligoclase,⁷ andesine,⁸ labradorite,⁹ and bytownite¹⁰ have been made. C. F. Rammelsberg¹¹ has shown that the many analyses of anorthite agree very well with the idealized formula $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, which has been interpreted in many different ways. G. Tschermak regarded it as a metasilicate because it furnished what he considered to be metasilicic acid when treated with hydrochloric acid. This idea gave him $\text{Ca}(\text{O} \cdot \text{Al} : \text{O}_2 : \text{SiO})_2$ or $\text{Ca}(\text{O} \cdot \text{SiO} \cdot \text{O} \cdot \text{AlO})_2$, and he preferred the latter. J. E. Reynolds' synthesis of what was thought to be anorthite by the action of oxygen and steam on CaSi_2Al_2 , led him to the formula $\text{Ca}(\text{O} \cdot \text{SiO}_2 \cdot \text{AlO})_2$. F. W. Clarke gave $\text{Ca}(\text{O} \cdot \text{Si} : \text{O}_3 : \text{Al})_2$, or else

The triclinic soda-lime-feldspars with oblique cleavages were grouped by A. Breithaupt as *plagioclase-feldspars*—from *πλάγιος*, oblique; and *κλάσις*, fracture. The relations have been much discussed. J. F. C. Hessel, in his paper: *Ueber die Familie Feldspath* (1826), stated that labradorite is closely related with the other feldspars, and it can be regarded as a mixture of albite and anorthite. W. S. von Waltershausen regarded the lime-soda-feldspars as isomorphous mixtures of anorthite and the alkali-feldspar. C. F. Rammelsberg, D. Gerhard, T. Scheerer, A. E. Deslesses and T. S. Hunt, held similar views. The subject was taken up by G. Tschermak in his memoir: *Die Feldspathgruppe* (Wien, 1865). He showed that the *lime-soda-feldspars* are isomorphous mixtures of albite, $\text{NaAlSi}_3\text{O}_8$, and anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$. This is known as *Tschermak's theory of the isomorphism of the lime-soda-feldspars*. This view was supported by A. Streng, who objected to the assumption that atoms of unequal valency like Na and Ca, or Al and Si, can replace one another isomorphously, and he represented albite and anorthite respectively by the doubled formulæ $\text{Na}_2\text{Si}_2\text{Al}_2\text{Si}_4\text{O}_{16}$ and $\text{Ca}_2\text{Al}_2\text{AlSi}_4\text{O}_{16}$; he also assumed that in the end-members there might be some $\text{CaSi}_2\text{Al}_2\text{Si}_4\text{O}_{16}$ and $\text{Na}_4\text{Al}_2\text{AlSi}_4\text{O}_{16}$. C. F. Rammelsberg, however, pointed out that this last assumption does not agree with the best analyses, and added that the isomorphism cannot be attributed to the number or to the equivalency of the constituent atoms. The subject was discussed by G. Tschermak, G. vom Rath, W. C. Brögger, A. Arzruni, J. W. Retgers, and F. Sandberger. The question has been raised whether some of the isomorphous mixtures of albite and anorthite represent definite compounds which can commingle isomorphously in various proportions; and discussed by A. des Cloizeaux and C. Friedel, F. Fouqué and A. Michel-Lévy, H. Bücking, A. Michel-Lévy and A. Lacroix, W. Tarassenko, F. Wallerant, E. S. von Federoff, T. Petersen, etc. As indicated below, the general physical and chemical properties of the isomorphous mixtures give no evidence of the formation of definite compounds of albite and anorthite. The isomorphism appears to be complete in the strictest sense of the term. As F. Fouqué expressed it:

La loi de Tschermak fournit un excellent moyen de contrôle et permet d'arriver à des déterminations très suffisantes. La simplicité, la bauté des conclusions ne doit pas faire oublier l'imperfection des prémisses.

E. T. Wherry has discussed the various hypotheses which have been proposed to explain the isomorphism of compounds of apparently dissimilar chemical type like the end-members of the plagioclase feldspars $\text{NaAlSi}_3\text{O}_8$ and $\text{CaAl}_2\text{Si}_2\text{O}_8$. P. Groth emphasized the view that in isomorphous crystals, the elements concerned should be capable of playing an analogous rôle in the chemical mol., and that the space units of these elements should be characterized not only by like symmetry, but by nearly the same linear dimensions, and, consequently, nearly the same vol. He added :

The isomorphism of two substances depends on the fact that the entrance of the atoms or groups of atoms which replace one another produces a similar change in the crystal structure of the compound from which they are in common derived. Since the extent of this change depends not only on the nature of the substituting atoms or groups of atoms, but also on that of the original substance, it follows that the differences which are to be observed in cases of isomorphous replacement by the same substitutions are different in different isomorphous series; and, in general, they must be smaller, the greater the number of atoms common to the isomorphous substances.

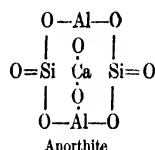

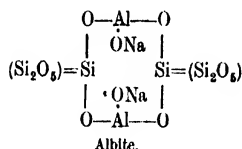

J. D. Dana cited cases to show that the mol. vol. of an isomorphous group of minerals have values approaching equality, and that the crystallographic relationship depends on mol. vol., and not on chemical composition—*vide* titanium dioxide. It has long been recognized that the mol. vol. of anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$, and of albite, $\text{NaAlSi}_3\text{O}_8$, are the same, but this is not a sufficient criterion for explaining the isomorphism, even though G. T. Prior has shown that many substances with nearly the same mol. vol. and with apparently distinct types of formula are isomorphous. The identity of the mol. vol. shows that the isomorphism of the plagioclases is based on a 1 : 1 ratio of amounts indicated by the formulæ of the two end-members of the series.

Since the difference between albite and orthoclase consists merely in the replacement of one univalent element by another, it might be predicted that orthoclase would be isomorphous with anorthite. R. Freis showed that the potash-feldspar can dissolve small quantities of lime-feldspar; in nature, however, soda-feldspar is always present as well. F. Gonnard assumes that if a monoclinic lime-feldspar did occur it would be isomorphous with potash-feldspar; and A. Schwantke assumed the existence of a compound $\text{Ca}_2\text{Al}_2\text{Si}_3\text{O}_{16}$ which is miscible with $\text{K}_2\text{Al}_2\text{Si}_6\text{O}_{16}$. E. Dittler, W. Wahl, and H. J. L. Vogt have made some observations on the system $\text{KAlSi}_3\text{O}_8 - \text{CaAl}_2\text{Si}_2\text{O}_8$. E. Dittler obtained over-growths or zonal structures so long as the potash-feldspar did not exceed 10–20 per cent., and with 70 per cent. of lime-feldspar, the two components crystallized separately. If increasing proportions of soda-feldspar be added, potash- and lime-feldspars become more and more miscible. H. Alling suggested that potash- and soda-feldspars are isomorphous, and he called the series *oranite*. There are no representatives of this series in nature, and the evidence adduced points only to the formation of limited non-isomorphous solid soln. Similarly, it might be anticipated that *carnegieite* would be isomorphous with anorthite since the only difference between the two silicates consists in the substitution of one bivalent atom by two univalent atoms. The evidence, however, shows that in *anemousite* only a very small proportion of *carnegieite* is present; and N. L. Bowen has shown that *carnegieite* holds only 5 per cent. of anorthite in solid soln., while anorthite holds only 2 per cent. of *carnegieite*.

It is curious that in the feldspars, ferric iron does not readily take the place of aluminium for when any ferric oxide has been incorporated with a native feldspar, it has apparently separated as hæmatite inclusions. The artificial *ferric-feldspar*, KFeSi_3O_8 , reported by P. Hautefeuille and A. Perrey, is very unstable; and the gem orthoclase of Madagascar is almost unique. The fact that ferric oxide can replace alumina in garnet, tourmaline, etc.; and the general unstability of the ferrites as contrasted with the aluminates, led W. Vernadsky to suggest that the aluminium in garnet, etc., belongs to the basic radicle, but in feldspars, to the acidic

radicle. E. T. Wherry arranges the hypotheses invented to explain these facts into three groups:

1. *Structural theories*.—Here it is assumed that the elements retain the same valence in the solid and liquid states, and that the isomorphism of the basic radicles is always valence for valence; but widely dissimilar acidic radicles may be isomorphous. W. Vernadsky assumes that the feldspars have a group of atoms which he called the mica nucleus. He considered alumina to be part of the acidic radicle, but the formula to be otherwise different (*vide supra*, orthoclase):

F. W. Clarke, as indicated above, also has the quadrivalent radicle Si_3O_8 in albite, and SiO_4 in anorthite. The ring formulae of W. and D. Asch belong to this type. B. Gossner writes $\text{SiO}_3\text{Na}_2[\text{SiO}_2\text{Al}_2\text{O}_3]4\text{SiO}_2$ for albite, and $\text{SiO}_3\text{Ca}[\text{SiO}_2\text{Al}_2\text{O}_3]$ for anorthite, where the 4SiO_2 of albite is missing from anorthite. These explanations cannot be called *hypotheses touchés*, for they do not look two ways at once. In straining after similarity with the basic radicle, diversity with the acidic radicle is ignored. No attempt is made to account for the other peculiarities indicated above.

2. *Arithmetical relations*.—Here the simple integral relationship between the constituents or their properties is used to explain isomorphism. The valence-volume theory of W. Barlow and W. J. Pope (1. 5, 18) is based on the chance relation that quadrivalent carbon occupies approximately four times the vol. of univalent hydrogen. The total valence of albite and anorthite is 32, and the groups NaSi and CaAl of valency 5 are supposed to be mutually replaceable. Other silicates have total valencies of 32, but are not isomorphous with albite or anorthite. R. B. Sosman argued that the oxides of ordinary silicates tend to unite in simple numerical proportions regardless of structural relations, so as to form molecular compounds. This would double the above formula for albite. I. Langmuir's hypothesis (4. 27, 4) assumes that elements are radicles possessing a like electronic structure, are isomorphously eq. though chemically dissimilar. Albite and anorthite alike possess 64 electrons, and hence they should be isomorphous. *Au contraire*, calcium is isoteric with potassium but not with sodium, meaning that anorthite should be more fully isomorphous with orthoclase than with albite—which is not in agreement with facts. Hence, continued E. T. Wherry:

This group of hypotheses does not furnish any adequate explanation of the complexity of isomorphous relationships. If carried to their logical extreme they would predict numerous cases of isomorphism which do not occur. They require that in the plagioclases, one univalent, one bivalent, or one trivalent radicle should be replaceable by another corresponding valence—lithium or potassium for sodium, strontium or barium for calcium, or ferric iron or chromium for aluminium, yet not one of these actually occurs.

3. *Atomic isomorphism*.—Isomorphism is assumed to occur only between mutually similar atoms or groups of atoms irrespective of the valence exhibited by the same atoms or groups of atoms in soln. This is illustrated by the case of calcite, CaCO_3 , and soda-nitre, NaNO_3 , which are closely isomorphous, while CaCO_3 and Na_2CO_3 or CaCO_3 and $\text{Ca}(\text{NO}_3)_2$ are not isomorphous. The structural hypothesis would indicate that $\text{Ca}=\text{O}_2=\text{C}=\text{O}$ should be isomorphous with $\text{Na}_2=\text{O}_2=\text{C}=\text{O}$, but not with $\text{Na}-\text{O}-\text{N}-\text{O}_2$. P. Groth applied the idea to the plagioclases, and the hypothesis was developed by H. S. Washington. Here, albite becomes $(\text{NaSi})(\text{AlSi}_2\text{O}_8)$, and anorthite, $(\text{CaAl})(\text{AlSi}_2\text{O}_8)$, where the (NaSi) -group and the (CaAl) -group are quinquevalent. This renders it unnecessary to assume iso-

morphism between widely dissimilar acidic radicles; it does not account for the failure of one atom to replace another of the same valence; and it splits up the atomic grouping without any vindictory evidence.

P. Niggli, and J. Jakob applied the co-ordination theory and wrote the formula of anorthite in several different ways, among others, they gave

P. Erculisse did not favour formulæ of the type $\text{AlSiO}_4 \cdot \text{SiO}_2 \cdot \text{O} \cdot \text{Si}(\text{OH})_2 \cdot \text{SiO}_4\text{Al}$, but regarded the plagioclases as solid soln. of the acids H_3AlSiO_6 and $\text{H}_2\text{Al}_2\text{SiO}_6$.

Assuming atomic isomorphism between Ca and Na, and Al and Si, M. E. Denaeher, and P. Erculisse also used the co-ordination theory in this connection. P. A. von Bonsdorff argued that while alumina usually acts as a base, it can also act as an acid, and take the place of silica mol. for mol. The idea was developed by T. Scheerer, and D. A. Brauns, but opposed by V. Wartha. E. T. Wherry argued that the non-replaceability of aluminium by ferric iron in these feldspars requires the aluminium to be definitely associated with the alkali or alkaline earth metal; and the co-ordination plan requires the aluminium atom to be dominant and in a central position. He therefore postulated the formulæ $[\text{NaAl}(\text{Si}_3\text{O}_8)]$ for albite and $[\text{CaAl}(\text{AlSi}_2\text{O}_8)]$ for anorthite; or, omitting the square brackets, $\text{NaAl}(\text{Si}_3\text{O}_8)$ and $\text{CaAl}(\text{AlSi}_2\text{O}_8)$ respectively.

W. Barlow and W. J. Pope assume that isomorphism depends on the replacement of atoms of similar sizes as well as on like valency. F. Zambonini, and E. T. Wherry agree in attributing the isomorphism of albite and anorthite to a close agreement in the at. vol. of the vicariant elements, but the former also considers that equality of the sum of the valencies of the replacing elements is essential. E. T. Wherry considers the valence relations are negligible. R. W. G. Wyckoff believes that sufficient data are not available to settle the question. F. Rinne's interpretation of the X-radiograms of anorthite and oligoclase is indicated in Fig. 163. Comparing this diagram with Fig. 138, it follows that the chemical mol. of albite is $\text{NaAl}[\text{Si}(\text{SiO}_4)_2]$, and that of anorthite $\text{CaAl}[\text{Al}(\text{SiO}_4)_2]$; or, in words, **calcium aluminium aluminodiorthosilicate**.

The modern theories of crystal structure show that atomic isomorphism should be the rule whenever the atoms concerned are so nearly equal in vol. as to fit into the geometrical arrangement. W. L. Bragg showed that sodium normally occupies a vol. slightly greater than calcium, and silicon a little less than aluminium; on the other hand, potassium occupies a decidedly larger vol. than sodium or calcium, so that potassium nitrate cannot be expected to be isomorphous with calcite, nor orthoclase with anorthite. In the case of cagneite with its two sodium atoms for one calcium atom in anorthite, the larger vol. required by the two sodium atoms should make isomorphism even less possible.

The plagioclase feldspars of the less siliceous rocks have a tendency to approach the anorthite end-member as the proportion of silica decreases. C. H. Warren¹² found anorthite as a contact mineral of limestone. Anorthite and the plagioclases have been observed in meteorites.

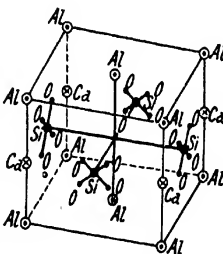

FIG. 163.—Stereochemical Scheme of Anorthite.

Anorthite is the felspar which is most easily obtained pyrogenetically, and its crystallization tendency is comparatively great. A. L. Day and co-workers¹³ readily obtained it in a crystalline form by simply fusing a mixture of the constituent oxides. F. Fouqué and A. Michel-Lévy, A. S. Ginsberg, and A. Brun also obtained anorthite directly from its components. G. A. Rankin's diagram, Fig. 161, shows the range of stability of anorthite in the ternary system, $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$. J. H. L. Vogt observed it in various slags; S. Meunier found it in the masonry of a gas-furnace at Vaugirard; A. Mañard, in the ashes from a colliery; and C. Vélain, in the glass produced during the burning of a corn mill. J. Morozewicz obtained felspars ranging from labradorite to nearly pure anorthite in his experiments on magmas. S. Meunier fused a mixture of silica, lime, and aluminium fluoride, and obtained sillimanite, tridymite, and anorthite. Anorthite is also produced when many complex silicates are fused. Thus, A. des Cloizeaux obtained anorthite by fusing together garnet and vesuvianite; and C. Doelter and E. Hussak obtained similar results; and K. Petrasch obtained it by fusing a mixture of granite and andesite. C. Doelter obtained anorthite in the products obtained by fusing epidote, axinite, chabazite, heulandite, laumontite, and scolecite; and also by melting calcspar with basalt. C. Medanich obtained it by fusing a mixture of granite and sodium phosphate, boric oxide, and tin chloride; and K. Bauer, by fusing a mixture of diorite with sodium, potassium, or calcium fluoride. C. and G. Friedel made anorthite by the hydrothermal process, namely, by heating a mixture of lime, calcium chloride, muscovite, and a little water in a steel tube at 500° ; J. E. Reynolds, by the action of steam on his silicacyanide; and M. Schläpfer, by heating a mixture of the constituents of anorthite, calcium chloride, and water in a bomb at 470° . W. Eitel obtained anorthite (plagioclase) by heating nephelite (q.v.) and calcium carbonate at press. below 65 kgms. per sq. cm.

F. Fouqué and A. Michel-Lévy made felspars analogous to anorthite, oligoclase, and labradorite with strontium, barium, or lead in place of calcium. Mixtures of silica, alumina, sodium carbonate, and the proper oxide were heated at temp. a little below the fusion point. This gave *strontia-felspar*, *baryta-felspar* (celsian), and *lead-felspar*. Plagioclase containing potassium in place of sodium were made by E. Dittler; and also hyalophane as a solid soln. of orthoclase and celsian. F. von Kobell suggested that in *tschermakite* the magnesia replaces lime in felspar in the form of *magnesia-felspar*; but a subsequent examination by G. W. Hawes, F. Pisani, and A. des Cloizeaux showed that there is much less magnesia present than F. von Kobell supposed. H. Schulze and A. Stelzner found what they regarded

as *zinc-anorthite* in the walls of a zinc furnace. C. Doelter did not succeed in making *ferric anorthite*.

It is possible that Z. Weyberg made *potash-anorthite* in his synthetic experiments on kaliophilite. J. Lemberg did not succeed in making *soda-anorthite*, but S. J. Thugutt's product, obtained by rapidly cooling fused nephelite hydrate, was probably this compound. The triclinic nephelite reported by E. Esch from the Etinde volcano, West Africa, was probably *soda-anorthite*. H. S. Washington and F. E. Wright found *soda-anorthite*, i.e. *carnegieite*, to be a constituent of a felspar from the island of Lenosa, near Tunis, and they synthesized the mineral by heating to 1080° , the glass obtained by fusing a mixture of the

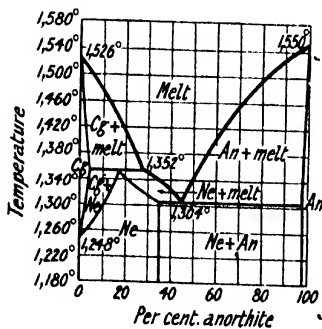

FIG. 164.—Freezing-point Curves of the Binary System: $\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_8$ — $\text{CaAl}_2\text{Si}_2\text{O}_8$.

constituents. N. L. Bowen charted the equilibrium diagram of the binary system, $\text{Na}_2\text{Al}_2\text{Si}_2\text{O}_8$ (soda nephelite or *carnegieite*) and $\text{CaAl}_2\text{Si}_2\text{O}_8$ (anorthite),

and found that the sodium compound is stable in nephelite below 1248° , as carnegieite is above that inversion temp.—Fig. 164. The eutectic occurs at 1304° with 45 per cent. of anorthite; and mixed crystals range from nephelite (Ne) to $\text{Ne}_{85}\text{An}_{15}$; and the maximum amount of anorthite taken up by carnegieite (Cg) is $\text{Cg}_{95}\text{An}_5$.

O. Andersen has studied the binary and ternary systems with anorthite, forsterite, and silica as components. The curves, Figs. 165–168, of the system,

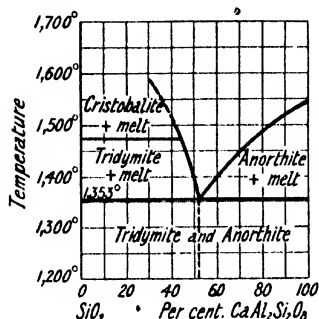

FIG. 165.—Freezing-point Curves of the Binary System: Anorthite-Silica.

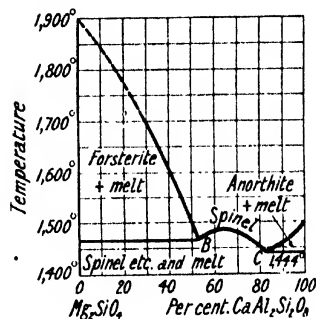

FIG. 166.—Freezing-point Curves of the Binary System: Anorthite-Forsterite.

Anorthite-Silica, show that no higher silicate is stable under the experimental conditions; and the f.p. curves, Fig. 166, of the system, anorthite-forsterite, show that the curve BC has not the maximum shown on the liquidus curves of ordinary two-component systems by a binary compound, since spinel, $\text{Mg}(\text{AlO}_2)_2$, cannot be considered a binary compound of the components Mg_2SiO_4 and $\text{CaAl}_2\text{Si}_2\text{O}_8$. The ternary system, Fig. 167, shows no combinations of the components $\text{CaAl}_2\text{Si}_2\text{O}_8$,

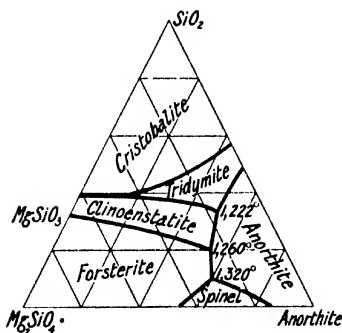

FIG. 167.—Ternary System: Forsterite-Anorthite-Silica.

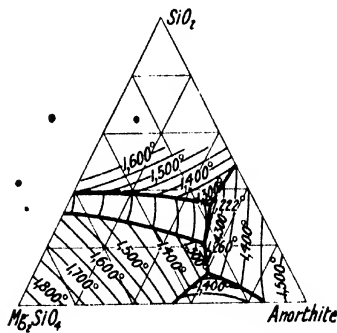

FIG. 168.—Isothermal Freezing Curves of the Ternary System: Anorthite-Forsterite-Silica.

Mg_2SiO_4 , and SiO_2 . The spinel field is not a ternary compound of the components of the system, but represents the products obtained by the breaking down of the anorthite. It would appear as a compound in the quaternary system $\text{MgO}-\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$. Magnesium metasilicate is unstable at the m.p. The isothermal curves of the system are shown in Fig. 168. P. Lebedeff studied mixtures of anorthite and wollastonite. N. L. Bowen's curves for the binary systems: anorthite-diopside and albite-diopside, are illustrated in the diagrams respectively,

Figs. 165 and 170. The isothermal lines for the ternary system : albite-anorthite-diopside, are shown in Fig. 171. Following similar lines to those employed

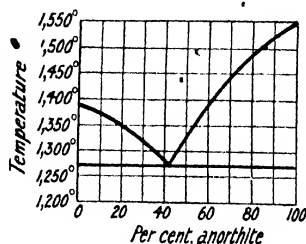

FIG. 169.—Freezing-point Curves of the System : Diopside-Anorthite.

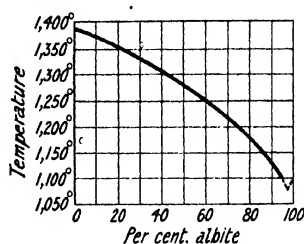

FIG. 170.—Freezing-point Curves of the System : Diopside-Albite.

for anorthite, P. Hautefeuille¹⁴ F. Fouqué and A. Michel-Lévy, A. L. Day and E. T. Allen, K. Bauer, K. Petrasch, and G. Medanisch synthesized oligoclase :

F. Fouqué and A. Michel-Lévy, A. L. Day and E. T. Allen, and J. Morozewicz synthesized *andesine*; and F. Fouqué and A. Michel-Lévy, A. L. Day and E. T. Allen, J. Morozewicz, S. Meunier, and K. Petrasch synthesized labradorite and bytownite. Labradorite has been reported by K. Hausmann in blast-furnace slags, and by F. Sansoni, in the masonry of a kiln at Naples. S. J. Thugutt obtained a *hydrated chloro-anorthite*, $9\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 2\text{CaCl}_2 \cdot 20\text{H}_2\text{O}$, by the action of calcium chloride on sodalite.

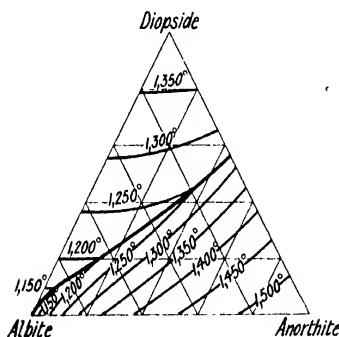

FIG. 171.—Freezing-point Curves of the System : Diopside-Albite-Anorthite.

The physical properties of the lime-felspars.—Many of the general properties of the alkali-felspars are also characteristic of the lime-felspars. The

remarks on colour, the effect of impurities on the colour, and the schillerization also apply to anorthite and the plagioclases. Sunstone and aventurine felspars are also found among these felspars. Labradorite is of a dull smoke-grey colour, but when it is observed at a particular angle, the surface lights up with brilliant play of colours—blue, green, red, bronze, etc.—and the mineral is accordingly cut and polished for jewellery and small ornamental objects. The effect is attributed to the presence of a large number of minute scales and needles of included minerals.

The **crystals** have been studied by G. Rose,¹⁵ J. D. Mackenzie, F. Rinne, J. Kratzert, A. des Cloizeaux, G. vom Rath, etc.—*vide supra*, the isomorphism of albite and anorthite. The general results show that the crystals belong to the triclinic system. A. des Cloizeaux, and N. von Kokscharoff gave for anorthite, $a:b:c = 0.63473 : 1 : 0.55007$, and $\alpha = 93^\circ 13\frac{1}{2}'$, $\beta = 115^\circ 55\frac{1}{2}'$, and $\gamma = 91^\circ 11\frac{3}{4}'$. J. Beckenkamp gave $0.63473 : 1 : 0.55007$, and $\alpha = 93^\circ 13\frac{1}{2}'$, $\beta = 115^\circ 55\frac{1}{2}'$, and $\gamma = 91^\circ 11\frac{3}{4}'$; and J. Kratzert, $0.63523 : 1 : 0.55048$, and $\alpha = 93^\circ 55'$, $\beta = 115^\circ 52.6'$, and $\gamma = 91^\circ 16.4'$. P. Groth and E. Schmidt gave for labradorite, $a:b:c = 0.6377 : 1 : (0.5)$, and $\alpha = 93^\circ 31'$, $\beta = 116^\circ 3'$, and $\gamma = 89^\circ 54\frac{1}{2}'$; G. vom Rath gave for andesine, $a:b:c = 0.63556 : 1 : 0.55204$, and $\alpha = 93^\circ 22\frac{1}{2}'$, $\beta = 116^\circ 28\frac{1}{2}'$, and $\gamma = 89^\circ 58\frac{5}{8}'$; and for oligoclase, $a:b:c = 0.63206 : 1 : 0.55239$, and $\alpha = 93^\circ 4\frac{1}{2}'$, $\beta = 116^\circ 22\frac{1}{2}'$, and $\gamma = 90^\circ 4\frac{1}{2}'$. According to J. P. Iddings, the data in Table XXVI may be taken as representative values. E. Schmidt, and E. A. Wülfing gave for plagio-

TABLE XXVI.—CRYSTALLOGRAPHIC CHARACTERS OF THE PLAGIOCLASES.

	$a:b:c$	α	β	γ
Anorthite	0.6347 : 1 : 0.5501	93° 13'	115° 55'	91° 12'
Labradorite	0.6377 : 1 : 0.5547	93° 31'	116° 3'	89° 54'
Andesine	0.6357 : 1 : 0.5521	93° 23'	116° 29'	89° 59'
Oligoclase	0.6321 : 1 : 0.5524	93° 4'	116° 23'	90° 5'
Albite	0.6335 : 1 : 0.5577	93° 3'	116° 29'	88° 9'

class with 0, 50, and 100 per cent. anorthite, $\alpha = 94^\circ 31'$, $93^\circ 27'$, and $93^\circ 05'$ respectively; $\beta = 116^\circ 38'$, $116^\circ 10'$, and $115^\circ 51'$ respectively; and $\gamma = 87^\circ 01'$, $90^\circ 06'$, and $91^\circ 34'$ respectively. The idealized crystal of anorthite, Fig. 173, has the faces $A(100)$, $B(010)$, $C(001)$, and $M(\bar{1}10)$, $m(110)$, $m'(111)$, $c(021)$, $t(201)$, $x(101)$, and $y(201)$; and the angles BC , $85^\circ 50'$; Bm , $58^\circ 4'$; mM , $59^\circ 29'$; Cm , $65^\circ 53'$; Cm , $69^\circ 20'$; CA , $63^\circ 57'$; Cx , $51^\circ 26'$; Cy , $81^\circ 14'$; and $42^\circ 38'$. The change in the angle BC , Fig. 173, with temp. is illustrated by Fig. 172. The crystallographic and optical properties of anorthite were studied by J. Kratzert. E. Kittl, and E. Dittler have studied the **velocity of crystallization** of anorthite and labradorite. The habit of crystals of the plagioclase-felspars resembles that

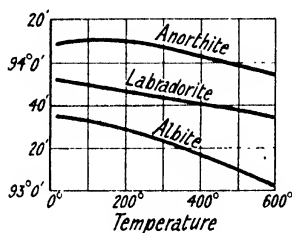

FIG. 172.—Effect of Temperature on the Angles of Plagioclase.

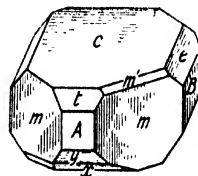

FIG. 173. Idealized Crystal of Anorthite.

of the alkali-felspars, but in megascopic crystals it is oftener tabular; and in microscopic forms, oftener prismatic. F. Rinne obtained **X-radiograms** of anorthite and oligoclase. For the deduction from these results, *vide* Figs. 139 and 163. A. Hadding investigated the X-radiograms of labradorite, and anorthite. Sections of the crystals of soda-lime-felspars often exhibit a concentric zonal structure with different zones exhibiting different optical orientations. Usually the innermost zone is the most calcareous; the sodiferous and calciferous alternate with one another. **Twinning** occurs, according to the Carlsbad, Manebach, Baveno, albite, and pericline laws cited in connection with the alkali-felspars. G. A. Rankin and F. E. Wright found the polysynthetic twinning of artificial anorthite to be very characteristic. When the albite twinning of the plagioclases is repeated many times the alternate lamellæ with their reversed optical orientation appear in thin sections between crossed nicols, in striped bands alternately light and dark. The bands may taper out or end abruptly at any place. They are clearest and sharpest-edged when the section is perpendicular to the (010)-plane of twinning. E. Herrmann has written *Ueber Zwillingsverwachsungen gesteinerbildender Plagioklase*; and the subject was studied by A. Köhler, C. W. Carstens, etc. For the **cleavage** and fracture, see alkali-felspars. The cleavage of oligoclase was investigated by S. L. Penfield.

The **optic axial angles** of anorthite were studied by M. Schuster, who found $2H_0 = 114^\circ 10'$ for the red ray and $114^\circ 47'$ for the green ray. F. Fouqué found $2V$ ranging from $77^\circ 18' - 77^\circ 55'$; and $2E = 147^\circ$; J. Kratzert gave $2V = 102^\circ 28'$

for anorthite, for labradorite and bytownite he found $2V=76^{\circ} 10'-79^{\circ} 40'$; for andesine, $2V=87^{\circ}-88\frac{1}{2}^{\circ}$; and for oligoclase, $2V=81^{\circ}-89^{\circ}$. F. Becke and M. Goldschlag obtained for andesine, $2V=90^{\circ}-98^{\circ}$; for labradorite and bytownite, for the red ray $2H_a=84^{\circ} 29'-89^{\circ} 10'$; and $84^{\circ} 23'-87^{\circ} 49'$ for the blue ray. A. de Clozeaux gave for andesine, $68^{\circ} 58'-103^{\circ}$ for $2H_a$ with the red ray, and $2H_e=84^{\circ} 31'-125^{\circ} 18'$ for the blue ray. He also gave for oligoclase, $2H_a=56^{\circ} 30'-101^{\circ} 36'$ for the red ray, and $2H_e=89^{\circ} 10'-105^{\circ} 24'$ for the blue ray. Other observations were made by E. S. von Federoff, F. Becke, H. Gylling, F. J. Wiik, D. Orueta, etc. The following data show the effect of different molar percentages of anorthite on the optic axial angle $2V$ of the plagioclase crystal:

Anorthite	0.5	13	20	25	37	52	56	63	75	100
$2V$	78°	85°	94°	99°	90°	75°	75°	82°	94°	103.5°

The effects of variations of temp. on the optic axial angle were investigated by J. Beckenkamp, F. Rinne, B. Hecht, and L. Fletcher; and the mixed crystals, by E. Köstermann and co-workers.

G. Tschermak¹⁶ computed the values indicated in Table XXVII for the **specific**

TABLE XXVII.—SPECIFIC GRAVITY AND COMPOSITION OF THE PLAGIOCLASES

Ab _a : An _m	Sp. gr.	Composition.				
		SiO ₂	Al ₂ O ₃	CaO	Na ₂ O	
Albite	1 : 0	2.624	68.7	19.5	0	11.8
	12 : 1	2.635	66.6	20.9	1.6	10.9
	8 : 1	2.640	65.7	21.5	2.4	10.4
	6 : 1	2.645	64.9	22.1	3.0	10.0
Oligoclase	4 : 1	2.652	63.3	23.1	4.2	9.4
	3 : 1	2.659	62.0	24.0	5.3	8.7
	2 : 1	2.671	59.9	25.4	7.0	7.7
Andesine	3 : 2	2.680	58.1	26.6	8.4	6.9
	4 : 3	2.684	57.4	27.1	8.9	6.6
	1 : 1	2.694	55.6	28.3	10.4	5.7
Labradorite	3 : 4	2.703	53.7	29.6	11.8	4.9

	1 : 6	2.742	46.6	34.4	17.4	1.6
	1 : 8	2.747	45.9	34.9	18.0	0.2
Anorthite	0 : 1	2.758	43.2	36.7	20.1	0

gravity of plagioclases of different composition. Sp. gr. determinations were made on many of the samples which have been analyzed, and on those whose optical properties have been measured. V. Goldschmidt has collected data on this subject. The observed values for anorthite with very low alkalis range from G. vom Rath's 2.668 to his 2.812; for bytownite, from T. Wada's 2.62 to G. H. Williams' 2.74; for labradorite, from G. vom Rath's 2.608 to his 2.814; for andesine, from C. von Hauer's 2.36 to H. Abich's 2.7328; and for oligoclase, from A. E. Delesse's 2.586 to M. F. Heddle's 2.834. Errors due to inclusions, cavities, etc., no doubt affect the extremes of these results. L. Ahlers gave for the sp. gr. of theoretically pure anorthite, 2.752-2.754 at 4°. J. A. Douglas found the sp. gr. of natural crystals of anorthite to be 2.750, and for the cold glass, after fusion, 2.665, corresponding

with 3.18 per cent. expansion. A. L. Day and E. T. Allen found for the sp. gr. of artificial plagioclases—crystal and glass:

	An	Ab ₁ An ₉	Ab ₂ An ₈	Ab ₃ An ₇	Ab ₄ An ₆	Ab ₅ An ₅	Ab
Crystals	2.765	2.733	2.710	2.679	2.660	2.649	2.605
Glass	2.700	2.648	2.591	2.535	2.483	2.458	2.383

The sp. gr. of artificial preparations are often low, owing to the presence of minute sealed gas pores. A. L. Day and E. T. Allen observed no differences in the sp. gr. of glasses cooled at different rates. The hardness of anorthite is 6 or a little over; that of labradorite and of andesine, 5-6; and that of oligoclase, about 6.

P. J. Holmquist measured the cutting hardness of albite, oligoclase, labradorite, and anorthite using carborundum of grain-size 0.006-0.012 mm. on different faces of the crystals. The results are illustrated by Fig. 174, where the dotted lines show the probable course of the curves freed from errors of experiment. L. H. Admas and E. D. Williamson found the compressibility of oligoclase, Ab₇₈An₂₂, to be $\beta = 1.74 \times 10^{-6}$ at 0 megabars press.; 1.71×10^{-6} at 2000 megabars; and 1.58×10^{-6} at 10,000 megabars; or $\beta = 0.051712 - 0.010166(p - p_0)$; labradorite, Ab₄₈An₅₂, had a value $\beta = 1.74 \times 10^{-6}$ at 0 megabars press.; 1.71×10^{-6} at 2000 megabars; and 1.58×10^{-6} at 10,000 megabars; or $\beta = 0.051508 - 0.010218(p - p_0)$; for anorthite, $\beta = 1.1 \times 10^{-6}$ at 2000-10,000 megabars press.; for andesine, Ab₂An, $\beta = 1.63 \times 10^{-6}$ at 2000 megabars, and $\beta = 1.49 \times 10^{-6}$ megabars; and for Ab₁An₂, $\beta = 1.37 \times 10^{-6}$ at 2000 megabars, and 1.30×10^{-6} at 10,000 megabars.

J. Beekenkamp found the linear coeff. of thermal expansion of anorthite in the three principal directions to be 0.00001758, 0.00000854, and -0.000032. Some observations were made by E. S. von Federoff. P. E. W. Oeberg gave for the specific heat of anorthite, 0.1937; F. E. Neumann gave for labradorite, 0.1926; J. Joly, 0.19317-0.19351 between 12° and 100°. J. Joly also gave for oligoclase, 0.19967-0.20600, and R. Ulrich 0.2048 between 18° and 98°. A. Brun gave for the melting point of anorthite, 1490°-1520°; J. H. L. Vogt, 1220°; C. Doelter, 1150°-1220° and 1250°-1350°; E. Dittler gave 1240°. G. A. Rankin gave 1550° ± 2° for the m.p. of artificial crystals of anorthite. Y. Yamashita and M. Majima gave for the m.p. of anorthite 1528°-1533°; andesine, 1333°; and oligoclase-andesine, 1232°. A. Brun gave for the m.p. of oligoclase, 1260°; J. Joly gave 1220°; A. L. Fletcher, 1270°; C. Doelter, 1130°-1175°; and later, 1170°-1250°. A. Brun gave for andesine, 1280°, and C. Doelter, 1180°-1280°. C. Doelter gave for labradorite, 1210°-1300°; J. Joly, 1230°; A. L. Fletcher, 1273°-1285°. E. Dittler gave for artificial labradorite, 1370°; A. L. Day and R. B. Sosman, 1477°; and A. L. Day and E. T. Allen, 1463°. For artificial oligoclase, A. L. Day and R. B. Sosman gave 1345°, and A. L. Day and E. T. Allen, 1340°; while for artificial andesine, A. L. Day and R. B. Sosman gave 1375°, and A. L. Day and E. T. Allen, 1419°; the last-named also found for the series:

	An	Ab ₁ An ₉	Ab ₂ An ₈	Ab ₃ An ₇	Ab ₄ An ₆	Ab ₅ An ₅	Ab
M.p.	1532°	1500°	1463°	1419°	1367°	1340°	

N. L. Bowen's freezing curves for the plagioclases are shown in Fig. 175, and he gives 1550° for the m.p. of anorthite. The remarks as to the effect of the size of grain

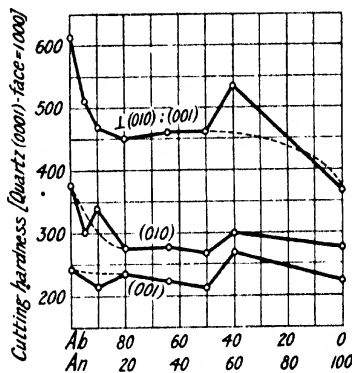

FIG. 174.—Cutting Hardness of the Albite-Anorthite Felspars.

and speed of heating on the m.p. indicated in connection with the alkali-felspars are applicable here—with this difference, unlike orthoclase, anorthite has a congruent

m.p. in which the liquid has the same composition as the crystals. A. L. Day and E. T. Allen found a sharply defined m.p. C. Doelter found that the fusion temp. really stretches over an interval:

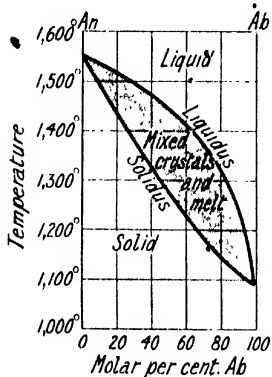

Fig. 175.—Freezing Curve of the Plagioclases.

	Ab, An ₂	Ab, An ₂	Ab, An
M.p.	1465°–1521°	1372°–1490°	1287°–1450°
	Ab ₂ An		Ab ₃ An
M.p.	1205°–1394°		1175°–1362°

H. Lictmeier observed that a sample of labradorite from Kieff, when very slowly heated had a m.p. 1245°–1250°, but was not then completely fused. A. L. Day and E. T. Allen found that microscopic crystals of a homogeneous compound, when slowly heated can persist 150° or more above the temp. at which fusion begins, since the viscosity or rigidity of the amorphous melt is of the same order as that of the crystals. The absorbed heat of fusion is distributed over this interval.

They state that powdered crystalline plagioclase felspars, which are free from inclusions and from glass, even when very fine, do not sinter until melting begins; powdered glasses of like composition sinter readily at relatively low temp. (700°–900°) depending primarily upon the degree of comminution. J. H. L. Vogt estimated the total heat of fusion from –273° to be 503 cals., and the latent heat of fusion to be 100 cal.

The indices of refraction of the plagioclases have been measured by A. Michel-Lévy and A. Lacroix,¹⁷ F. Fouqué, E. Offret, C. Viola, M. Schuster, A. N. Winchell, O. Grosspietsch, C. Riva, F. Becke, H. Rosenbusch and E. A. Wülfing, H. Tertsch, G. Linck, A. des Cloizeaux, E. S. von Fedoroff, F. Klein, W. Luczizky, E. Mallard, F. Pockels, G. Wulff, etc. The general results show that for anorthite the values of α range between 1.5740 and 1.5757; β , from 1.5810–1.5837; and γ , from 1.5860–

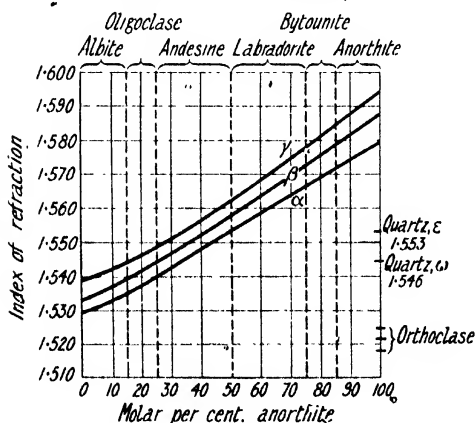

Fig. 176.—Indices of Refraction of the Plagioclase Felspars.

$\alpha=1.575$, $\beta=1.583$, and $\gamma=1.588$. F. Becke and M. Goldschlag measured the indices for some andesines. J. P. Iddings' diagram showing the indices of refraction of the lime-soda-felspars between albite and anorthite is given in Fig. 176. The data are derived from the following observations:

1.5884. Bytownite, α , from 1.5597–1.5617; β , from 1.5628–1.5647; and γ , from 1.5677–1.5689. Labradorite, α , from 1.5540–1.5167; β , from 1.5570–1.5647; and γ , from 1.5620–1.5689. Andesine, α , from 1.5490–1.5548; β , from 1.5530–1.5578; and γ , from 1.5560–1.5625. Oligoclase, α , from 1.5337–1.5389; β , from 1.5376–1.5431; and γ , from 1.5420–1.5469. G. A. Rankin and F. E. Wright gave for artificial anorthite, $\alpha=1.576$, $\beta=1.585$, and $\gamma=1.589$. J. Kratzert gave for anorthite,

	Ab ₁₀₀ An	Ab ₈₇ An ₁₃	Ab ₇₈ An ₂₂	Ab ₆₀ An ₄₀	Ab ₅ An ₉₅
α	1.5291	1.5337	1.5389	1.5490	1.5752
β	1.5332	1.5376	1.5430	1.5530	1.5833
γ	1.5390	1.5429	1.5466	1.5560	1.5884

E. Offret studied the effect of *temperature* on the refractive indices of oligoclase, and a selection from his results is given in Table XXVIII. S. Tsuboi studied the

TABLE XXVIII.—THE EFFECT OF TEMPERATURE ON THE REFRACTIVE INDICES OF THE PLAGIOCLASES.

	Red.		Yellow.		Green.		Blue.
	$\lambda_{Li}=0.6706$	$\lambda_{Ca}=0.6437$	$\lambda_{Na}=0.588$	$\lambda_{Cl}=0.5377$	$\lambda_{Ca}=0.5084$	$\lambda_{Cl}=0.4799$

optical dispersion of the plagioclase feldspars. The **birefringence** of anorthite ranges from 0.0120–0.0132; labradorite, from 0.0069–0.0089; andesine, from 0.0070–0.0077; and oligoclase, from 0.0080–0.0092. E. Offret found the birefringence at 0°, $\gamma-\beta=0.00393$, changed -0.00001 for 100°; $\beta-\alpha=0.00414$, changed $+0.00011$ for 100°; and $\gamma-\alpha=0.00879$, changed $+0.00007$ for 100°. The **optical character** of andesine with 37 molar per cent. anorthite is neutral, and that of the other plagioclases depends on the composition. Expressing the proportion of anorthite in molar percentages:

Anorthite	0.5	13	20	25	37	52	56	63	75	100
Optical char.	+	+	-	-	0	+	+	+	-	-

The plagioclase feldspars are very similar but vary continuously in composition from albite to anorthite. Methods for distinguishing between the different plagioclases based on differences in their optical characters—*e.g.* in the orientation of their axes, and in the planes of optical symmetry relatively to their crystal structures—have been developed by M. Schuster, A. Michel-Lévy, E. S. von Fedoroff, and W. W. Nikitin, L. Duparc and M. Reinhard, E. D. Stratanowitsch, H. Sigg and co-workers, M. Berck, R. Sabot, and M. A. Ouroussoff.

A. de Gramont¹⁸ examined the **spectra** of anorthite, labradorite, and oligoclase. W. W. Coblenz found oligoclase has no marked absorption bands in the **ultra-red transmission spectrum**; but there is a depression in the transmission curve at 3.3μ . W. Vernadsky found anorthite to exhibit a feeble **triboluminescence**. E. Engelhardt observed a pale blue luminescence with anorthite exposed to **ultra-violet light**; and K. Keilhack found anorthite to be luminescent when exposed to **X-rays**. C. Doelter's measurements of the **electric resistance** of labradorite are summarized in Fig. 177.

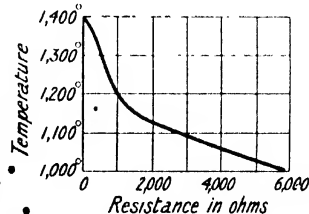

FIG. 177.—Electrical Resistance of Labradorite.

The chemical properties of the plagioclases.—C. Doelter¹⁹ digested anorthite in **water** at 80°, and after 30 days found that small quantities of silica and lime were dissolved, but only a trace of alumina. G. A. Bender worked with **water** at 90° and obtained crystals which were too small to investigate quantitatively, but which were thought to be chabasite. F. W. Clarke found that oligoclase moistened with **water** gave an alkaline reaction with phenolphthalein. G. Steiger found **water** has a slight solvent action on oligoclase. J. R. Müller investigated the action of carbonated **water** on oligoclase and found it to be more soluble than orthoclase. A. Johnstone also examined the action of carbonated **water** on oligoclase and labradorite. C. Doelter found that carbonated **water** in a sealed tube at 200° for 14 days converted anorthite into products with the optical properties of heulandite and chabasite. J. Splichal concluded from his experiments on the action of **carbonic acid** on anorthite, that lime and alkalis are extracted and a kaolinitic product is formed. E. Reymond studied the action of **chlorine** and of **hydrogen chloride** on labradorite. Anorthite is soluble in **acids**. As a rule, anorthite is decomposed by acids with the separation of gelatinous silica, and the less the proportion of anorthite in a given plagioclase, the less readily is it attacked by acids. H. S. Washington obtained a polysilicic acid, $H_5AlSi_2O_8$, by the action of acids on anorthite. J. Splichal found that **acetic, chloric, and perchloric acids** partially dissolve anorthite. He found great differences in the character of the silica gels with variations in the nature and conc. of the acids. Forty-five per cent. **formic acid** gives a gelatinous silica. J. Splichal found that with **hydrochloric acid** of sp. gr. 1.19, oligoclase is partly dissolved, and from the results inferred that the plagioclases are solid soln. and not mechanical mixtures. P. Jannasch showed that labradorite is attacked with difficulty by hydrochloric acid. W. Tarassenko studied the action of hydrochloric acid on labradorite. W. B. Schmidt found that **sulphurous acid** attacks oligoclase and labradorite more than does carbonic acid. H. Lotz examined the action of air charged with **sulphur dioxide** on labradorite. J. Lemberg found that a soln. of **sodium carbonate** converted anorthite into a mixture of calcium carbonate and a cancrinite-like substance. C. Doelter digested anorthite with a 10 per cent. soln. of sodium carbonate for four weeks at 180°, and found 3.1 per cent. of silica, 5.26 per cent. of alumina, and 12.1 per cent. of lime were dissolved. J. Splichal obtained rather different results, for only traces of lime passed into soln. J. Lemberg also studied the action of soln. of sodium carbonate on oligoclase. J. Lemberg observed that a soln. of **potassium carbonate** converted anorthite into a zeolitic substance— a kind of *potash-anorthite*, $K_2Al_2Si_2O_8$. A soln. of **sodium silicate** furnishes acicular crystals of a calcium sodium aluminosilicate. He also examined the effect of soln. of potassium and sodium carbonates and of **potassium and sodium chlorides** on labradorite—crystals and glass. C. Doelter and E. Hussak, and J. Lenarcic examined the effect of molten fluxes on labradorite. F. W. Clarke and G. Steiger examined the action of **ammonium chloride** on heated oligoclase, and found that the dried residue contained 0.32 per cent. of ammonia. Washing with **water** afterwards removed 0.96 per cent. CaO, and 2.71 per cent. Na_2O . V. P. Smirnov examined the action of **humic and crenic acids** on anorthite, and oligoclase.

The remarks on the effects of natural agents on alkali-feldspars (*q.v.*) apply also to the lime-feldspars; the products from the latter usually have a higher proportion of lime and magnesia. C. R. van Hise²⁰ discussed the change of anorthite into prehnite, zoisite, meionite, scolesite, laumontite, gismondite, and thomsonite; C. F. Rammelsberg, the change into amfodelite; A. E. Nordenskjöld, the change into sundvikite; A. des Cloizeaux, the alteration to polyargite, and tankite; and R. Hermann, and J. Roth, the change into lindsavite.

H. Sjögren²¹ found a mineral in the manganese mines of Jakobsberg, Sweden; its composition corresponded with the barium analogue of anorthite, *baryta-feldspar*; and he called it **celsian**—in honour of A. Celsius. W. S. von Waltershausen had previously obtained a complex baryta-potash-feldspar from the same locality,

and he called it **hyalophane**—from *υαλέος*, glass-like; and *φαίνω*, appearance. Analyses of hyalophane were made by G. A. Kenngott, T. Petersen, L. J. Igelström, C. F. Rammelsberg, F. Sandberger, J. C. Heusser, etc. G. Tschermak showed that hyalophane can be regarded as a mixture of baryta-anorthite, orthoclase, and albite. E. Taccioni shows that the mineral *paraëlsian* which he found near Candoglia, Italy, is really an impure celsian. Baryta-felspar has also been described by A. Knop, F. A. Genth, S. L. Penfield and E. S. Sperry, and L. J. Igelström. A. des Cloiseaux described a triclinic form which he regarded as a *barium-plagioclase*. A Mitscherlich, and H. S. Washington also mentioned finding up to about 1.10 per cent. of baryta and 0.30 per cent. of strontia in a number of orthoclase felspars. As indicated with anorthite, F. Fouqué and A. Michel-Lévy synthesized both baryta-felspar, and strontia-felspar. E. Dittler also made *baryta-felspar*, $\text{BaAl}_2\text{Si}_2\text{O}_8$. P. Eskola found that the baryta or strontia-felspar could be crystallized by fusion with molten barium or strontium vanadate, at 1400° for about 12 hrs., and washing the soluble matters from the cold mass. The crystals of baryta-felspar are mostly Carlsbad twins, and the apparent rhombic characters observed by F. Fouqué and A. Michel-Lévy, and E. Dittler are misleading because the crystals are monoclinic. Basal cleavage is not well developed. The indices of refraction indicate a negative character; for the *D*-ray, $\alpha=1.587$, $\beta=1.593$, and $\gamma=1.600$ —all ± 0.002 . α for the *F*-line is 1.593; for the *Tl*-line, 1.590; and for the *G*-line, 1.585. No twinning of *strontia-felspar*, $\text{SrAl}_2\text{Si}_2\text{O}_8$, crystals was detected; and no well-formed crystals were observed. The crystals of radiating fibres did not permit a determination of crystallographic characters. The indices of refraction for the *D*-line were $\alpha=1.574$, $\beta=1.582$, and $\gamma=1.586$ —all ± 0.002 . The optical properties of anorthite and of strontia-felspar were very similar. Evidence showed that strontia-felspar probably forms a complete series of solid soln. with anorthite.

The crystals of celsian were first stated by H. Sjögren to be triclinic, but later they were shown by F. F. Strandmark to be monoclinic with axial ratios $a : b : c = 0.657 : 1 : 0.554$, and $\beta=115^\circ 2'$. Twinning according to the Carlsbad, Baveno, and Manebach types has been described. The crystals of hyalophane were examined by W. S. von Waltershausen, G. vom Rath, F. Rinne, and G. A. Kenngott. A. Hadding examined the X-radiograms of hyalophane, and celsian. According to A. von Obermayer, the axial ratios of the monoclinic crystals are $a : b : c = 0.658395 : 1 : 0.55121$, and $\beta=64^\circ 25' 15''$; P. Groth gave $0.6584 : 1 : 0.5512$, and $\beta=115^\circ 35'$. The crystals of hyalophane have the adularia habit, and they sometimes have a zonal structure with the central portions richer in barium, and the outer portion richer in potassium. H. Sjögren gave $2V=86^\circ 22'$ for the optic axial angle of celsian. The plane of the optic axes for hyalophane is vertical to the (010)-face; and the optic axial angle, according to A. des Cloiseaux, is $2E=60^\circ$ at 20° ; and, according to F. Rinne, for Li-, Na-, and Tl-light, $2H_a$ is respectively $83^\circ 50'$, $83^\circ 25'$, and $83^\circ 2'$; $2H_o$ respectively $107^\circ 17'$, $107^\circ 30'$, and $107^\circ 52'$; and $2V$, respectively $79^\circ 21' 14''$, $79^\circ 2' 50''$, and $78^\circ 42' 14''$.

H. Sjögren gave for the sp. gr. of celsian 3.37; F. A. Genth found the sp. gr. of hyalophane with 3.71 per cent. of BaO is 2.692, and with 7.30 per cent. BaO, 2.835. W. S. von Waltershausen gave 2.771–2.832. F. F. Strandmark gave for the orthoclase (Or)-celsian (Ce) series of felspars:

	Or	Or ₁₀ Ce	Or ₁₁ Ce	Or ₁₂ Ce	O ₂ Ce	Ce ₂ Ce ₃	Ce
Sp. gr.	2.550	2.593	2.645	2.725–2.733	2.756	2.818	3.384

F. Fouqué and A. Michel-Lévy's preparations had sp. gr., *baryta-oligoclase*, 2.906, *baryta-labradorite*, 3.333, and *baryta-anorthite*, 3.573; and his *strontia-oligoclase*, 2.610, *strontia-labradorite*, 2.862, and *strontia-anorthite*, 3.043. The effect of the at. vol. of potassium, sodium, and barium on the isomorphism of orthoclase and baryta-orthoclase has been discussed by E. T. Wherry. The hardness of celsian and the hyalophanes is about 6 or over. The indices of refraction of celsian, given

by F. F. Strandmark, are $\alpha=1.5837$, $\beta=1.5886$, and $\gamma=1.5940$; for hyalophane, F. Rinne found Li-, Na-, and Ti-light, $\beta=1.5388$, $\gamma=1.5392$, and 1.5416 , respectively. The optical characters of celsian and hyalophane are negative. Hyalophane is scarcely affected by acids. A. S. Ginsberg studied the system $\text{CaAl}_2\text{Si}_2\text{O}_8$ — $\text{BaAl}_2\text{Si}_2\text{O}_8$, and found the excess of the latter crystallizes as hexagonal plates corresponding with nephelite. Mixed crystals with up to 20 per cent. of nephelite have $2V=68^\circ$, while anorthite has $2V=80^\circ$.

F. L. Ransome²² discovered a kind of hydrated anorthite in the glaucophanic schists of Tibaron Peninsula, California, and he called the mineral **lawsonite**—after A. C. Lawson. Since then, the mineral has been found in several other localities by C. Viola, A. Lacroix, E. Manasse, J. P. Smith, A. S. Finkle, S. Franchi. Analyses by F. L. Ransome and C. Palache, J. R. Schnell, W. T. Schaller and W. F. Hillebrand, F. Zambonini, A. F. Rogers, J. P. Smith, A. Lacroix, show that the composition approximates to $\text{H}_3\text{CaAl}_2\text{Si}_2\text{O}_{10}$, or **calcium dialuminium tetrahydroxydimetasilicate**, $(\text{HO})_4\text{CaAl}_2(\text{SiO}_3)_2$. F. L. Ransome and C. Palache gave this formula, and also $(\text{AlOH})_2\text{H}_2\text{Ca}(\text{SiO}_4)_2$; P. Groth gave $\text{Ca}\{\text{Al}(\text{OH})_2\}_2(\text{SiO}_3)_2$; and F. W. Clarke tripled the formula:

Lawsonite is thus related to carpholite in which manganese replaces calcium. W. Vernadsky made some observations on the constitution of lawsonite. A. F. Rogers saw that the extinction is parallel in one part of a crystal from Calaveras Valley, and in the other part has an extinction angle of 5° to the long edge of the crystal. This may mean that lawsonite, like carpholite, is monoclinic. J. P. Smith saw that lawsonite represents the anorthite portion of plagioclase set free in the chemical adjustment during metamorphic changes, and the albite portion of plagioclase either furnishes albite crystals, or contributes to the formation of glaucophane. Lawsonite is pale blue or greyish-blue in colour. Hibsite is colourless or pale yellow. The large prismatic or tabular crystals belong to the rhombic system; and, according to C. Palache, have the axial ratios $a:b:c=0.66524:1:0.7385$. The crystals have also been studied by A. F. Rogers. The twinning plane is (110). The faces (110) and (011) are striated parallel with (001). The cleavage parallel to (010) and (001) is perfect; and the cleavage parallel to (110) is indistinct. The optic axial angles $2H_a=88^\circ 27'$; $2H_0=103^\circ 16'$; and $2V_a=84^\circ 6'$ for yellow light. F. Cornu reported octahedral crystals of a mineral from Murienburg which had the same composition as lawsonite, but crystallized in the cubic system. He called the mineral *hibsite*, and considered it to be a dimorphous variety of lawsonite. The sp. gr. of lawsonite is 3.084–3.091, and the hardness 8½. The sp. gr. of the ignited powder is 2.558. The sp. gr. of hibsite is about 3.5, and the hardness about 6. The indices of refraction of lawsonite are $\alpha=1.6650$, $\beta=1.6690$, and $\gamma=1.6840$; and the birefringence $\gamma-\alpha=0.019$ for yellow light. The optical character of lawsonite is positive. The index of refraction of hibsite is 1.67. Lawsonite resists attack by acids, but after ignition it is decomposed by acids with the separation of gelatinous silicic acid. According to F. Cornu, hibsite adsorbs the dye from soln. of fuchsine; the moistened powdered mineral has an acid reaction, but after calcination an alkaline reaction; it is strongly attacked by acids—even by acetic acid; and it is decomposed by alkaline soln.

The so-called *lime-mica* was described by F. Mohs²³ as *pearly mica*. C. C. von Leonhard said that the Tyrolese mineral dealers called it **margarite**—from *μαργαρίτης*, a pearl—its present-day name.

J. L. Smith designated the micaceous mineral accompanying the smirgel of Naxos and Asia Minor, *emerylite*; and J. L. Smith and G. J. Brush showed that emerylite is identical with the margarite of Tyrol. B. Silliman gave the name *clingingmanite* to a mica accompanying the corundum of North Carolina, and the name *corundelite* to a mica associ-

ated with the corundum and smirgel of Unionville, Penn. J. D. Dana, and G. Tschermak showed that all these minerals are margarites. N. Nordenskjöld found a mica in the emerald mines of the Ural, to which he applied the term *diphanite*—from *δῖς*, twice; *φαῖνω*, to appear—in allusion to its appearance when viewed in different directions. A. Breithaupt showed that diphanite is identical with margarite.

C. F. Rammelsberg's review of the analyses correspond with $(\text{H}, \text{R})_2\text{CaAl}_4\text{Si}_2\text{O}_{12}$, or R_2SiO_4 . G. Tschermak, and R. Brauns gave for the idealized mineral $\text{H}_2\text{CaAl}_4\text{Si}_2\text{O}_{12}$; P. Groth, $\text{R}_2\text{CaAl}_4\text{Si}_2\text{O}_{12}$; and F. J. Wülk. $2\{(\text{H}_2\text{Ca})\text{Al}_2\text{SiO}_6\}$. S. Weyberg assumed the existence of a *margaritic acid*, $\text{H}_2\text{Al}_2\text{SiO}_6$, and he claimed to have made salts of this acid by the action of potassium chromate on china clay; and addition products with calcium chloride or bromide. E. V. Shannon described a specimen coloured with chromium. F. W. Clarke made two suggestions:

but prefers the former. This would make margarite, **calcium dihydrotetra-aluminyldiorthosilicate**. K. von Chroustschoff claimed to have prepared margarite by melting together a mixture of lepidolite, silicic acid, alumina, and alkali fluorides. The statements, however, require confirmation.

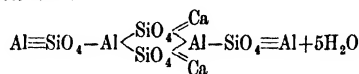

The colour of margarite is white, with a grey, red, pink, or yellow tinge. Distinct crystals are rare. It usually forms aggregates of plates, or it may be massive with a scaly structure. The crystals are monoclinic with axial ratios close to those of biotite. The habit of the crystals is tabular. Twinning is common as in mica. The cleavage is like that of mica, but the laminae are rather brittle and non elastic. The percussion figure is like that of mica. A. des Cloizeaux gave for the optic axial angle $2E=109^\circ 32'-128^\circ 48'$ for red light; M. Bauer gave $2E=76^\circ-86^\circ$; G. Tschermak, $2E=120^\circ$ for Na-light; and G. H. Williams, $114^\circ 30'$. E. V. Shannon gave $2V=30^\circ$ for the biaxial mineral. The sp. gr. ranges from 2.99-3.08; and the hardness from 3.5-4.5. G. Tschermak gave for the index of refraction $\beta=1.64-1.65$; and the birefringence is feeble for $\gamma-\alpha=0.009$. E. V. Shannon gave $\alpha=1.625$, $\beta=1.633$, and $\gamma=1.634$. The optical character is negative. E. S. Larsen made observations on the optical properties of margarite. A. Kennigott found that the moistened powder reacts feebly alkaline to litmus; and if it has been previously calcined the reaction is feebler. The mineral is slowly and imperfectly decomposed by hydrochloric acid. V. Iskynl studied the action of hydrochloric acid. F. A. Genth observed the transformation of margarite into dudleyite (*q.v.*) by the substitution of the calcium by magnesium.

A zeolite which occurs at Kilpatrick, Scotland, in amygdaloidal masses was called by H. J. Brooke²⁴ **thomsonite**, in honour of T. Thomson; and D. Brewster called that which occurs in the lavas of Monte Somma, *comptonite*—after S. J. A. Compton. T. Monticelli and N. Covell, and A. Breithaupt grouped the two minerals together, and the analyses of C. F. Rammelsberg justified this.

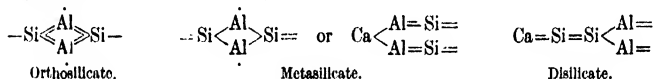

A. Breithaupt called thomsonite *triphoclase*. J. J. Berzelius called the concretions with a lamellar radiating structure at Nalso, Faroe Island, *mesole*—not mesolite—and M. F. Heddle, *faröelite*. E. T. Wherry claimed that the composition of good representative samples of faröelite approximate $\text{Na}_2\text{Ca}_2(\text{Al}_6\text{Si}_4\text{O}_{24})9\text{H}_2\text{O}$, and they have the average indices of refraction $\alpha=1.512$, $\beta=1.513$, and $\gamma=1.518$; and $\gamma-\alpha=0.006$. Hence, faröelite is optically and chemically distinct from thomsonite, and he favoured its being regarded as a definite mineral species. A. and R. Brauns considered harringtonite is the same as faröelite, and W. Haidinger, and A. des Cloizeaux showed that these minerals are varieties of thomsonite. R. D. Thomson called a mesole from Portrush, Antrim, *sconlerite*; T. Thomson, a reddish variety from the Donegore Mts., Antrim, *chaldite*; C. U. Shepard, a variety from the Ozark Mts., Arkansas, *ozarkite*; W. S. von Waltershausen, a variety in straw-yellow needles, from Hverfjörð, Iceland, *carphostilbite*; and S. F. Peckham and C. W. Hall, a green variety from Grand Marais, Lake Superior, *lintonite*—after L. A. Linton.

²⁵ Quite a large number of analyses has been reported.²⁵ The proportion of soda ranges from virtually zero up to nearly 12 per cent. The magnesia is usually

below one-half per cent., but in the so-called *microthomsonite*—from *πικρός*, bitter—of G. Meneghini and E. Bechi, the magnesia replaces soda, and may attain over 6 per cent. The sp. gr. is 2.278, and hardness 2. C. F. Rammelsberg²⁶ inferred from analyses of the mineral that there is a *soda-thomsonite*, $\text{Na}_2\text{Al}_2\text{Si}_6\text{O}_{16} \cdot 2\frac{1}{2}\text{H}_2\text{O}$, and a *lime-thomsonite*, $\text{Ca}_2\text{Al}_2\text{Si}_6\text{O}_{16} \cdot 2\frac{1}{2}\text{H}_2\text{O}$. P. Groth accepted C. F. Rammelsberg's formula, and C. Hintze doubled it; C. Doelter represented the idealized mineral as a hydrated anorthite, namely, $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, because when melted and allowed to cool, crystals of anorthite were formed. This view was adopted by F. W. Clarke in his later work :

If the analogy with anorthite be well-founded, idealized thomsonite would be $\text{CaAl}[\text{Al}(\text{SiO}_4)_2]2\frac{1}{2}\text{H}_2\text{O}$, or **hemipentahydrated calcium aluminium aluminodiorthosilicate**. The generalized formula, allowing for the soda, can be written $(\text{Ca}, \text{Na}_2)\text{Al}_2\text{Si}_2\text{O}_8 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, the $\text{Na}_2 : \text{Ca}$ ratio varying from 1:3 to 1:1. The replacement of up to about half the lime by soda, said F. W. Clarke, may be due to admixed carnegieite. S. G. Gordon found a variety with the ratio $\text{CaO} : \text{Na}_2\text{O} = 5 : 1$, and called it *calcio-thomsonite*. G. Tschermak assumed that there are three lime-thomsonites, and one soda-thomsonite. He further assumed that double salts can be formed with soda-thomsonite and the other lime-thomsonites. G. Tschermak suggested three possible types of formula; and for the sake of brevity, neglecting the oxygen atoms, these may be symbolized :

where the free ends of the hyphens represent the attachments for the bivalent base. He assumed that the silicic acid obtained by treatment with acid would decide which type of formula is best fitted for a particular zeolite. He said that with 10 per cent. hydrochloric acid, orthosilicic acid is formed, and he accordingly favoured the corresponding formula. Thomsonite often carries an excess of silica or silicic acid, possibly in solid soln. S. G. Gordon assumed as end-members $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, and $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot \text{H}_2\text{O}$ in order to represent the composition of the different thomsonites. The formulation of the composition of this mineral by the co-ordination theory with $\text{Ca} : \text{Na}_2$ approximately as 3 : 1 is

H. C. McNeil, and C. Hersch also proposed a structural formula for thomsonite. E. T. Wherry found that the analyses of thomsonite agree with that of the non-variable mineral $\text{NaCa}_2(\text{Al}_5\text{Si}_5\text{O}_{20})6\text{H}_2\text{O}$; and that the apparent variability is due to the admixture of this mineral with mesolite. O. B. Bögild found these two minerals show intergrowths.

F. Zambonini investigated the behaviour of the water on heating, and found that

	114°	158°	180°	248°	305°	365°
Loss in dry air	1.49	2.42	—	4.47	7.51	10.29 per cent
Loss in moist air	1.12	—	2.25	3.43	5.38	8.86 „

The evolution of water is greatly quickened at 400°, and the difference in the effects of dry and moist air becomes less marked. The rehydration of dehydrated thomsonite occurs in moist air; and the change is analogous to that which occurs with heulandite (*q.v.*). A. Damour found the mineral changes but slightly in moist air, but at 280° it loses 6.1 per cent. of water which it regains slowly when exposed to moist air. C. Hersch, and G. d'Achiardi also measured the loss of moisture which occurs when thomsonite is heated at different temp. The latter found

	80°-85°	145°-150°	205°-210°	255°-260°	325°-330°	Red heat.
Loss	0.942	1.69	1.107	1.365	2.179	6.556 per cent.

Thomsonite has not been prepared synthetically. It occurs in cavities in the more basic rocks and probably results from the alteration of the feldspathic constituents and nephelite.* It also occurs in crystalline schists as an alteration product of the lime-soda-feldspars. Thomsonite occurs in snow-white, reddish, green, or brown columnar masses, in radiated concretions and massive. Euhedral crystals are not so common. The crystals belong to the rhombic system, and, according to W. C. Brögger,²⁷ they have the axial ratios $a : b : c = 0.99324 : 1 : 1.00662$. The cleavage parallel to (010) is perfect; less so parallel to (100); and in traces parallel to (001). Twinning occurs on the (110)-plane, and this type has been discussed by E. Melly, and H. Guthe. The optic axial angle was found by A. Lacroix to be $2E = 82^\circ - 93^\circ 25'$ for the red ray, and $84^\circ 11' - 96^\circ 53'$ for the blue ray. V. von Lang gave $2E = 83^\circ 56'$ and $2H = 54^\circ$; and G. Cesaro, $2E = 78^\circ 86'$ for the red ray. Observations were made by H. Backlund. A. des Cloizeaux gave $2E = 85^\circ 47'$; $2V = 53^\circ 50'$; $2H_0 = 132^\circ 26'$; and $2H_a = 55^\circ 22'$; D. Hahn gave $2E = 60^\circ$. A. des Cloizeaux found at $17^\circ 2E = 78^\circ 48'$, and at 116.5° , $78^\circ 30'$. The sp. gr. ranges from 2.3-2.4; and the hardness 5-6. A colourless and radiating variety of lime-thomsonite was found by S. G. Gordon to have a sp. gr. 2.405. When warmed, clear crystals of thomsonite become turbid. As indicated above, C. Doelter found that when fused, anorthite crystallizes from the slowly cooled mass. A. des Cloizeaux gave for the indices of refraction for the red ray, $\alpha = 1.497$, $\beta = 1.503$, and $\gamma = 1.525$. O. B. Böggild said that these values are too low, and gave $\alpha = 1.497$, $\beta = 1.503$, and $\gamma = 1.525$. E. T. Wherry found $\alpha = 1.520$, $\beta = 1.525$, and $\gamma = 1.540$; S. G. Gordon, $\alpha = 1.517$ -1.529, $\beta = 1.520$ -1.531, and $\gamma = 1.530$ -1.541, and for a colourless variety of lime-thomsonite, $\alpha = 1.530$, $\beta = 1.532$, and $\gamma = 1.542$; A. H. Phillips, $\alpha = 1.529$, $\beta = 1.531$, and $\gamma = 1.541$; A. Scheit, $\alpha = 1.524$, $\beta = 1.525$, and $\gamma = 1.537$. Observations were also made by H. Michel, A. des Cloizeaux, A. Michel-Lévy and A. Lacroix, and J. Königsberger and W. J. Müller. The birefringence is strong up to about 0.02 negative, or weak up to about 0.005. Next to preolite, the birefringence is greater than that of any other zeolite, $\gamma - \alpha = 0.027$; G. Cesaro gave $\beta - \alpha = 0.0026$ -0.04. F. Rinne found that the double refraction is diminished when the mineral is warmed. Thomsonite is pyroelectric.

G. A. Kenngott²⁸ found that powdered and moistened thomsonite has an alkaline reaction, but if precalcined, the reaction is feebler. F. W. Clarke also found the moist mineral reacts strongly alkaline. Thomsonite decomposes when treated with acids, and, according to G. Tschermak, gelatinous orthosilicic acid is formed. A. Frenzel, K. D. Glinka, and J. R. Blum discussed the alteration of thomsonite in nature. K. D. Glinka obtained a crystalline substance which he called *hydrothomsonite*, $(\text{H}_2, \text{Na}_2, \text{Ca})\text{Al}_2\text{Si}_2\text{O}_8 \cdot 5\text{H}_2\text{O}$, as a decomposition product of thomsonite or scolesite at Tschakaw, near Batum. The sp. gr. was 2.0. J. Lemberg found that when digested with a soln. of potassium carbonate, a *potash-thomsonite* was formed by replacement of calcium by potassium; *soda-thomsonite* is formed when this is digested with sodium carbonate soln.; and lime-thomsonite if calcium chloride soln. is used. He also investigated the action of soln. of sodium and potassium chlorides, and hydroxides. G. Steiger found that with a soln. of silver nitrate there is a partial replacement of the bases by silver, forming a *silver-thomsonite*. G. Steiger found that when heated in the vap. of ammonium chloride there is a partial decomposition and an ammonium derivative is formed. H. C. McNeil investigated the action of molten sodium chloride. C. Gismondi²⁹ described a zeolitic mineral which he obtained in octahedral crystals from the lava of Capo di Bove; he called it *zeagonite*—from $\zeta\epsilon\upsilon\nu$, to boil; and *azyovos*, barren—and C. von Leonhard, in his translation of Gismondi's memoir, proposed calling the mineral *gismondite*. S. Breislak proposed the name *abrazite*—from *ā*, not; and *βραζείν*, to boil—and this term in some cases was corrupted to *aricite*. There seems to have been some confusion about the identity since properties described by T. Monticelli and

N. Covelli, and an analysis by P. Capri, do not agree with later observations. H. J. Brooke emphasized the relation of gismondite to phillipsite; and C. C. von Leonhard, the relations of both to harmotome; but it would appear from F. von Kobell that phillipsite from Capo di Bove and Vesuvius has been confused with gismondite from the same localities.

Analyses of gismondite have been reported by J. C. G. de Marignac,³⁰ F. von Kobell, F. Zambonini, A. Sachs, G. Tschermak, and S. J. Thugutt. As C. F. Rammeisberg showed, formulæ calculated from individual analyses are not always concordant—presumably for the reasons stated above. F. W. Clarke represented it as a hydrated anorthite, $\text{CaAl}_2(\text{SiO}_4)_2 \cdot 4\text{H}_2\text{O}$, and gave a constitutional formula similar to that employed for thomsonite. F. Zambonini and P. Groth also used the anorthite formula. This would make gismondite a **tetrahydrated calcium aluminium aluminodiorthisilicate**, $\text{CaAl}[\text{Al}(\text{SiO}_4)_2]_4\text{H}_2\text{O}$. The mineral usually contains some potash and soda, and similar hypotheses were suggested by S. J. Thugutt and G. Tschermak to explain their presence as were employed in the case of thomsonite. C. Friedel and A. Sarasin suggested the constitutional formula :

As in the case of thomsonite (*q.v.*), G. Tschermak obtained orthosilicic acid when gismondite is treated with 10 per cent. hydrochloric acid, and hence he favoured the orthosilicate type of formula. Since a mol of gismondite loses about a mol of water at 100° , he assumed that this represents the water of crystallization, and the remaining three mols of water are assumed to be an integral part of the mol which he symbolizes $\text{H}_6\text{CaAl}_2\text{Si}_2\text{O}_{11}$.

Gismondite has not been synthesized, and its high water-content indicates that it has been formed at a low temp. S. J. Thugutt showed that it is probably an alteration product of nephelite, and by the action of soln. of calcium salts on nephelite he was able to obtain a product somewhat like gismondite, and he assumed that in nature gismondite is formed in this manner. C. R. van Hise discussed the possible formation of gismondite from anorthite.

The habit of the crystals is a tetragonal pyramid more stumpy than that of the regular octahedron. The colour is white and may be tinged blue, grey, or red. J. C. G. de Marignac,³¹ G. Rose and A. Streng measured the crystal angles, and supposed gismondite to be tetragonal. H. Credner, and V. von Lang supposed it to be rhombic. A. des Cloizeaux could not decide whether the mineral was uniaxial or biaxial. Irregularities in the angles led A. Schrauf to assume that the pseudotetragonal crystals are produced by the twinning of triclinic individuals, and A. von Lasaulx came to the same conclusions from a study of the optical properties. The later observations of A. des Cloizeaux proved that the crystals are penetration twins, and that the variations in the extinction angles caused by the irregular grouping of the twins do not confirm the assumption that the individuals are triclinic. F. Rinne showed that the crystals are formed by the twinning of monoclinic individuals, and that by the raising of the temp. the variations in the extinction-angle observed by A. des Cloizeaux disappear, and the crystals become rhombic in structure. This was confirmed by F. Zambonini. Gismondite is therefore monoclinic at ordinary temp., and rhombic at a higher temp. The cleavage is not perceptible. F. Rinne found the optic axial angles for Li-light to be $2H_a = 86^\circ 58'$, $2H_o = 104^\circ 11'$, and $2V_a = 82^\circ 11' 18''$; for Na-light $2H_a = 87^\circ 34'$, $2H_o = 103^\circ 38'$, and $2V_a = 82^\circ 42' 44''$; and for Tl-light $2H_a = 88^\circ 10'$, $2H_o = 102^\circ 54'$, and $2V_a = 83^\circ 18' 40''$. J. E. Hibsche gave $2V = 86^\circ 46'$. A. des Cloizeaux found $2H$ varied from 80° – 93° . F. Rinne gave for the rhombic crystals $2H_a = 24^\circ 57'$. J. C. G. de Marignac gave 2·265 for the sp. gr., and 4·5 for the hardness. G. Tammann measured the vap. press. of the crystals with different proportions of water in equilibrium with water vap. at p mm. press. The gismondite initially contained 21·86 per cent. of water.

	14.55	12.48	6.05	1.23	0.11 mm.

F. Rinne gave for the index of refraction $\beta=1.5348$ for Li-light; 1.5385 for Na-light; and 1.5409 for Ti-light. J. E. Hirsch gave $\alpha=1.5308$, $\beta=1.5402$, and $\gamma=1.5484$ for Na-light. A. Lacroix found the dispersion $\gamma-\alpha=0.0082$ for Na-light. The optical character is negative. W. W. Coblentz found that the ultra-red transmission spectrum showed only those bands produced by water, *viz.* 1.5 μ , 2 μ , 3 μ , and 4.7 μ .

Gismondite is decomposed by acids, and according to G. Tschermak,³² gelatinous orthosilicic acid separates out. S. J. Thugutt noted that gismondite is coloured red by a soln. of silver nitrate and potassium chromate; and gismondite can be distinguished from phillipsite by its behaviour towards silver nitrate, and methylene blue. F. Grandjean found that dehydrated gismondite absorbs the vap. of mercury, cinnabar, calomel, iodine, bromine, or sulphur—*vide infra*, chabazite—and he measured the change which occurs in the optical properties of the products.

W. F. Foshag³³ applied the term *plazolite* to colourless rhombic dodecahedra occurring in the limestone of Crestmore, California. Analyses correspond with $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, or **dihydrated calcium dialuminoxylidiorthisilicate**, $\text{Ca}_3(\text{AlO}_2)_2(\text{SiO}_4)_2 \cdot 2\text{H}_2\text{O}$, in which some silica is replaced by carbon dioxide. The sp. gr. is 3.129; the hardness 6½; and the index of refraction 1.710. The mineral is readily dissolved by hydrochloric acid, it reacts slightly alkaline when moistened with water; and the reaction is strong after the mineral has been calcined.

J. N. von Fuchs³⁴ found a mineral at Mt. Monzoni, Fassa Valley, in isolated or aggregated crystals which he named **gehlenite**—after A. F. Gehlen. A. Breithaupt called it *stylöbate*—from *στυλόβατης*, base of a pillar—in allusion to the resemblance of the crystals to a square foot under a column.

H. C. Lewis found square prisms of a pseudomorphous mineral at Wakefield, Ottawa, which he named *cacoclase* from *κακός*, bad; and *κλάσις*, fracture in allusion to its want of cleavage. The crystalline form is probably tetragonal. Its sp. gr. is 3.053, and hardness 5–6. It was analyzed by F. A. Genth. The mineral appears to resemble gehlenite, and also sarcolite. E. Weinschenk described thick, four-sided, light apple-green crystals of a mineral from Monzenthal, which he called *fuggerite*. The crystals probably belonged to the tetragonal system; the basal cleavage was perfect; the sp. gr. 3.18; and the hardness 6½; and the index of refraction $\omega=\epsilon=1.691$ for Na-light. The birefringence was low. The mineral is related to akermanite and gehlenite—*vide infra*.

Analyses of gehlenite have been reported by C. F. Rammelsberg, O. B. Kuhn, J. Lemberg, V. von Zepharovich, F. E. Wright, J. Percy, J. F. L. Hausmann, J. H. L. Vogt, H. Bauerman, etc. C. F. Rammelsberg calculated the formula $\text{R}''_3\text{R}'''_2\text{Si}_2\text{O}_{10}$, or $\text{Ca}_3\text{Al}_2\text{Si}_2\text{O}_{10}$. Z. Weyberg regarded it as a basic orthosilicate, $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 2\text{CaO}$; and P. Groth, $\text{Ca}_3(\text{AlO})_2(\text{SiO}_4)_2$, *calcium dioxyaluminium diorthosilicate*. There are considerable deviations from these formulae. F. W. Clarke represented gehlenite as an aluminato-orthosilicate:

W. T. Schaller showed that like the melinites all the fuggerites and gehlenites can be represented as isomorphous mixtures of akermanite, velardenite, sarcolite, and soda-sarcolite; hence, he suggested that natural mixtures of two or more of these compounds be called by the group-name *meluite*, and that the terms *gehlenite* and *fuggerite* be dropped. J. B. Ferguson and A. F. Buddington call the silicate $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, *gehlenite*—*vide gelardenite*.*

Gehlenite is found as a secondary mineral produced by contact metamorphism in limestone. It is not infrequently found in furnace scoriae and slags, and reports of its occurrence in slags have been made by J. Percy, H. Bauerman, J. H. L. Vogt, P. Groth, J. F. L. Hausmann, and P. Heberdey. The mineral was synthesized by L. Bourgeois by simply fusing the constituents together. F. Fouqué and A. Michel-Lévy obtained good crystals by using mixtures containing magnesia, and iron

oxide. C. Doelter reported crystals resembling gehlenite to be formed when basalt is fused with limestone, and when vesuvianite is melted.

The crystals usually form short square prisms; they are sometimes tabular; and sometimes octahedral. The colour ranges from different shades of greyish-green to liver-brown. A. des Cloizeaux gave for the axial ratio of the tetragonal crystals $a : c = 1 : 0.4006$. The cleavage parallel to (001) is imperfect, and parallel to (100) in traces. V. Schumoff-Deleano and E. Dittler studied the rate of crystallization of fused gehlenite. The sp. gr. ranges from 2.90-3.07; and the hardness from 5½-6. A. Michel-Lévy and A. Lacroix gave for the indices of refraction for yellow light $\omega = 1.663$ and $\epsilon = 1.658$. The birefringence is weak being $\epsilon - \omega = 0.005$, or, according to H. Rosenbusch, 0.00618. C. Hlawatsch measured the index of refraction for different spectral lines. The optical character is negative. When treated with hydrochloric acid, the (calcined or uncalcined) mineral is easily decomposed with the separation of gelatinous silicic acid, and the soln. obtained with the fresh mineral contains ferrous and ferric chlorides. J. B. Ferguson and A. F. Buddington studied the solid soln. formed by akermanite, $\text{Ca}_2\text{MgSi}_2\text{O}_7$, and gehlenite, $\text{Ca}_2\text{Al}_2\text{SiO}_7$, and found a minimum in the curve at 1388° corresponding with 74 per cent. akermanite, of m.p. 1458° . Sp. gr. of the glasses confirmed this. Observations on the alteration of gehlenite in nature have been made by A. Cathrein, P. von Sustrinsky, C. R. van Hise, and J. Lemberg.

In the third century B.C., Theophrastus, in his *Περὶ λίθων*, referred to a mineral which he called *ἀνθραξ*; and about the beginning of our era, Pliny, in his *Historia naturalis* (37. 25-27), referred to the *carbunculus*. Theophrastus' term, meaning a burning coal, alluded to the internal fire-like colour and reflection; the same term was applied to some rubies. Pliny's term was derived from *carbo*, coal, and had the same signification as *ἀνθραξ*. These minerals are thought to be designated *granatus* by Albertus Magnus in his *De mineralibus* (2. 7) of the thirteenth century. The term was adopted by G. Agricola,³⁵ and J. G. Wallerius; it was translated into French *grenat* by J. B. L. Romé de l'Isle, and into English **garnet** by R. Kirwan. The term *granatus*, meaning like a grain, alluded to likeness of some garnets to the seeds of the pomegranate, which are small, numerous, and of a red colour.

The garnets form a class of isomorphous minerals belonging to the cubic system; and there is also an artificial product, soda-garnet. Their general formula is $\text{R}_3''\text{R}_2'''(\text{SiO}_4)_3$, where calcium, manganese, and ferrous iron may replace one another as R'' -bases; and aluminium, chromium, and ferric iron act as trivalent R''' -elements. In a few cases, titanium may act as a trivalent element replacing R''' , and it may also partially replace the silica. Thus, there are:

Sodium garnet	LAGORIOLITE, $\text{Na}_3\text{Al}_3(\text{SiO}_4)_3$
Calcium-aluminium garnet	GROSSULAR, $\text{Ca}_3\text{Al}_3(\text{SiO}_4)_3$
Magnesium-aluminium garnet	PYROPE, $\text{Mg}_3\text{Al}_3(\text{SiO}_4)_3$
Ferrous-aluminium garnet	ALMANDINE, $\text{Fe}_3\text{Al}_3(\text{SiO}_4)_3$
Manganese-aluminium garnet	SPESSARTITE, $\text{Mn}_3\text{Al}_3(\text{SiO}_4)_3$
Calcium-ferric garnet	ANDRADITE, $\text{Ca}_3\text{Fe}_3(\text{SiO}_4)_3$
Calcium-chromium garnet	OUVAROVITE, $\text{Ca}_3\text{Cr}_3(\text{SiO}_4)_3$
Calcium-ferrititanio-garnet	SCHORLOMITE, $\text{Ca}_3(\text{Fe,Ti})_3\{\text{Si,Ti}\}\text{O}_4)_3$

L. L. Fermor described *grandite* as a garnet between grossular and andradite; and *spandite*, between spessartite and andradite. The sodium present in some grossulars is assumed to be present as isomorphous lagoriolite, when not present with an included mineral. The titanium is assumed to be present in the form of $\text{Ca}_3\text{Ti}_2(\text{SiO}_4)_3$, and also as $\text{Ca}_3\text{Fe}_2(\text{TiO}_4)_3$; the ferrous-iron in the ferric garnets is assumed to be present as $\text{Fe}_3\text{Fe}_2(\text{SiO}_4)_3$; the manganese as $\text{Mn}_3\text{Fe}_2(\text{SiO}_4)_3$; the vanadium as $\text{Ca}_3\text{V}_2(\text{SiO}_4)_3$; the yttrium as $\text{Ca}_3\text{Y}_2(\text{SiO}_4)_3$; and the cerium as $\text{Ca}_3\text{Ce}_2(\text{SiO}_4)_3$. The inter-relations of the garnets³⁶ have been discussed by W. C. Brögger and H. Bäckström, E. Weinschenk, W. E. Ford, W. Eitel, H. E. Boeke, and J. Uhlig. W. E. Ford obtained the results indicated in Table XXIX. Lagoriolite has been discussed in connection with the alkali aluminium

TABLE XXIX.—COMPARISON OF THE GARNETS.

	Index of refraction.	Sp. gr.	Mol. wt.	Mol. vol.
Pyrope	1.705	3.510	404.5	115.2
Grossular	1.735	3.530	451.7	127.0
Spessartite	1.800	4.180	496.4	118.8
Almandine	1.830	4.250	499.1	117.4
Ouvarovite	1.870	—	—	—
Andradite	1.895	3.750	509.3	135.8

triorthosilicates. The others will be discussed in connection with the corresponding bases, and the descriptions referred to that of grossular which is taken as the type-member of the class. W. Eitel investigated the miscibility of the garnetic minerals.

A. G. Werner³⁷ applied the term **grossular** to a pale green garnet from Siberia. The name was derived from *grossularia*, the botanical name for the gooseberry, and applied in allusion to the colour. Various terms have been applied to grossular garnets of different colours.

A cinnamon-brown variety from Ceylon was called by A. G. Werner *Kancelstein* or *cinnamon-stone*; R. J. Haüy called it *hessonite* or *esakonite*—from *εσσω*, inferior—in allusion to its being less hard than the true hyacinth which it resembles. P. A. Dufrenoy applied the term *succinite* to an amber-yellow variety from Ala, Piedmont; and N. Nordenskjöld, *romanzovite*—after Count Romanzoff—to a brown variety from Kimito, Finland. A. Weisbach applied the term *tellmarkite* to a variety of grossular. Some of the green, yellow, and brown garnets may be iron-garnets. The lighter clear garnets are often called *hyacinths*, and regarded as gem-stones. The yellowish garnets thus furnish the so-called *jacinta la bella*; a yellowish-erimson garnet, the *guarnacino*; a somewhat similar variety, the *vermeille*, or *hyacinth-garnet*; and a reddish-violet garnet, the *rubino di rocca*, and also the *grenat syriam*—from Syriam, Pegu—and probably also the *amethyst-contes* of Pliny. The true precious garnet has a deep clear red colour like Burgundy wine, and is either a pyrope or an almandite.

Numerous analyses³⁸ of grossular have been made; some varieties are free from iron oxide, while other varieties may have up to about 8 per cent. A. Liversidge, G. A. König, and H. G. T. Wachtmeister found samples with up to 7.6 per cent. of manganese oxide; and L. Colomba, samples with nearly 5 per cent. of chromic oxide. C. F. Rammelsberg³⁹ summarized the various analyses by the formula $\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}$, which in turn may be regarded as a substitution product of normal aluminium orthosilicate, $\text{Al}_2(\text{SiO}_4)_3$, **calcium dialuminium orthosilicate**, $\text{Ca}_3\text{Al}_2(\text{SiO}_4)_3$. This view is adopted by F. W. Clarke, W. C. Brögger and H. Bäckström, and P. Groth. The graphic formula thus becomes $(\text{CaSiO}_4)_3\text{Al}_2$, or

F. W. Clarke's formula.

G. Tschermak's formula.

W. and D. Asch represent the garnets as being compounded of two silicates of the types $18\text{RO}.6\text{R}_2\text{O}_3.18\text{SiO}_2$, and $16\text{RO}.6\text{R}_2\text{O}_3.16\text{SiO}_2$; and apply the hexitepentine hypothesis to them. W. Vernadsky represents the garnets as being compounded of the mica nucleus (*q.v.*) with an orthosilicate, $\text{R}_2\text{Al}_2\text{Si}_2\text{O}_8.\text{R}_2\text{SiO}_4$. P. Erculisse regards the garnets as solid soln. of metasilicic acid and an aluminosilicic acid of the type $\text{H}_2\text{SiAl}_2\text{O}_6$. G. Tschermak claimed to have isolated mesotrisilicic acid, $\text{H}_4\text{Si}_3\text{O}_8$, from grossularite, and hence assumed that the mineral is a mesotrisilicate. The argument turns on the validity of the assumption that the product obtained actually represents the nature of the acidic radicle—*vide* the silicic acids.

W. C. Brögger showed that sodalite can be correlated with the garnets by substituting the bivalent AlO'' -group in place of sodium in soda-garnet; likewise

with the bivalent $\text{NaSO}_4\text{--Al''}$ -group for nosean (*q.v.*). The helvite family is also related with the garnets if the bivalent S.Mn.S'' -group be substituted for the base, and 3Be takes the place of 2Al, furnishing $(\text{Mn,Fe})_2(\text{MnS}_2)\text{Be}_3(\text{SiO}_4)_3$.

Grossularite is found principally in crystalline limestones where it has been developed by contact metamorphism. Grossular is a pyrogenic mineral, but its synthesis is not easy. T. H. Smith⁴⁰ described a colourless grossularite formed by deposition from magnetic waters acting on serpentine and gabbro. C. Doelter and E. Hussak found that it decomposes when melted—*vide infra*—and L. Bourgeois, and J. H. L. Vogt fused a mixture eq. to grossular and obtained anorthite and monticellite. The production of grossular must therefore be restricted to a limited range of temp.; the observations of L. L. Fermor on the probable formation of garnets at great depths show that press. may be an important factor: E. S. Sheperd and G. A. Rankin produced grossular by the action of aluminium chloride on calcium orthosilicate under press. A. Gorgeu obtained crystals of a substance like grossular by fusing pipe-clay with an excess of calcium chloride.

The garnets all crystallize in the cubic system. Grossular furnishes euhedral crystals which are commonly dodecahedrons, and icositetrahedrons, or these in combination; octahedral and cubic crystals are rare. The anedral crystals are often rounded or irregularly formed, and they may occur in grains and granular aggregates. Garnet may also occur massive, granular, or laminated. It may also appear to be compact and cryptocrystalline like nephelite. L. Cahn,⁴¹ and V. Goldschmidt and R. Schröder found growths of needle-like crystals of topaz on crystals of garnet. The colour of grossular may be white, pale green, amber, yellow, brownish-yellow, cinnamon-brown, pale rose-red, and, when chromium is present, emerald-green. Although belonging to the cubic system, D. Brewster showed that the crystals may be optically anomalous in exhibiting double refraction. This subject has been studied by A. Breithaupt, A. des Cloizeaux, M. Websky, A. Wichmann, A. von Lasaulx, P. von Jeremejeff, J. Hirschwald, E. Mallard, etc. E. Bertrand explained the phenomenon by assuming that the crystals were really pseudorhombic or pseudocubic produced by the complex twinning of triclinic individuals. C. Klein showed that the normal form of the garnet is cubic, and that the anomalous optical structure is a secondary mol. condition—probably produced by contraction after crystallization. The structure of the crystals is immediately connected with the external form, for the crystals can be regarded as being made up of a series of similar pyramids whose vertices meet at the centre. Indeed, many garnets can be easily separated into parts corresponding with these pyramids. C. Klein distinguished four types: (i) The *octahedral type* corresponding with eight triangular pyramids each of which is uniaxial and negative with the optic axis normal to the octahedral face which forms its base. (ii) The *dodecahedral type* corresponding with twelve rhombic pyramids whose bases coincide with the faces of the dodecahedron. The axial plane is parallel to the longer diagonal to which the bisectrix is normal. (iii) The *icositetrahedral type* corresponding with twenty-four pyramids whose bases are formed by the faces of the tetragonal trisoctahedron to which the optic axis or bisectrix of the pyramid is normal. (iv) The *hexoctahedral* or *topazolitic type* corresponds to forty-eight triangular pyramids with bases corresponding to the position of the faces of the vicinal hexoctahedron of topazolite. Each pyramid is biaxial. W. C. Brögger showed that garnets in igneous rocks which have been formed from magmas, or which have been embedded in rocks by regional metamorphism, are uniformly isotropic; while the crystals which have separated from hot soln. in crevices, or have been formed by contact metamorphism, usually exhibit the anomalous double refraction. The dodecahedral faces of the crystals are sometimes striated parallel to the longer diagonal. The cleavage or parting parallel to (110) is sometimes distinct. S. Nishikawa studied the X-radiogram of a garnet.

The sp. gr. of grossular ranges from 3.4–3.6. W. E. Ford gave 3.530; and P. J. Holmquist, 3.621. The sp. gr. decreases after grossular has been melted:

thus, M. Seebach found a sample with a sp. gr. 3.506 before fusion, and 2.866 after fusion. Analogous observations were made by G. Magnus, F. von Kobell, and A. H. Church. The hardness is near 7. P. J. Holmquist found that if quartz be 1000, the hardness of the (111)-face is 835; on the (110)-face, 866; and on the (100)-face, 1261. R. W. F. Oeberg found the sp. ht. of garnets ranged from 0.1744–0.1758. The garnets can be readily fused; C. Doelter gave 1110° for the m.p. of hessonite. C. Doelter and E. Hussak found that when fused alone, meionite, melilite, anorthite, lime-olivine, lime-nephelite, hematite, and spinel are produced; the products vary with the composition of the garnet. C. Doelter fused grossular with sodium and magnesium fluorides and obtained biotite, anorthite, meionite, olivine, and magnetite. A. Daunholm found the sp. ht. of garnet. A. des Cloizeaux gave 1.74 for the index of refraction. H. Rosenbusch found for a colourless sample 1.7394, 1.7438, and 1.7480 respectively for Li-, Na-, and Ti-light; similarly, for a reddish sample, 1.7399, 1.7441 and 1.7482; for a pale yellow sample, 1.7520, 1.7569, and 1.7617; and for a brown sample, 1.7575, 1.7626, and 1.7676. M. Seebach gave 1.7320, 1.7364, and 1.7411. The index of refraction of grossular which has been fused is smaller—W. E. Ford gave 1.735. H. W. Vogel measured the absorption spectrum; and W. W. Coblentz, the ultra-red transmission spectrum. Absorption bands were found in the yellowish green, and greenish-blue parts of the spectrum. In the ultra-red there is a wide absorption band extending from 1.2–2.6 μ , and complete opacity beyond 4.5 μ . S. C. Lind and D. C. Bardwell found that radium rays colour red garnet violet or purple; no fluorescence or thermoluminescence was observed. O. Mügge found specimens of garnet with radioactive haloes. B. Bavink measured the magnetic properties of garnet.

Grossular is not decomposed by acids, but after fusion acids decompose the product. G. A. Kenngott⁴² found that moist and powdered grossular has an alkaline reaction. E. C. Sullivan found that an exchange of bases occurs when garnet is treated with a soln. of cupric sulphate. E. Reymond studied the action of chlorine and of hydrogen chloride on hessonite. The transformation of grossular into chloride, epidote, meionite, wollastonite, etc., has been discussed by C. R. van Hise, E. Millosevich, E. S. von Federoff, R. von Fellenberg, C. A. Kersten, R. Hermann, G. Rose, J. R. Blum, etc. J. Roth called an earthy product of the alteration of grossular, *achtaragdlite*. J. Leimberg studied the action of a soln. of magnesium chloride on grossular which had been fused.

An isometric mineral from Achtaragda, Siberia, was named *achtaragdlite* by E. F. Glocker; *achtarandite*, by A. Breithaupt; and *achdargulite*, by F. Auerbach. It was analyzed by R. Hermann, and N. von Kokscharoff. The composition was 28.27–40.10 per cent. SiO₂; 11.11–13.06, Al₂O₃; 14.07–17.09, Fe₂O₃; 0.42, FeO; 11.27–14.41, CaO; 3.60–20.07, MgO; 8.64–12.27, H₂O. A. Breithaupt suggested that the crystals are pseudomorphs after helvite; G. Rose, after grossular; and R. Pröndel, after boracite.

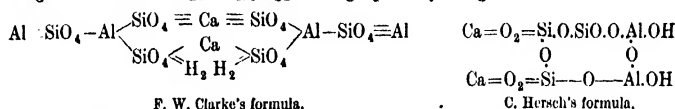

N. L. Bowen⁴³ found a fibrous white mineral in the calcite near the Abitibi River, Canada, and he named it *echellite*—from *échelle*, a ladder—in allusion to the ratio 1 : 2 : 3.4 for the components (Ca,Na₂) : Al₂O₃ : SiO₂ : H₂O, calculated from the analysis. He represents it by the formula (Ca,Na₂)(AlOH)₂Al₂(SiO₄)₃·3H₂O, or **calcium dihydroxytetraluminium triorthosilicate**, Ca(AlOH)₂Al₂(SiO₄)₃·3H₂O, a formula which recalls that of zoisite, Ca₂(AlOH)Al₂(SiO₄)₃. The mineral is probably rhombic; the indices of refraction are $\alpha=1.530$, $\beta=1.533$, and $\gamma=1.545$; the optic axial angle is 50°; and it is soluble in hydrochloric acid.

B. G. Sage,⁴⁴ and J. B. L. Romé de l'Isle mentioned a mineral resembling chrosylite from the Cape of Good Hope, and the latter regarded it as a kind of schorl. A. G. Werner named it *prehnite*—after Col. Prehn. R. J. Haty found specimens of the mineral in France. J. C. Delaméthérie called a mineral similar from the Pyrenees, *coupfolite*—from *κοῦφος*, tender—because it occurred in fragile masses made of small thin laminae or scales. L. P. Walmstedt called a prehnite

from Aedelfors, Sweden, *adelite* or *edelite*; and specimens from Keweenaw Point, and Isle Royale were called by J. D. Whitney, *jacksonite*—after C. T. Jackson.

A mineral with radiated fibres found by J. D. Whitney ⁴⁵ on Isle Royale, Lake Superior, was called *chloraströlite*—from *χλωρός*, green; and *αστρον*, a star. Analyses were made by J. D. Whitney, and G. W. Hawes. H. Groth gave for the formula $(\text{Ca}, \text{Fe}, \text{Na})_2[(\text{Al}, \text{Fe})\text{OHSiO}_4]$. F. W. Clarke gave $\text{H}_2\text{Ca}_2\text{Al}_2(\text{SiO}_4)_2$, analogous to the formulae of natrolite, and scolecite. C. F. Rammelsberg, G. W. Hawes, and C. Hintze regard chloraströlite as an impure prehnite; J. D. Dana, and P. G. Groth as analogous with carpholite; J. D. Whitney, a hydrated zoisite; and A. Lacroix, thomsonite. The colour is light bluish-green, and the mineral is slightly chatoyant on the rounded edges. The sp. gr. is 3.18; the hardness 5-6. It is decomposed by hydrochloric acid with the separation of flocculent silicic acid. W. M. Foote described a mineral occurring at Neepigon Bay, Lake Superior, which was called *zonochlorite* in allusion to its having banded zones with different shades of green. G. W. Hawes found the mineral is not homogeneous, and he regards it as impure prehnite. The sp. gr. is 3.113, and the hardness 6-7. M. F. Heddle found white or yellowish sheafy clusters of plates of a mineral at Uig, Isle of Skye, and he called it *uigite*. The sp. gr. is 2.284, and the hardness $5\frac{1}{2}$. It is regarded as a decomposition product of prehnite. C. W. Blomstrand found colourless crystals, tinged yellow or green, on Hvitholm, Spitsbergen. He called the mineral *arctolite*, or rather *arktolite*. The composition corresponds with $\text{H}_2(\text{Ca}, \text{Mg})_2\text{Al}_2\text{Si}_3\text{O}_{11}$; it thus resembles prehnite with magnesium in place of some of the calcium—*calcium magnesium dialuminium dihydrotriorthosilicate*. Really, very little is known about arctolite. The sp. gr. is 3.03, and the hardness 5.

Early analyses were made by J. H. Hassenfratz, ⁴⁶ M. H. Klaproth, L. N. Vauquelin, A. Laugier and A. F. Gehlen. A. G. Werner assumed that the contained water is zeolitic, and the mineral is sometimes regarded as a zeolite, but C. F. Rammelsberg showed that the water is expelled only at a red heat, and is therefore very different from zeolitic water. Numerous other analyses have been reported. ⁴⁷ C. F. Rammelsberg ⁴⁸ calculated from the analyses the formula $\text{H}_2\text{Ca}_2\text{Al}_2\text{Si}_3\text{O}_{12}$, and assumed it to contain silicic acid, and aluminium and calcium orthosilicates. F. W. Clarke gave $\text{Al}_2(\text{SiO}_4)_3\text{Ca}_2\text{H}_2$, **calcium dialuminium dihydrotriorthosilicate**, analogous to biotite, $\text{Al}_2(\text{SiO}_4)_3\text{Mg}_2\text{KH}$; graphically, he gave:

F. W. Clarke's formula.

C. Hersch's formula.

G. Tschermak gave $(\text{O} \cdot \text{Al} \cdot \text{O} \cdot \text{Ca} \cdot \text{O})_2\text{Si}(\text{O} \cdot \text{Si} \cdot \text{O} \cdot \text{H})_2$. The analyses indicated 2.66-5.30 per cent. of contained water. W. Dittrich and W. Eitel found that good samples contained about 4.88 per cent. As in C. F. Rammelsberg's experiment just cited, the water is retained very tenaciously up to a red heat. E. A. Schneider found only 0.17 per cent. is lost at 105°, and 0.31 between 250° and 300°. C. Hersch obtained a similar result. F. W. Clarke and G. Steiger observed the following percentage losses:

	100°	180°	250°	350°	Red heat.	Bright red.	Blast-flame.
Loss	0.21	0.18	0.10	0.11	0.28	4.05	0.09

F. Zambonini similarly obtained small losses up to 430°, and hence he considered the water to be constitutional. E. Norin gave 725°-750° for the dehydration temp., and also showed that the water is constitutional. G. Tammann found the vap. press. of the mineral at 25° to be 0.39 mm. when 0.2 per cent. was removed.

Prehnite occurs principally in basic eruptive rocks—basalt, diabase, etc.—as a secondary mineral—may be in veins. It is often associated with zeolites, pectolite, datolite, calcite, etc. A. Lacroix ⁴⁹ has described a case where it was formed by contact metamorphism. It has not been prepared synthetically, and it is doubtful if it has been formed at a high temp. Euhedral crystals are rare; their habit is generally tabular, sometimes prismatic and acute pyramidal. The aggregates of tabular crystals are united to make broken forms sometimes barrel-shaped. It also furnishes reniform, globular, or stactitic masses. The structure may be columnar, lamellar, or granular. The colour may be white, grey, or green, and the green colour

may fade on exposure. The crystals belong to the rhombic system, and A. Streng gave $a:b:c=0.84009:1:0.55494$ for the axial ratios; and A. Beutell gave $0.8420:1:1.1272$. Observations were made by W. H. Miller, G. Flink, V. M. Goldschmidt, C. F. Naumann, and A. des Cloizeaux. The cleavage parallel to (001) is distinct; but that parallel to (110) is not clear. A. des Cloizeaux found the optic axial angles are variable for the red ray, $2H$ varying from $73^\circ 43' - 76^\circ 7'$, and $2E$ from $122^\circ 59' - 129^\circ 9'$. A. Beutell found that for the red ray $2H=77^\circ 41'$, and $2E=135^\circ 16'$; for the yellow ray, $2H=77^\circ 44'$, $2E=135^\circ 26'$, and $2V=69^\circ 22'$; and for the blue ray, $2H=77^\circ 53'$, and $2E=135^\circ 54'$. H. von Eckerman gave $2V=65^\circ 52' - 68^\circ 40'$. A. des Cloizeaux found that raising the temp. from $9^\circ - 146\frac{1}{2}^\circ$ changed $2E$ from $129^\circ 48'$ to $131^\circ 50'$; and in another case, raising the temp. from $9^\circ - 121^\circ$ changed $2E$ from $52^\circ 20'$ to $50^\circ 28'$. Prehnite exhibits in some cases optical anomalies. The grouping of the parts in the aggregated forms is sometimes highly complex, and consequently there are marked variations in the optical characters. For instance, A. Mallard observed the crossed dispersion characteristic of the monoclinic system; and there may be microscopic lamination such as occurs with microcline. The subject has been investigated by A. des Cloizeaux, A. Mallard, B. K. Emerson, and A. Beutell.

The sp. gr. of prehnite ranges from 2.80-2.95; and the hardness is below 5. J. Joly gave 0.2003 for the sp. ht. of prehnite. According to C. Doelter, when prehnite is fused, and the melt slowly cooled, crystals of plagioclase and of wollastonite are formed: $\text{H}_2\text{Ca}_2\text{Al}_2\text{Si}_3\text{O}_{12} = \text{H}_2\text{O} + \text{CaSiO}_3 + \text{CaAl}_2\text{Si}_2\text{O}_8$. E. Norin studied the thermal dissociation of prehnite. According to A. des Cloizeaux, and A. Michel-Lévy and A. Lacroix, the indices of refraction for yellow light are $\alpha=1.616$, $\beta=1.626$, and $\gamma=1.649$. The double refraction is strong; A. Lacroix gave $\gamma-\alpha=1.0336$. H. von Eckermann gave $\alpha=1.6152-1.6157$, $\beta=1.6243-1.6250$; and $\gamma=1.6454-1.6462$ for Na-light. The optical character is positive. R. J. Haiy, C. A. S. Hofmann, C. C. von Leonhard, P. T. Riess and G. Rose, and G. W. Hankel made observations on the pyroelectric properties. The polarity is central, the analogous poles are at the centre of the base, and the antilogs poles at the extremities of the brachydiagonal.

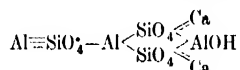

G. A. Kenngott⁵⁰ found that powdered and moistened prehnite has an alkaline reaction towards litmus. According to C. Doelter, prehnite is attacked with difficulty by hydrochloric acid, with the separation of granular silicic acid; but strongly calcined, or fused prehnite is readily attacked by acids with the separation of gelatinous silicic acid. Similar results were obtained by E. Norin. For thermal dissociation of prehnite, *vide supra*. E. C. Sullivan studied the action of soln. of cupric sulphate on prehnite. The natural transformations of prehnite into green earth, feldspar, etc., have been discussed by C. R. van Hise, J. R. Blum, H. Laubmann, P. von Sustrinsky, V. von Zepharovich, C. N. Fenner, K. Peters, etc. When the mineral is heated in the vapour of ammonium chloride, F. W. Clarke and G. Steiger observed no absorption of ammonia. When prehnite is digested with water at $210^\circ - 220^\circ$ for 342 hrs., J. Lemberg found that a hydrated silicate is formed, $\text{Ca}_2\text{Al}_2\text{Si}_3\text{O}_{11} \cdot 3\text{H}_2\text{O}$.

In 1806, A. G. Werner⁵¹ received a specimen of a mineral from Baron von Zois; and it appears to have been called by the Carinthian mineralogists *saualpite*, being found on the Saualpe, Carinthia. A. G. Werner called it *zoisite*; C. C. von Leonhard, *illuderite*. R. J. Haiy, and J. J. Bernhardt associated zoisite with epidote, and in this they were followed by many others. H. Steffens emphasized the physical differences, and H. J. Brooke separated the two minerals on crystallographic grounds. In this, he was supported later by the optical work of A. des Cloizeaux.

H. J. Brooke applied the term *thulite*—after *Thule*, an ancient name for Norway—to a rose-red mineral from Tellemarken, Norway, which he regarded as a variety of epidote. The red colour of the *porfido rosso antico* is in part due to the presence of thulite produced by the alteration of feldspar. A. des Cloizeaux, W. C. Brögger, and G. Tschermak showed

that thulite is a variety of zoisite. B. Silliman found a white mineral at Unionville, Penn.; he called it *unionite*. J. L. Smith and G. J. Brush at first regarded it as a variety of oligoclase, but later showed that it is a variety of zoisite. *Vide* saussurite, which often contains some zoisite.

c. The first analysis of zoisite was made by M. H. Klaproth,⁵² and varieties were later analyzed by C. F. Bucholz, and A. Laugier. These were followed by analyses made by others. C. F. Rammelsberg⁵³ deduced the formula $\text{Ca}_6\text{Al}_8\text{Si}_6\text{O}_{36}$; and later gave $\text{H}_2\text{Ca}_4\text{Al}_6\text{Si}_6\text{O}_{26}$. G. Tschermak, and E. Ludwig recommended the same formula and assumed zoisite to be isodimorphous with $\text{H}_2\text{Ca}_4\text{Fe}_2\text{Al}_4\text{Si}_6\text{O}_{26}$. A. Breithaupt and F. Sandberger supposed that chromic oxide can take the place of part of the alumina. C. F. Rammelsberg showed that the boric oxide found by A. des Cloizeaux, and the zirconia reported by A. von Schrötter, are to be regarded as accidental impurities. H. Laspeyres tried to show that zoisite is a salt of silicic acid, $\text{H}_4\text{SiO}_4 \cdot 25$; and G. Tschermak, that it is the salt of his garnitic acid, $\text{H}_4\text{Si}_3\text{O}_8$, namely, $(\text{AlOH})(\text{CaAlO}_2)_2\text{Si}_3\text{O}_8$. W. Vernadsky regarded it as a complex $3\text{Ca}_2\text{Al}_2\text{Si}_2\text{O}_8 \cdot \text{Ca}(\text{OH})_2$; and F. W. Clarke ascribed it to the formula, $\text{Ca}_2(\text{AlOH})\text{Al}_2(\text{SiO}_4)_3$, **calcium dialuminium aluminohydroxytriorthosilicate**:

Part of the alumina can be replaced by ferric oxide owing presumably to the existence of an incomplete isomorphous series with the end-members, *aluminium-zoisite*, $\text{H}\text{Ca}_2\text{Al}_3\text{Si}_3\text{O}_{13}$, and *iron-zoisite*, $\text{H}\text{Ca}_2\text{Fe}_3\text{Si}_3\text{O}_{13}$ —*vide infra*, epidote.

Zoisite is of secondary origin. It occurs chiefly in crystalline schists especially in those characterized by amphibolic minerals. It is also found in some granites, and in beds of sulphide ores. The formation of zoisite in nature has been discussed by A. Cathrein,⁵⁴ C. F. Chandler, F. Becke, F. A. Genth, C. R. van Hise, W. Vernadsky, and T. Hiertdahl and M. Irgens. A. Brun reported the formation of zoisite by fusing a mixture of silica, alumina, and lime. This conclusion is doubtful because the product contained no water.

Zoisite occurs in indistinct prismatic or columnar forms, and in fibrous aggregates. The euhedral prismatic crystals are sometimes striated or furrowed parallel to the *c*-axis. The colour may be white or tinged grey, yellow, green, brown, red, or, in the case of thulite, rose-red. H. J. Brooke,⁵⁵ as indicated above, showed that zoisite is crystallographically different from epidote; and A. des Cloizeaux found the crystals to be rhombic, not monoclinic like epidote. A. F. Rogers described the monoclinic crystals of clinozoisite. G. Tschermak gave for the axial ratios of zoisite $a:b:c=0.61963:1:0.34295$. Observations were also made by W. C. Brögger, F. Zambonini, G. P. Williams, H. Traube, and J. D. Dana. The cleavage parallel to (010) is perfect; and it is sometimes developed parallel to (100). G. Tschermak made observations on the twinning of the crystals. P. Termier assumed that there are polymorphous zoisites; in α -zoisite, the plane of the optic axis is parallel to (010), and in β -zoisite, this plane is parallel to (001). P. Termier suggested that both forms of crystals are really triclinic and pseudorhombic. This hypothesis has not been confirmed. F. Becke said that the aluminio-zoisites correspond with P. Termier's α -zoisite, and the ferruginous-zoisites with the β -zoisites. The optic axial angles may be variable even in the same crystal. A. des Cloizeaux gave for red light, $2E=42^\circ 50'$; for green light, $50^\circ 54'$; and for blue light, $65^\circ-70^\circ$. G. Tschermak gave $2E=94^\circ 59'$ for red and $93^\circ 6'$ for blue light. A. Lacroix gave $2E=95^\circ$ and $2V=51^\circ$. A. F. Rogers gave $2V=90^\circ$ nearly. A. Arzruni gave $2H_0=108^\circ 14'$ for Li-light, $109^\circ 48' 20''$ for Na-light, and $111^\circ 13' 30''$ for Ti-light. A. des Cloizeaux found the optic axial angle increases rapidly with rise of temp., passing from $94^\circ 59'$ at 21.5° to $107^\circ 28'$ at $195^\circ 8'$.

E. Weinschenk proposed the name *clinozoisite* for the monoclinic epidotes which are near zoisite in composition, but monoclinic in crystallization—*vide* epidote. The **pale**

rose-red crystals of epidote from Goslerwand, Tyrol, may be regarded as clinozoisite. They are optically positive; index of refraction, 1.7195; birefringence, $\gamma - \alpha = 0.0056$; optic axial angle, $2V = 81^\circ 40'$; and sp. gr., 3.372. The variety from Rothenkopf, Zillerthal, was optically negative, with the birefringence $\gamma - \alpha = 0.0105$. The monoclinic mineral named *fouquéite*—after L. Fouqué—by A. Lacroix is white or yellow, and resembles zoisite in composition. It occurs in the gneiss at Salem and Candy, Ceylon. The optical character is negative; the birefringence $\gamma - \alpha = 0.020$; and sp. gr., 3.24–3.31.

A. Breithaupt found the sp. gr. of a white variety to be 3.108, and that of a brown variety 3.381. The sp. gr. ranges from 3.1–3.4. The hardness is 6. J. J. Berzelius found that when heated before the blowpipe, zoisite swells up, forming a bubbly mass, and finally melts to a glassy slag. A. des Cloizeaux obtained a grey enamel. P. Herter made some observations on this subject. E. Norin studied the thermal dissociation of zoisite, and gave 900° – 970° for the dehydration temp. R. Cusack gave 995° for the m.p.; A. L. Fletcher, 1045° ; and C. Doelter, 1080° – 1090° . G. A. König found that when heated in a tube, the red colour of zoisite becomes grey, and when cooled again, the original colour returns. C. F. Rammelsberg said that after calcination the proportion of $\text{FeO} : \text{Fe}_2\text{O}_3$ increases; H. Laspeyres showed that the opposite result obtains. E. Weinschenk gave for the indices of refraction $\alpha = 1.6973$, $\beta = 1.7002$, and $\gamma = 1.7061$; A. Michel-Lévy, $\alpha = 1.696$, $\beta = 1.696$, and $\gamma = 1.702$; K. Zimanyi, $\alpha = \beta = 1.700$, and $\gamma = 1.705$; and P. Termier, $\alpha = \beta = 1.696$, and $\gamma = 1.7034$. A. F. Rogers gave $\alpha = 1.715$, $\beta = 1.717$, and $\gamma = 1.721$ for clinozoisite with Na-light. The respective birefringences are $\gamma - \alpha$ 0.0088, 0.006, 0.005, and 0.0073. C. Doelter investigated the action of X-rays on zoisite and found its transparency relative to tin-foil to be as 1 : 14.

G. A. Kenngott⁵⁶ found that powdered and moistened zoisite reacts alkaline with litmus; he also reported that zoisite is scarcely affected, if at all, by nitric acid. C. F. Rammelsberg found that only zoisite which has been calcined is decomposed by hydrochloric acid with the separation of gelatinous silicic acid. E. Norin obtained a similar result. The observations of G. J. Brush, E. Ludwig, R. Hermann, F. Pisani, and T. Scheerer showed that the effect of acid is determined by the composition of the mineral. According to H. Laspeyres, the fine powder is completely decomposed by boiling hydrochloric acid. C. Doelter found that sulphur dioxide passed over the mineral at a red-heat has no appreciable influence. J. Lemberg studied the action of a soln. of potassium carbonate at 200° – 210° for 708 hrs.; with sodium carbonate soln., a soda-lime-cancrinite was formed. C. Doelter passed water vap. over a molten mixture of manganous chloride and zoisite, and obtained anorthite and a lime-augite. The changes which zoisite undergoes in nature have been studied by J. R. Blum, and C. R. van Hise.

About 1783, J. B. L. Romé de l'Isle⁵⁷ and others referred to *schorl vert du Dauphiné*; J. C. Delamétherie called it *thallite*—from *θαλλός*, the colour of young twigs—in allusion to the colour; H. B. de Saussure, *delphinite*, after the locality where it was found, and *oisante*, after Bourg d'Oisans; D. L. G. Karsten, *arendalite*, after Arendal; M. F. R. d'Andrada, *akanthikonite*—from *ἀκανθίς*, a goldfinch—in allusion to the colour; M. H. Klaproth, *scorza*, A. G. Werner, *pistacite*, from *πιστάκια*, pistachio nut—in allusion to the colour; and R. J. Haiiy, **epidote** from *ἐπίδοσις*, increase—in allusion to the base of the rhomboidal prism having one side longer than the other.

A. Lévy named a mineral from Arendal, *bucklandite*—after W. Buckland. G. Rose, and G. vom Rath referred to a mineral in such terms as to make it appear as if orthite was in question. G. Rose referred later to a black epidote from Achmatovsk which N. von Kokscharoff called bucklandite. A green mineral from the same locality was called *achmatite*—after B. von Achmaloff—by G. Rose. K. Hermann showed that M. von Kokscharoff's *bagrationite*—after P. Bagration—from Achmatovsk, is not an epidote but a variety of orthite. D. Brewster applied the term *willamite*—after H. Witham—to a red epidote from Glencoe, Scotland. J. A. Wagner called a mineral from Ekaterinburg, Ural, *puschkinite*—after M. Puschkin—A. Osersky, and N. von Kokscharoff showed it to be a variety of epidote. T. Scheerer called an epidote from Maggiathale, *escherite*—

after C. Escher van der Linth. G. Munteanu-Murgoci described green massive aggregates of a mineral from Lotru, Transylvania, which he called *lotrite*. Its composition approximates $3(\text{Ca}, \text{Mg})\text{O} \cdot 2(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, its sp. gr. is 3.23; its hardness $7\frac{1}{2}$; index of refraction, 1.67; birefringence, $\gamma - \alpha = 0.014$; $2V = 30^\circ$; $2V = 18^\circ$; and it is optically positive. It is supposed to be monoclinic. The mineral *hancockite*—after E. P. Hancock—was described by S. L. Penfield and C. H. Warren. It occurs at Franklin, New Jersey, and resembles epidote in its general properties. Its composition is $(\text{Ca}, \text{Pb}, \text{Sr})_2(\text{FeOH})\text{Al}_2(\text{SiO}_4)_3$. A. Breithaupt's *beustite*—after M. von Beust—from Predazzo, Tirol, is regarded as a variety of epidote. See clinozoisite. A. Damour and A. des Cloizeaux reported crystals of a kind of *magnesia-epidote* from Lake Baikal, Siberia. They called it *pieroepidote*.

H. V. C. Descotils⁵⁸ published the first analysis of this mineral, and this was followed by the analyses of L. N. Vauquelin, M. H. Klaproth, C. F. Bucholz, R. Hermann, C. F. Rammelsberg, R. Richter and T. Scheerer. Numerous other analyses have since been published.⁵⁹ E. Ludwig⁶⁰ made direct determinations of the water in a number of epidotes, and found from 1.67–2.35 per cent.; M. Dittrich and W. Eitel found from 0.32–2.14 per cent.; and F. Zambonini found after successively heating to the following temp.:

	80°	120°	370°	460°	471°
Water lost	0.06	0.10	0.10	0.10	0.10 per cent.

Attempts to deduce a formula were made by T. Scheerer,⁶¹ R. Hermann, V. Hartwall, and A. Sobrero; and by C. F. Rammelsberg, who represented the idealized mineral by $\text{Ca}_8\text{R}_2\text{Si}_6\text{O}_{36}$. G. Tschermak, and G. A. Kenngott gave $\text{H}_2\text{Ca}_4\text{Al}_6\text{Si}_6\text{O}_{26}$. E. Ludwig confirmed this result, which was later accepted by C. F. Rammelsberg. As in the case of zoisite, more or less of the alumina can be replaced by ferric oxide, changing *aluminium-epidote*, $\text{HCa}_2\text{Al}_3\text{Si}_3\text{O}_{13}$, into *iron-epidote*, $\text{HCa}_2\text{Fe}_3\text{Si}_3\text{O}_{13}$. These form an incomplete series of solid soln., for the most ferruginous epidote known can have only 40 per cent. of iron-epidote. G. Tschermak first assumed that epidote and zoisite are isomorphous; C. F. Rammelsberg showed that these two minerals have the same composition but different crystalline forms; and G. Tschermak that they are isodimorphous. The subject was discussed by F. Kreutz, W. C. Brögger, E. Weinschenk, P. Termier, F. J. Wiik, A. Arzruni, A. Schwantke, and H. J. Barvir. Zoisite is the only representative of the rhombic epidotes. The monoclinic epidotes are:

Clinozoisite	$\text{Ca}_2(\text{AlOH})\text{Al}_2(\text{SiO}_4)_3$
Epidote	$\text{Ca}_2\{(\text{Al}, \text{Fe})\text{OH}\}(\text{Al}, \text{Fe})_2(\text{SiO}_4)_3$
Piedmonite	$\text{Ca}_2(\text{AlOH})(\text{Al}, \text{Mn})_2(\text{SiO}_4)_3$
Allanite or ortolite	$(\text{Ca}, \text{Fe})_2(\text{AlOH})(\text{Al}, \text{Fe}, \text{Ce})_2(\text{SiO}_4)_3$
Hancockite	$(\text{Ca}, \text{Pb}, \text{Sr})_2(\text{FeOH})\text{Al}_2(\text{SiO}_4)_3$

F. Balzac found an epidote approaching the end-member clinozoisite in the Ala Valley. H. Laspeyres assumed that epidote is a salt of a polysilicic acid with the empirical formula $\text{H}_4\text{Si}_6\text{O}_{25}$. E. Ludwig found no satisfactory evidence in favour of this hypothesis. G. Tschermak assumed epidote to be a salt of garnetic acid, $\text{H}_4\text{Si}_6\text{O}_{25}$; and he considered epidote to be like grossular with an atom of lime replaced by the radicle AlOH . W. and D. Asch postulated a series of nine typical epidotes and adapted their hexites and pentites to them. V. Goldschmidt regarded epidote as constituted: $3\text{R}''\text{R}_2''' \text{Si}_2\text{O}_8 + \text{H}_2\text{CaO}_2$, and F. J. Wiik, as $\text{H}_2\text{Ca}_2(\text{Al}, \text{Fe})_2\text{Si}_2\text{O}_{10} \cdot 2\text{CaAl}_2\text{Si}_2\text{O}_8$. F. W. Clarke employed a similar formula to that for zoisite (*q.v.*), thus making aluminium-epidote, $\text{Ca}_2(\text{AlOH})\text{Al}_2(\text{SiO}_4)_3$, or **calcium dialuminium aluminohydroxytriorthosilicate**; and iron-epidote, $\text{Ca}_2(\text{AlOH})\text{Fe}_2(\text{SiO}_4)_3$, or **calcium diferric aluminohydroxytriorthosilicate**. P. Groth gave for epidote $\text{AlOH} = \text{SiO}_4 = \text{Al}_2(\text{Si} \equiv \text{O}_4)_2 \equiv \text{Ca}_2$. W. Vernadsky regarded epidote and zoisite as addition products of the mica nucleus $3\text{R}_2(\text{Al}, \text{Fe})_2\text{Si}_2\text{O}_8$ with $\text{R}''(\text{OH})_2$.

Epidote is a mineral found in crystalline schists, and is common in gneiss, garnet rocks, amphibolitic, paragonitic, and glaucophanic rocks, and phyllites. It is a contact mineral in limestones; and when calcareous ferromagnesian minerals

form chlorite, epidote is simultaneously produced. Epidosite is an epidotic quartzose rock developed from diabase. C. R. Keyes⁶² showed that epidote is probably a primary mineral in some granites; A. Michel-Lévy, B. S. Butler, etc., have given other examples. The epidotization of feldspar, pyroxene, amphibole, biotite, scapolite, garnet, etc., has been discussed by numerous observers. Epidote has not been made artificially. C. Doelter⁶³ obtained indications of re-crystallization of epidote by fusing the powdered mineral with sodium and calcium fluorides. Garnet, melonite, anorthite, olivine, and magnetite were simultaneously produced. When epidote alone was fused, anorthite, and a lime-augite were produced. E. S. von Federoff made some observations on this subject.

Epidote occurs in crystals which are usually prismatic but sometimes acicular. It also occurs in fibrous and granular masses, and as epidote sand (scorza). The colour is usually a peculiar yellowish-green—pistachio green—seldom found in other minerals. This colour, however, shades into brownish-green, greenish-black, and black. The mineral also occurs white, grey, yellow, and red, the colour depending on the proportion of iron oxide. Measurements of the crystals were made by R. J. Häuy,⁶⁴ C. S. Weiss, A. T. Kupffer, F. Mohs, F. Hessenberg, W. Haidinger, L. J. Spencer, W. H. Miller, E. Artini, T. Scheerer, A. Lévy, K. Zimanyi, G. vom Rath, F. Babanek, G. Flink, J. C. G. de Marignac, J. Gränzer, B. Jezek and A. Krejci, M. von Tarassoff, A. des Cloizeaux, C. Bodewig, F. A. Quenstedt, A. Schrauf, F. Auerbach, V. von Zepharovich, etc. H. Bücking gave a historical review of the different observations which have been made on this subject. J. C. G. de Marignac measured the axial ratios of the monoclinic crystals, and N. von Kokscharoff gave $a : b : c = 1.58073 : 1 : 1.80574$, and $\beta = 64^\circ 36'$, while his son gave $1.57874 : 1 : 1.80362$, and $\beta = 64^\circ 36' 50''$. The latter values are considered to be more exact. For clinozoisite, with 1.68 per cent. Fe_2O_3 , N. von Kokscharoff gave $1.5853 : 1 : 1.8117$, and $\beta = 64^\circ 30' 21''$; F. Zambonini gave for an epidote with 14.99 per cent. Fe_2O_3 , $1.58187 : 1 : 1.80758$, and $\beta = 64^\circ 36'$; G. Boeris, for an epidote with 16.22 per cent. Fe_2O_3 , $1.57886 : 1 : 1.80181$, and $\beta = 115^\circ 22' 30''$; and N. von Kokscharoff, for bucklandite with 16.90 per cent. of Fe_2O_3 , $1.5807 : 1 : 1.8057$ and $\beta = 64^\circ 36'$. A. H. Westergaard showed that an increase in the proportion of contained ferric-epidote increases all the mol. axial ratios. The twinning parallel to (100) is sometimes lamellar; twinning parallel to (001) is rare. The cleavage parallel to (001) is perfect; and imperfect parallel to (100). H. Baumhauer, and J. Gränzer found the corrosion figures corresponded with the symmetry of the monoclinic system. A. des Cloizeaux found the optic axial angle for red light to be $2H = 92^\circ 1' - 94^\circ 6'$; $2H_0 = 115^\circ 20'$; and $2V = 74^\circ 47' - 49'$. C. Klein gave for red light $2H_a = 91^\circ 12' - 91^\circ 26'$; $2H_0 = 144^\circ 56'$; and $2V = 73^\circ 36' - 73^\circ 48'$; for yellow light, $2H_a = 91^\circ 4' - 91^\circ 20'$; $2H_0 = 145^\circ 38'$; and $2V = 73^\circ 26' - 73^\circ 39'$; and for green light, $2H_a = 90^\circ 56' - 91^\circ 12'$; $2H_0 = 146^\circ 36'$; and $2V = 73^\circ 13' - 73^\circ 26'$. E. Artini gave for Na-light, $2H_0 = 144^\circ 10'$; $2H_a = 96^\circ 18'$; and $2V = 73^\circ 59' - 77^\circ 54'$. E. H. Forbes, E. Weinschenk, M. Bauer, W. Ramsay, O. Andersen, C. Klein, E. Ludwig, and C. Schlemmer have noted the effect of ferric iron on the optical constants of epidote with M molar per cent. of ferric epidote:

M	0	3	11	14	19	23	27	37
$2V_a$	$114^\circ 40'$	$98^\circ 20'$	$90^\circ 32'$	$87^\circ 46'$	$79^\circ 55'$	$73^\circ 39'$	$73^\circ 30'$	$68^\circ 46'$

A. des Cloizeaux found that the optic axial angles are not much affected by raising the temp., the maximum change being $1^\circ 30'$ when the temp. rose from $36.5^\circ - 146.5^\circ$. M. Goldschlag found for epidotes with 0 (clinozoisite), 19 (epidote), and 37 (pistacite) per cent. of ferric-epidote, respectively:

λ		588.8	558.0	528.0	510.7
Clinozoisite		$113^\circ 47'$	$111^\circ 29'$	$109^\circ 41'$	$108^\circ 11'$
Epidote		$79^\circ 34'$	$79^\circ 9'$	$79^\circ 7'$	$78^\circ 58'$
Pistacite		$68^\circ 53'$	$68^\circ 50'$	$68^\circ 58'$	$69^\circ 1'$

H. Haga and F. M. Jäger studied the X-radiogram of epidote. The reported values for the sp. gr. of epidote vary from about 3.04-3.554. The former was obtained by D. Lovisato for an epidote with about 12 per cent. of Fe_2O_3 and is probably low, and the latter by V. von Zepharovich for a sample with about 18 per cent. of Fe_2O_3 . J. Kehlörfer found 3.365 and E. Weinschenk 3.370 for samples with about 1.68 per cent. of ferric oxide. The relation between the sp. gr. and ferric oxide content is more or less obscured by other factors:

Fe_2O_3	.	.	.	3	3.52	5.67	9.67	12.03 per cent.
Sp. gr.	.	.	.	3.370	3.399	3.367	3.440	3.386

Determinations have been reported by A. Breithaupt, A. Renard, J. W. Mallet, C. Klein, O. Andersen, A. Lacroix, H. Wulf, R. Hermann, F. J. Wiik, G. vom Rath, C. Schlemmer, E. Ludwig, T. Scheerer, etc. The hardness is about 6. The sp. gr. is lowered by calcination; thus, G. vom Rath found at 13.5° , the sp. gr. of an epidote was so reduced from 3.361-3.316. F. von Kobell found for another sample a reduction from 3.46-3.38; and C. F. Rammelsberg, a reduction from 3.403-3.271. W. Suida, C. F. Rammelsberg, H. Laspeyres, D. Lovisato, etc., found that the proportion of ferric oxide in epidote was lowered by calcination, or by fusion with borax. The loss on ignition is therefore not all due to the loss of water and organic matter. T. Scheerer, E. Ludwig, and H. Laspeyres attributed the causes of the reduction of the ferric oxide to reducing gases from the flame; and C. F. Rammelsberg, and W. Suida to the dissociation of the ferric oxide at the temp. of the ignition. H. Fizeau found for the coeff. of linear expansion for the chief axis and for the two axes in the plane of symmetry, respectively $\alpha_1 = 0.0593126$, $\alpha_2 = 0.0533400$, and $\alpha_3 = 0.04108600$; this makes the coeff. of cubical expansion $\alpha_1 + \alpha_2 + \alpha_3 = 0.0423335$; and the mean linear coeff. 0.057778 . E. Jannettaz gave 0.634 for the square root of the ratios of the conductivities in the directions of the α - and γ -axes; and 1.088 in the directions of the β - and γ -axes; he also found the axial ratios $\alpha : \beta : \gamma$ of the isothermal ellipse to be 0.934 : 1 : 1.088, and the ratios of the thermal conductivities in these directions, 0.87 : 1 : 1.18; he found that the vertical axis $c(001)$ and the principal axis made an angle $-14^\circ 30'$. H. Fizeau made some observations on this subject. P. E. W. Oeberg found the sp. ht. of epidote to be 0.1861 between 16° and 100° ; and J. Joly found 0.1877 between 13° and 100° . R. Cusack gave for the m.p., 954° - 976° ; A. L. Fletcher, 1001° - 1026° ; A. Brun, 900° - 1250° ; and C. Doelter, 1095° . E. Norin studied the thermal decomposition of epidote and gave 900° - 1000° for the dehydration temp.

M. Goldschlag found the indices of refraction increase in magnitude as the proportion of ferric epidote increases. This is illustrated by the values of the indices of refraction for light of different wave-lengths, λ , shown in Table XXX. E. H. Forbes, E. Weinschenk, M. Bauer, W. Ramsay, O. Andersen, C. Klein,

TABLE XXX.—THE INDICES OF REFRACTION OF EPIDOTE.

λ	Clinzoisite.			Epidote with 19 per cent. of ferric-epidote.			Epidote with 37 per cent. of ferric-epidote.		
	α	β	γ	α	β	γ	α	β	γ
656.3	—	1.7132	—	1.7174	1.7372	1.7445	—	1.7591	—
588.3	1.7136	1.7172	1.7188	1.7217	1.7422	1.7500	1.7291	1.7634	1.7796
558.0	1.7178	1.7204	1.7222	1.7244	1.7455	1.7540	1.7315	1.7655	1.7815
528.0	1.7182	1.7219	1.7237	1.7265	1.7479	1.7570	1.7339	1.7676	1.7836
523.2	—	1.7228	—	1.7270	1.7493	1.7579	—	1.7691	—
510.7	1.7201	1.7238	1.7258	1.7286	1.7504	1.7593	1.7375	1.7702	1.7867
476.0	—	1.7277	—	1.7319	1.7551	1.7651	—	1.7725	—

E. Ludwig, and C. Schlemmer have also investigated the indices of refraction of epidote with *M* molar per cent. of ferric-epidote, and found

<i>M</i>	0	3	11	14	19	23	27	37
α	1.7124	1.7176	1.7140	1.7240	1.7228	—	1.7336	1.7260
β	1.7138	1.7195	1.7160	1.7244	1.7413	1.7582	1.7593	1.7620
γ	1.7175	1.7232	1.7240	1.7344	1.7533	—	1.7710	1.7796
$\gamma - \alpha$	0.0051	0.0056	0.0080	0.0144	0.0305	0.0350	0.0374	0.0536

The double refraction of the epidotes low in iron is positive and negative with those rich in iron. The transition occurs with epidotes containing 7–11 per cent. of ferric-epidote. The pleochroism and interference phenomenon were investigated by D. Brewster, J. B. Biot, A. Bertin, and W. Voigt; and H. Nagaoka examined the effect of temp. on the pleochroism. The absorption phenomena were studied by C. Klein, H. Laspeyres, C. Pulfrich, E. Carvallo, W. Ramsay, and H. Becquerel. V. Agafonoff studied the absorption of ultra-violet rays. W. W. Coblentz found the ultra-red transmission spectrum showed the hydroxyl band at 3μ ; and additional bands at 4.3μ , 4.7μ , 5.0μ , 5.3μ , 5.6μ , 5.9μ , 6.6μ , and 7.4μ . Some of these are common with those of silica. W. Arnold, and L. P. Thompson studied the dichroism of epidote for X-rays; and C. Doelter found that the transparency of epidote for the X-rays is small. E. Jannettaz studied the electrical conductivity of epidote. W. Finke measured the magnetic susceptibility of epidote. A. des Cloizeaux found that fused epidote is non-magnetic. B. Bavink studied the properties of the crystals.

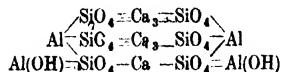

H. Laspeyres⁶⁵ found dark green or brownish-green globules of glass in epidote which had been calcined. W. Hermann heated epidote to dark redness in a stream of various gases; and found in oxygen, the colour becomes more yellow and darker; in hydrogen, dark yellow; in coal gas, greener and darker; and in nitrogen, more yellowish-green. The changes are connected with the relative colouring effects of ferrous and ferric oxides. T. Scheerer, and E. Ludwig found that the water which is expelled from epidote by calcination has an acid reaction. G. A. Kenngott found that epidote powdered and moistened has a distinct alkaline reaction towards litmus, and the reaction is rather faster if the mineral has been calcined. G. A. Binder found that epidote heated, with carbonated water in a sealed tube at 160° for 4 weeks, is partly decomposed, but an inappreciable quantity passes into soln. E. W. Hoffmann, W. B. and R. E. Rogers, and C. G. C. Bischof have made observations on this subject. E. Ludwig, and C. F. Rammelsberg (1846) found that epidote is not attacked by hydrochloric acid, but the calcined mineral is completely decomposed with the separation of flocculent silicic acid. G. vom Rath said epidote is not soluble in hydrochloric acid whether the mineral has or has not been calcined. F. von Kobell, W. Baer, and C. F. Rammelsberg (1856) found epidote is partially decomposed by hydrochloric acid, but H. Laspeyres, J. Cordier, and A. E. Nordenskjöld said epidote is completely decomposed by the boiling acid. A. Renard said that epidote is completely dissolved by hydrochloric acid in a sealed tube at 125° – 130° . C. Doelter found a small decomposition when epidote is heated in a stream of sulphur dioxide. H. Behrens and P. D. C. Kley found epidote to be only slightly attacked by sulphuric acid. G. A. Kenngott said that epidote is but slightly attacked by nitric acid, but the calcined mineral is easily decomposed with the separation of gelatinous silica. E. Norin obtained a similar result. E. Raymond studied the action of chlorine and of hydrogen chloride on epidote. E. C. Sullivan studied the exchange of bases which occurs in soln. of cupric sulphate. Epidote is less liable to alteration than a good many silicates; the contained iron is mostly present as ferric oxide. C. Simmonds found that epidote does not show any definite reduction by hydrogen at a red heat. The transformations of epidote in nature have been discussed by C. R. van Hise,⁶⁶ W. Haidinger, J. R. Blum, G. Rose, E. Döll, J. Morozewicz, C. Doelter, C. Heusser and G. Claraz, A. Lagorio, P. von Jeremejeff, etc.

The crystals of a mineral from Vesuvius were at first regarded as a variety of

hyacinth; accordingly, M. A. Cappellar⁶⁷ called it *hyacinthus octodecahedricus*; J. B. L. Romé de l'Isle, *hyacinte da Vesuve*; J. Demesté, *hyacinte volcanique*; P. S. Pallas, *Hyacinth-Krystalle*; and J. C. Delamétherie, *hyacinthine*. J. F. W. Widenmann called it *volcanic schorl*; A. G. Werner, and M. H. Klaproth, *vesuvian*—from the first known locality; and R. J. Haüy, *idocrase*—from *εἶδω*, I see; and *κράσις*, mixture—in allusion to a resemblance between its crystalline forms and those of other species. J. D. Dana changed A. G. Werner's term *vesuvian* into *vesuvianite*.

A. G. Werner assumed that the mineral is exclusively volcanic. An identical mineral was found by C. A. Murray, at Gökum, Finland, and called by J. von Lobo *galnite*—after J. C. Gahn; J. J. Berzelius called it *loboite*—after J. von Lobo da Silveira; and T. Thomson, *gökumite*. A magnesian variety from Frugard was called by N. Norden-skjöld, *frugardite*; it had a sp. gr. 3.349, while a non-magnesian variety of sp. gr. 3.390 from the same locality was called *jevreinovite*. A sub-columnar brown variety from Eger, Bohemia, was called *egeran* by A. G. Werner. J. J. Berzelius called a bluish variety containing a trace of copper *cyprine*. It was found at Tellemarken, Norway, and analyzed by G. Lindström. J. V. Lewis and L. H. Bauer found a specimen in Franklin, New Jersey, and it was analyzed and described by E. V. Shannon. T. Thomson called a yellowish-brown variety from Amity, New York, *anthile*—from *ἄνθος*, yellow. R. Hermann found small green prisms of a variety of vesuvianite at Zlatoust, Ural, and called it *heteromerite*—from *ἑρεpos*, other; *μέρος*, part—in allusion to a supposed variation in the normal composition. A. von Lasaulx called a manganiferous variety from St. Marcel, Piedmont, and from Pajsberg, *mangan-idocrase*, or *mangan-vesuvianite*. See colophonite. The mineral *viluite* or *vilitite* from Wilui or Vilui, Siberia, described by N. von Kokscharoff, A. T. Kupffer, P. S. Pallas, A. Estner, M. H. Klaproth, R. J. Haüy, C. C. von Leonhard, C. A. S. Hofmann, and V. von Zepharovich occurs associated with grossular, and is considered to be a boriferous variety of vesuvianite. The mineral *californite*, found by G. F. Kunz in California, has the appearance of jade, and it takes a high polish. It is a variety of vesuvianite.

M. H. Klaproth,⁶⁸ and F. von Kobell analyzed the mineral, but the results were not unlike those for garnet. G. Magnus believed that garnet and vesuvianite had the same composition; but R. Hermann held a different view. G. Magnus said that, on melting, the sp. gr. is reduced while the weight is not affected; but C. F. Rammelsberg showed that there is a 2.3 per cent. loss owing to the expulsion of water. This was later confirmed by G. Magnus, and T. Scheerer. The latter said that the water is not to be regarded as a secondary but rather as a primary constituent. M. Weibull, G. Lindström, L. Iwanoff, E. Grill, and J. H. Vogel found samples with up to nearly 2 per cent. of fluorine; and C. F. Rammelsberg, R. A. Prendel, P. Jannasch, E. T. Wherry and W. H. Chapin, samples with up to 10.20 per cent. of boric oxide. Many attempts have been made to find the primary compound in vesuvianite. It is probably a solid soln. of several minerals. C. F. Rammelsberg required four formulæ to represent the compositions of different varieties of the mineral. P. Jannasch and P. Weingarten gave $\text{Ca}_2(\text{OH})\text{AlSi}_2\text{O}_7$; M. Weibull, $\text{CaR''Al}_2\text{R'''(OH,F)Si}_5\text{O}_{20}$, where R'' represents Mg, Fe, Ca, Mn, Na, K, H₂ or $(\text{MgOH})_2$; while R''' represents Al, Fe, Ti, or B; H. Sjögren, $\text{R''}[R'''\text{Al}(\text{SiO}_4)_3]_2$, where R'' denotes $(\text{AlOH})'$, $(\text{AlF})'$, Ca, Mg, Na, H₂, and $(\text{CaOH})_2$; P. Groth, $\{\text{Al}(\text{OH},\text{F})\}\text{Ca}_6\text{Al}_2(\text{SiO}_4)_5$; G. Tschermak, $\text{H}_4\text{Ca}_{12}\text{Al}_6\text{Si}_{10}\text{O}_{43}$; and F. W. Clarke, $\text{R}'_4\text{Ca}_7\text{Al}_2\text{Si}_6\text{O}_{24}$, where R' may be Ca, $(\text{AlOH})_2$, $\{\text{Al}(\text{OH})_2\}_4$, or H₄. There are some replacements of calcium by magnesium and iron; a little of the hydroxyl may replace fluorine, and some boric oxide may be present. F. W. Clarke gave the graphic formula:

which is very like that of epidote, but with Ca₃ in place of Al₂. E. V. Shannon represented its composition by $4\text{R''O} \cdot \text{R}_2\text{O}_3 \cdot 3\text{SiO}_2$ with part of the oxygen replaced by F- and HO-groups.

Vesuvianite is found among the ancient ejecta of Vesuvius, and in the dolomitic

blocks of Monte Somma. It occurs as a product of contact metamorphism in granular limestones, and it is then associated with pyroxene, scapolite, garnet, epidote, diopside, and wollastonite. It is also found in serpentines, gneiss, chlorite schists, and related rocks. V. Goldschmidt⁶⁹ considers that as a contact mineral it is formed by the association of garnet, wollastonite, and water; $\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12} + \text{H}_2\text{O} + \text{CaSiO}_3 = 2\text{Ca}_2\text{AlSi}_2\text{O}_7(\text{OH})$. E. Mitscherlich, and R. A. Prendel found crystals of what was considered to be vesuvianite in blast-furnace slags, but F. Fouqué, and F. Fouqué and A. Michel-Lévy doubted the inference. A. Daubrée reported the synthesis of a product like vesuvianite by the action of silicon tetrachloride on a mixture of alumina and lime. H. St. C. Deville said that the product was probably something other than vesuvianite. F. Fouqué and A. Michel-Lévy, and C. Hintze said that it is doubtful if vesuvianite has been synthesized. M. K. Klaproth obtained a crust of what he regarded as crystals of vesuvianite by cooling the molten mineral. A. des Cloizeaux obtained crystals in an analogous manner, but F. Fouqué and A. Michel-Lévy showed that they were a mixture of melanite, anorthite, and pyroxene. C. Doelter and E. Hussak also showed that the fusion of vesuvianite is attended by its decomposition, forming melonite, melilite, anorthite, and a calcium-chrysolite. C. Doelter also tried to obtain crystals by heating vesuvianite with calcium or ammonium fluoride, and by heating mixtures of grossular and wollastonite with sodium or calcium fluoride, but obtained *gehlenitartige Körper*, not vesuvianite.

Vesuvianite occurs in euhedral crystals; in irregular anhedral crystals; in aggregates of prisms; and in granular cryptocrystalline masses. The colour is brown to green, and sometimes sulphur-yellow or pale-blue. M. Weibull⁷⁰ has compiled a table showing the colours of crystals containing different proportions of ferrous and ferric oxides. He said that the yellow crystals have but little ferrous oxide, and up to about 3 per cent. of ferric oxide; the green crystals have up to about 1 per cent. of ferrous oxide, and 4 per cent. of ferric oxide; while the brown crystals have over 2 per cent. of ferrous oxide and about the same quantity of ferric oxide. The crystals were examined by J. B. L. Romé de l'Isle, R. J. Haüy, N. von Kokscharoff, A. Breithaupt, R. A. Prendel, P. Groth, L. Wiser, C. Doelter, A. Cathrein, W. J. Lewis, M. Tarassoff, G. Strüver, F. Tannau, etc. A. T. Kupffer gave for the axial ratio of the tetragonal crystals $a : c = 1 : 0.537195$; and V. von Zepharovich, $1 : 0.537541$. The cleavage parallel to (110) is not very distinct; and the cleavage parallel to (100) and (001) is still less so. There is sometimes a lamellar structure with a tendency to scale in thin layers. The corrosion figures were examined by F. Leydolt, and R. A. Prendel. Some crystals of vesuvianite are optically anomalous and exhibit biaxial phenomena; indeed, A. Brezina found crystals from Ala with an optic axial angle $2E = 62^\circ 25'$ for red rays, $62^\circ 47'$ for yellow rays. The phenomenon was studied by A. Madelung, E. Mallard, A. von Lasaulx, F. Klocke, and R. A. Prendel. The crystals appear to be made up of segments with different optical properties, and oriented with respect to the outward form of the mineral as in the case of garnet, analcite, etc. The structure seems to have been produced by strains subsequent to crystallization. F. Klocke found that compression changed biaxial into uniaxial crystals. A. des Cloizeaux observed no change in the optical behaviour by raising the temp. from 12° – 161° . C. Doelter found that by heating to redness the axial angle, if small, increased, and if large, decreased. R. A. Prendel found that near 300° biaxial wiluite became uniaxial.

The sp. gr. of vesuvianite ranges from 3.35–3.55. G. Magnus found the sp. gr. after fusion is reduced to 2.95; and E. Varrentrapp, to 2.93. The hardness is 6–7. A. Brun gave for the m.p. 800° – 1000° ; R. Cusack, 1024° – 1025° ; and A. L. Fletcher, 1074° – 1085° . As indicated above, the mineral decomposes when melted. R. A. Prendel found the coeff. of thermal expansion between 20° and 120° to be 0.00095–0.00111 parallel to the chief axis, and 0.00077–0.00091 perpendicular to the chief axis. J. Joly gave 0.19457–0.19529 for the sp. ht. E. Jannettaz found the square root of the ratio of the thermal conductivities perpendi-

cular and parallel to the chief axis to be 0.95. R. A. Prendel found the conductivity parallel to the chief axis is greater than perpendicular thereto. The indices of refraction are high. A. des Cloizeaux gave $\epsilon=1.719-1.722$, and $\omega=1.718-1.720$ for yellow rays; H. Rosenbusch, $\epsilon=1.7226$, and $\omega=1.7235$; C. Hlawatsch, $\epsilon=1.701-1.726$, and $\omega=1.705-1.732$; F. Zambonini, $\epsilon=1.7004-1.7216$, and $\omega=1.7032-1.7324$; and E. V. Shannon, $\omega=1.710$, and $\epsilon=1.698$. The birefringence is weak. F. Zambonini gave $\omega-\epsilon=0.0018-0.0034$; and C. Hlawatsch gave 0.00301 for the *B*-ray; 0.00274 for the *D*-ray; 0.00245 for the *F*-ray; and 0.00187 for the *G*-ray. The optical character is usually negative, that of wiluite is positive. As indicated above, the colour, optical character, and refractive index may be variable in successive concentric layers of the same crystal. The pleochroism is not usually strong. A. des Cloizeaux, and A. von Lasaulx reported that ϵ is colourless or yellowish, and ω is reddish, yellowish, or greenish. E. Bertrand found a mangiferous vesuvianite from Jakobsberg showed an orange and amethyst-violet colour. A. Sohneke, and A. Engelhardt observed the fluorescence of vesuvianite. H. Becquerel studied the absorption spectrum. C. Doelter found vesuvianite to be more transparent for X-rays than calcspar. G. W. Hankel studied the pyroelectric properties, and B. Bavink, the magnetic properties of vesuvianite.

G. A. Kenngott⁷¹ found the powdered and moistened mineral reacts alkaline towards litmus. Hydrochloric acid has scarcely any effect on the mineral, but after calcination, or better, after fusion, vesuvianite is attacked by the acid with the separation of gelatinous silicic acid. E. C. Sullivan studied the basic exchange of vesuvianite in cupric sulphate soln. Vesuvianite under various natural conditions alters to clinocllore, mica, diopside, and garnet. These alterations have been investigated by J. R. Blum, P. Jeremejeff, P. Miklaschewsky, G. Sillem, G. Tschermak, and J. Lemberg. The last-named studied the action of soln. of magnesium sulphate and chloride on vesuvianite at 130°-180°.

F. E. Wright⁷² found a mineral like gehlenite in the Velardena mining district, Mexico; and W. T. Schaller considers that the analysis corresponds with a mixture of what he called **velardenite**, $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, with about 20 per cent. of akermanite, $4\text{MgO} \cdot 8\text{CaO} \cdot 9\text{SiO}_2$. The composition of the assumed velardenite is that of **calcium dialuminatometasilicate**, $\text{SiO}(\text{AlO}_2 \cdot \text{CaO})_2$, or, as W. T. Schaller writes it, $(\text{CaAlO}_2 \cdot \text{O})_3\text{Si} \cdot \text{O} \cdot \text{SiO} \cdot \text{O} \cdot \text{Si} \cdot (\text{O} \cdot \text{CaAlO}_2)_3$. J. B. Ferguson and A. F. Buddington apply the term *gehlenite* to this compound. The compound was artificially prepared by Z. Weyburg by fusing china clay with a small proportion of calcium bromide, and washing out the matters soluble in water. The descriptions of the properties of the mineral by F. E. Wright, and of the artificial crystals by Z. Weyburg and

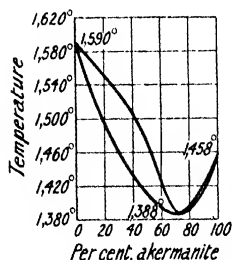

FIG. 178. — Freezing-point Curves of Mixtures of $2\text{CaO} \cdot 2\text{SiO}_2$ and $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$.

G. A. Rankin and co-workers, are very much alike. Thus, writing the properties of the mineral first, both furnish tetragonal crystals, the cleavage (001) is imperfect and the prism cleavage is poor; the (001) cleavage is distinct. The sp. gr. is 3.039, and 3.038; the hardness 5 and 6; the m.p. 1590°; the indices of refraction, $\omega=1.666$ and 1.667, and $\epsilon=1.661$ and 1.658; while $\omega-\epsilon=0.0055$ and 0.009. E. V. Shannon gave $\omega=1.657$, and $\epsilon=1.653$. The refractive index of the glass is 1.638. The optical character of both is negative. G. A. Rankin and F. E. Wright's diagram, Fig. 158, shows the regions of stability of this compound. Its m.p. is $1590^\circ \pm 2^\circ$. F. E. Wright added further that the colour of velardenite is dark grey or greyish-black owing to minute inclusions of magnetite, etc.; the colour is rarely amber-yellow. The fracture is irregular and uneven, conchoidal to splintery. The mineral is gelatinized by acids.

J. B. Ferguson and A. F. Buddington obtained the f.p. diagram, Fig. 178 for

binary mixtures of akermanite, $2\text{CaO} \cdot \text{MgO} \cdot 2\text{SiO}_2$, and gehlenite, $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$. There is a series of solid soln. with a minimum m.p. at 1388° , a little below the m.p. of diopside, and corresponds with 74 per cent. of akermanite and 26 per cent. of $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$. They found for the sp. gr., the sp. vol. of crystals and glass of the binary series, at 25° :

Akermanite	0	25	50	75	100 per cent.
Sp. gr. (Crystals)	3.038	3.018	2.993	2.969	2.944
(Glass)	2.884	2.903	2.919	2.938	2.955
Sp. vol. (Crystals)	90.4	90.8	91.5	92.1	92.8
(Glass)	95.2	94.5	93.8	93.1	92.4

This conforms with the isomorphous character of the system. The optical characters of the crystals for Na-light are:

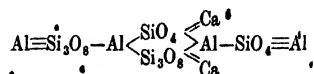

Akermanite	0	20	40	50	75	100 per cent.
ω	1.669	1.664	1.657	1.653	1.643	1.632
ϵ	1.658	1.657	1.654	1.652	1.647	1.639
ω/ϵ	0.011	0.007	0.004	0.001	0.004	0.007
Character		--	--	--	+	+

The references of I. S. R. I. Eques a Born,⁷³ F. de St. Fond, and J. B. L. Romé de l'Isle, to a *zeolithus crystallisatus cubicus* or *zeolite en cubes*, probably apply to the zeolite called by B. d'Antic, and R. J. Haüy, *chabasie*, and by C. A. S. Hoffmann (1818), **chabasite**—from *χαβασιος*, *qui désignoit une certaine espèce de pierre*.

The corrupted form *schabasite* was used by C. A. S. Hoffmann (1812), and *chabasin* by D. L. G. Karsten. C. S. Weiss called the mineral *Kubozite*. The *acadolite* or *acadulite* from Nova Scotia—the Acadia of the old French—mentioned by J. D. Dana, T. Thomson, and E. Hoffmann, is, according to the analyses of A. A. Hayes and C. F. Rammelsberg, nothing but a reddish chabazite. The *haydenite* of P. Cleaveland—named after H. H. Hayden—found near Jones' Falls, Baltimore, is, according to A. Lévy, H. J. Brooke, A. E. Delesse, and J. D. Dana, an altered chabazite. F. Tammnau found twinned crystals of a mineral at Leipa, Bohemia, and he called it *phacolite*—from *φάκος*, a bean—in allusion to its lenticular shape. A. Breithaupt, G. Rose, and J. F. L. Hausmann showed that phacolite is only a variety of chabazite. This mineral was studied by G. F. H. Smith and co-workers. A. Lévy applied the term *herschelite*—after J. F. W. Herschel—to a rhombic mineral found in the lava at Aci Castello, Sicily. It was analyzed by A. Damour, and W. S. von Waltershausen, and shown by A. Breithaupt to be a variety of chabazite. According to W. Haidinger, the *mesolite* of J. J. Berzelius was probably chabazite, although J. D. Dana, C. Doelter, and A. des Cloizeaux regarded it as levyne. A siliceous herschelite from Australia was named *seebachite*—after K. von Seebach—by M. Bauer; but C. F. Rammelsberg, and G. vom Rath showed that it is an impure chabazite. T. Thomson's *dorante* from Antrun was shown by J. D. Dana to be a variety of chabazite; A. des Cloizeaux regarded it as a variety of analcite. E. Renèvier found a mineral in cavities between the crystals of calcspar of Molasse, Lausanne. He called it *adipite*—from *adeps*, fat. J. D. Dana regarded it as chabazite. F. Gonnard found a zeolite in cavities in the basalts near Montbrison, Loire, in hexagonal plates. He called it *offretite*. V. Dürffeld described a similar mineral from Paul's Island. The analysis of offretite corresponded with $(\text{K}_2\text{Ca})_2\text{Al}_6\text{Si}_4(\text{O}_{39} \cdot 17\text{H}_2\text{O})$; and F. W. Clarke considers it to be compounded of potash- and lime-chabazites of the general formulæ $\text{K}_2\text{HAl}_3(\text{Si}_3\text{O}_9)_3 \cdot 8\text{H}_2\text{O}$, and $\text{CaHAl}_3(\text{SiO}_4)_3 \cdot 8\text{H}_2\text{O}$. The sp. gr. is 2.13.

The first analysis of chabazite was made by L. N. Vauquelin.⁷⁴ Numerous analyses of chabazite have since been reported. As in the case of other zeolites one species has been confused with others—*e.g.* chabazites have been confused with gmelinite and levyne—and, as just indicated, some impure or slightly altered chabazites have been given special names. This subject has been discussed by J. Lemberg,⁷⁵ A. Streng, G. vom Rath, G. Tammann, G. Rose, and F. Tammnau. C. F. Rammelsberg⁷⁶ was not very successful in 1875 in generalizing the chemical analyses into a formula. The formula $\text{CaAl}_2\text{Si}_4\text{O}_{12} \cdot 6\text{H}_2\text{O}$ is generally considered as representing the composition of the idealized mineral. This would make it **hexahydrated calcium dialuminium tetrametasilicate**. Structural formulæ have

been proposed by R. Gans, F. Singer, C. Hersch, and F. W. Clarke. The last-named gave

A. Streng arranged the chabazites into three groups, $\text{R}'\text{Al}_2\text{Si}_3\text{O}_{10} \cdot 5\text{H}_2\text{O}$; $\text{R}''\text{Al}_2\text{Si}_4\text{O}_{12} \cdot 6\text{H}_2\text{O}$; and $\text{R}'''\text{Al}_2\text{Si}_5\text{O}_{14} \cdot 7\text{H}_2\text{O}$. He regarded the chabazites as isomorphous mixtures of different silicates of the same type. C. F. Rammelsberg (1885-95), W. F. Fresenius, P. Groth, and J. Lemberg adopted similar hypotheses. G. Tschermak, and F. Doelter consider chabazite to be a compound of calcium aluminium silicate and silicic acid, and the former considers that the silicate $\text{H}_4\text{CaAl}_2\text{Si}_2\text{O}_{10}$ is the chabazite nucleus, Cz, and that the chabazites are formed by the association of this with four different silicic acids, making $\text{H}_8\text{Si}_4\text{O}_{12} \cdot \text{Cz} \cdot 2\text{Aq.}$; $\text{H}_4\text{Si}_2\text{O}_6 \cdot \text{Cz} \cdot 2\text{Aq.}$; $\text{H}_4\text{Si}_2\text{O}_4 \cdot \text{Cz} \cdot 2\text{Aq.}$; and $\text{H}_2\text{Si}_2\text{O}_3 \cdot \text{Cz} \cdot 2\text{Aq.}$ E. Baschieri, and G. Tschermak believe that the silicic acid which is furnished by the decomposition of chabazite with dil. hydrochloric acid is of the leucitic acid type, $\text{H}_8\text{Si}_4\text{O}_{12}$.

The analyses of the chabazites indicate the presence of 17.83-22.32 per cent. of water. Attempts have been made to find out the nature of the water associated with chabazite.⁷⁷ S. J. Thugutt found that there is from 0.41-1.21 per cent. more water in chabazite of grain-size up to 10μ , than in chabazite of grain-size 0.1-0.5 mm.—indicating that the finer the grain, the more the contained water. Presumably the greater the surface-area of the fine-grained powder, the greater the amount of absorbed water. G. Friedel, indeed, inferred that at ordinary temp. the chabazites are not in equilibrium with atm. moisture until they have absorbed 5-7 per cent. more. C. Hintze found that chabazite lost 2 mols. of water when kept over calcium chloride for a week; and A. Damour, 7.2 per cent. of water after five months' exposure to dry air. The lost water, and 0.15 per cent. more was regained on exposure for some months to ordinary air. Measurements of the loss of water at different temp. have been made by C. F. Rammelsberg, A. Damour, C. Bodewig, A. Streng, A. Bygden, E. Manasse, L. Pelacani, F. W. Clarke and G. Steiger, etc. C. Hersch found:

	102°	125°	155°	195°	240°	265°	290°	Red heat.
Loss . . .	5.77	6.51	9.22	11.29	13.55	14.44	14.81	22.47 per cent.

He obtained similar results with phacolite. G. Friedel found the percentage loss (—) or gain (+) when chabazite is heated to θ° in a stream of air sat. with water at θ_0° , to be:

θ . . .	12°	66°	112°	148°	263°	410°	570°
θ_0 . . .	6.5°	9.0°	7.5°	6.5°	6.5°	6.5°	6.0°
Per cent. . .	+0.22	-3.16	-7.00	-11.41	-17.33	-19.16	-19.42

A correction is needed for the absorption of air, for chabazite can absorb up to 2.7 per cent. of air. Thus, a specimen which lost 21.9 per cent. of water at 800° when cooled 15 mins. in dry air appeared to have lost 19.56 per cent. The difference represents the air absorbed in cooling. Hence, the determination of water as loss on ignition may be vitiated by the absorption of air. G. Stoklossa obtained breaks in the rehydration curve of dehydrated chabazite representing 10 hydrates. G. vom Rath, G. Tammann, and E. Löwenstein measured the vap. press. of the water of chabazite. The last-named found at 25° , over sulphuric acid of different conc. and their corresponding different vap. press. of water in mm. of mercury:

Vap. press.	21.58	17.63	8.82	1.75	0.56	0.18 mm.
Loss water	0.21	0.64	0.97	2.94	4.67	6.90 per cent.

A. Damour observed that the 19 per cent. loss which chabazite suffered at a red-heat was regained on exposure to a moist atm. for 3 days; but when calcined to dull redness, 21 per cent. was lost, and the mineral was no longer hygroscopic.

Similar results were obtained with phacolite. J. Lemberg found that artificial potash-chabazite which had lost 16.98 per cent. of water by gentle ignition, regained 16.10 per cent. on exposure to moist air; but after calcining to the sintering temp. only 3.84 per cent. was regained after immersion in water for 2 months. Soda-chabazite similarly lost 19.33 per cent. of water by gentle ignition, and regained only 8.39 per cent. on exposure to moist air. The differences, 0.88 per cent. in the case of potash-chabazite, and 10.94 per cent. in the case of soda-chabazite, were regarded as basic water.

G. Friedel's views⁷⁸ on the nature of zeolitic water—*vide* zeolites—are supported by the fact that the water in the dehydrated chabazite can be replaced by many other substances. G. Friedel showed that the water can be restored after dehydration, and F. Grandjean found that if the dehydrated mineral be placed in an atm. of dry ammonia, dry hydrogen sulphide, ethyl alcohol, and silicon tetrafluoride or tetrachloride, iodine, bromine, mercurous chloride, mercury, mercuric sulphide, and sulphur, these compounds are absorbed instead of water. He measured the optical properties of the products. F. Rinne found that carbon disulphide or dioxide, chloroform, benzene, aniline, and ether are absorbed; and O. Weigel and E. Steinhoff, water, methyl and ethyl alcohols, ether, acetone, benzene, and formic acid. R. Seeliger and K. Lapkamp, and R. Nacken and W. Wolff studied the absorption of helium, neon, nitrogen, oxygen, methane, nitric oxide, carbon dioxide, ethane, hydrogen, and ammonia by 80 per cent. dehydrated chabazite. The vol., v , of gas is a function of the press., p cm., so that $v = ap^n$, where a is a constant varying from 0.06–138.00, and is dependent on the nature of the gas; and n is a constant also dependent on the nature of the gas varying from 0 to 96. The action is either a mechanical condensation of the gas or a mol. action. F. Rinne found that a partially dehydrated crystal plate of the mineral when placed in liquid carbon bisulphide exhibits a gradual change in extinction angles, and becomes more strongly birefringent; on heating the plate, the carbon bisulphide is expelled with a return to the original optical characters. The absorption of carbon dioxide, alcohol, chloroform, benzene, or aniline is accompanied by similar changes in the optical characters; R. Nacken and W. Wolff found that dehydrated chabazite absorbed 1.3 per cent. by weight of nitrogen; and that it absorbed air, carbon dioxide, and coal gas.

The formation of chabazite as a *Sekretionsprodukt* of archaic shales was discussed by F. Schaleh,⁷⁹ A. des Cloizeaux, and O. Sismonda. E. Baur noted the formation of chabazite by hydrothermal processes, and A. Daubrée observed chabazite crystals were produced in cavities in the brick-masonry and about the thermal springs at Plombières, Luxeuil, Haute Saône; Bourbonne-les-Bains, Haute Marne; and Oran, Algiers. J. R. Blum found chabazite crystals on pieces of lignite, wood, etc. in a mine at Marienberg, Nassau. G. Tamnau found crystals of chabazite lining fossil shells of the *Venus islandica* in a recent deposit of Husavic, Iceland. C. Doelter, K. Hofmann, C. R. van Hise, A. Himmelbauer, and F. Cornu observed the formation of chabazite from other silicates—anorthite, plagioclase, trachyte, haüyne, etc. H. St. C. Deville obtained hexagonal plates of what he regarded as levyne by heating a soln. of potassium and sodium aluminates in a sealed glass tube. The product is now regarded as an alkali-chabazite. C. Doelter digested the powdered mineral in water sat. with carbon dioxide in a sealed tube for 9 days at 150°, and obtained minute rhombic crystals. Similar results were obtained with liquid carbon dioxide in place of carbonated water. C. Doelter obtained a similar product by the prolonged digestion of a mixture of freshly precipitated silicic acid, aluminium hydroxide, calcium hydroxide, and carbonated water in a sealed tube at 200°. R. Gans made soda-chabazite by dissolving silicic acid and aluminium hydroxide in soda-lye. C. Doelter obtained chabazite as a by-product in a number of reactions—e.g. by digesting okanite, ammonium chloride, sodium carbonate, and carbonated water in a sealed tube at 220°; the rhombohedral crystals of chabazite were decomposed by analcite and apophyllite. Chabazite was obtained by digesting a mixture

of powdered anorthite, freshly precipitated silicic acid, and carbonated water for 14 days at 200°.

Chabazite occurs massive, as incrustations, and in crystals of a white or brick-red colour. M. Websky⁸⁰ found that when brown or orange chabazite from Striegau is heated in a closed tube, it is blackened, and some tarry matters are distilled off; on cooling, the colour becomes bluish-grey. The crystals belong to the scalenohedral section of the trigonal system, and, according to W. Phillips, they have the axial ratio $a:c=1:1.0860$. G. Tschermak regarded the crystals as monoclinic with $a:b:c=0.4630:1:0.3406$, and $\beta=83^\circ 31'$, and as forming a family group with gmelinite, and levyne. G. F. H. Smith and co-workers also studied this family group. Rhedral crystals generally appear as simple rhombohedrons resembling a cube, with angles varying so little from 90° that the crystals have been mistaken for cubes. The crystals have been discussed by A. des Cloizeaux, W. H. Miller, A. Streng, A. Schrauf, G. vom Rath, F. Tamnau, etc. G. Tschermak said that chabazite crystals mimic monoclinic crystals of axial ratios $a:b:c=0.4630:1:0.3406$, and $\beta=83^\circ 34'$. The cleavage parallel to (10 $\bar{1}$ 1) is rather distinct. Twinning by penetration is common; while contact twins about the composition plane (1011) are rare. D. Brewster found that the crystals are optically anomalous because sometimes they appear distinctly biaxial. F. Becke assumed that the rhombohedral crystals are produced by the twinning of six or more triclinic individuals. C. Klein showed that different crystals or different parts of the same crystal exhibit wide variations in the double refraction, and inferred that these differences are connected with a loss in the zeolitic water, for as E. Mallard showed, heating increases the double refraction, and brings out areas which did not exist before, or develops the existing areas in extent and distinctness. When the crystals cool, the original conditions are not restored. F. Rinne concluded that by heat and consequent loss of water the chabazites gain the optical characters of the negative varieties; but they are changed into those with a strong positive double refraction. The distinction between optically positive and negative crystals is considered to be connected with the proportion of water present. R. Brauns, and G. Tschermak attribute the optical anomalies to the isomorphous association of different individuals. The optical anomalies of chabazite have been discussed by P. Groth, J. F. W. Johnston, A. des Cloizeaux, P. Groth and A. Arzruni, A. Streng, A. von Lasaulx, C. F. Rammelsberg, G. Tschermak, etc. L. Vegard and H. Schjelderup studied the X-radiogram of chabazite. A. Michel-Lévy and A. Lacroix gave for the optic axial angle $2V_{ig}=0^\circ-18^\circ$; P. Groth and A. Arzruni, $2V=27^\circ-40^\circ$; and F. Becke, $2V=32.3^\circ$ for red light, and $2V=31.6^\circ$ for green light. The sp. gr. of chabazite ranges from 2.05-2.14; G. vom Rath found phacolite with a sp. gr. 2.135; and J. E. Hilsch and F. Seemann gave 2.096 for a sample of chabazite. A. Streng obtained evidence that the higher the ratio $SiO_2:Al_2O_3$, the lower the sp. gr.—thus, for the ratio $SiO_2:Al_2O_3=3.85:1$, the sp. gr. was 2.133; 4.12:1, 2.115; 4.3:1, 2.112; 4.9:1, 2.093; and 4.93:1, 2.093. The hardness is from 4.0-5.5. The action of heat on the contained water, and the vap. press. have been previously indicated; A. Damour said all the water is lost at a bright red heat, and the residue fuses with intumescence to form a blebby mass. A. Kennigott, and V. Goldschmidt made some observations on this subject. C. Doelter found that by slowly cooling melted chabazite, crystals of anorthite embedded in a glassy matrix were obtained. E. Jannetaz found the ratio of sq. roots of the thermal conductivities in a direction parallel and vertical to the principal axis is 0.96. P. E. W. Oeberg found the sp. ht. of colourless crystals of chabazite to be 0.3799. O. Mulert found the rate of dissolution of chabazite in mixed hydrofluoric and hydrochloric acids is so slow, that it was not possible to measure the heat of soln. A. Michel-Lévy and A. Lacroix found for the index of refraction of chabazite 1.50, and for herschelite, 1.46. A. Lacroix gave $\omega-\epsilon=0.0020-0.0028$. The birefringence was feeble and generally negative, but as A. des Cloizeaux showed, it is

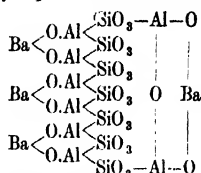

sometimes positive. As indicated above, F. Rinne found that the double refraction assumes a negative value on heating; and in all cases when still more strongly heated, the double refraction of chabazite becomes strongly positive. O. Weigel investigated the electrical conductivity of chabazite.

G. A. Kenngott⁸¹ found that powdered and moistened chabazite reacts alkaline to litmus; the calcined mineral exhibits a feeble reaction. F. Cornu, and F. W. Clarke made similar observations. G. Steiger found that after standing in contact with water at 21° for a month, the water had dissolved a little soda. C. Doelter found the solubility to be greater in carbonated water; and the mineral also dissolves in liquid carbon dioxide. He also observed that some lime and silica are removed by a soln. of sodium carbonate. The action of soln. of sodium carbonate was also investigated by J. Lemberg, and S. J. Thugutt. J. T. Way, and H. Eichhorn showed that when chabazite is treated with a soln. of sodium chloride, calcium is displaced, and a *sodium-chabazite* is formed; J. Lemberg obtained the same compound by the action of sodium chloride soln. on potassium-chabazite, as well as on ordinary chabazite. J. Lemberg obtained sodium-chabazite by the action of a soln. of sodium silicate on albite. H. C. McNeil fused chabazite with sodium chloride, and obtained what was regarded as a substitution product, *sodium-chlorochabazite*, which F. W. Clarke considers to be a mixture $5\text{Na}_3\text{Al}_2(\text{Si}_3\text{O}_8)_2\text{Cl} + 3\text{Na}_3\text{Al}_2(\text{SiO}_4)_2\text{Cl}$. J. Lemberg, and S. J. Thugutt obtained *potassium-chabazite* by digesting chabazite with a soln. of potassium chloride at 100°. E. Löwenstein found that the vap. press. varied continuously as the water was removed. J. Lemberg obtained a product like potassium-chabazite by the action of a soln. of potassium carbonate on natrolite, spodumene, andesine, labradorite, jadeite, or analcite. H. Eichhorn, and J. Lemberg prepared *ammonium-chabazite* by the prolonged action of a hot soln. of ammonium chloride on chabazite. R. Gans, and I. Zoch also made the ammonium derivative in a similar manner; and G. Steiger, by the action of ammonium chloride on chabazite in a sealed tube at 350° for 5-6 hrs. I. Zoch treated chabazite with a soln. of cupric chloride, and obtained evidence that there is an exchange of a small proportion of the base, forming *copper-chabazite*. G. Steiger heated chabazite with silver nitrate for 24 hrs. at 250°-290°, and obtained a *silver-nitrate-chabazite*, which F. W. Clarke formulated $3\text{Ag}_3\text{Al}_2(\text{Si}_3\text{O}_8)_2\text{NO}_3 + \text{Ag}_3\text{Al}_2(\text{SiO}_4)_2\text{NO}_3$. J. Lemberg prepared *barium-chabazite* by the action of a soln. of barium chloride on chabazite for 5 months; and by digesting potassium-chabazite with a soln. of barium chloride, he obtained a *barium-chlorochabazite*; $\text{Ba}_3\text{Al}_4(\text{Si}_3\text{O}_8)_4\text{Cl}_2 + \text{Ba}_3\text{Al}_4(\text{SiO}_4)_4\text{Cl}_2$. If barium-chabazite be treated with a soln. of calcium chloride, calcium-chabazite is formed. J. Lemberg obtained *magnesium-chabazite* by the action of a soln. of magnesium sulphate on chabazite in a sealed tube at 180° for 12 hrs. By the action of thallium nitrate on chabazite in a sealed tube at 250°-290°, G. Steiger obtained *thallium-nitrate-chabazite*, which F. W. Clarke formulated $3\text{Tl}_3\text{Al}_2(\text{Si}_3\text{O}_8)_2\text{NO}_3 + \text{Tl}_3\text{Al}_3(\text{SiO}_4)_3$. S. J. Thugutt found that sebachite is not coloured by a soln. of methylene blue. G. Friedel found that natural or slightly dehydrated chabazite can absorb colouring matters from soln.; it also absorbs potassium permanganate, which is rapidly decomposed, staining the mineral yellow. J. Lemberg found that chabazite is stained red or orange by treatment with silver nitrate and potassium chromate. Chabazite is rapidly decomposed by acids with the separation of gelatinous silica which G. Tschermak considered to be analogous with leucitic acid, $\text{H}_4\text{Si}_2\text{O}_6$. V. Goldschmidt, E. Löwenstein, and F. Cornu studied the action of hydrochloric acid on chabazite. The transformation of chabazite into natrolite, etc., has been discussed by J. Roth, A. Streng, G. Suckow, J. R. Blum, J. D. Dana, T. Grandjean, R. Brauns, C. G. C. Bischof, C. R. van Hise, etc.

E. Artini⁸² found fibrous radiated groups of crystals of a mineral in druses of the pegmatite at Baveno, Italy, which he called *bavenite*. The analysis corresponds with $\text{Ca}_3\text{Al}_2\text{Si}_6\text{O}_{18} \cdot \text{H}_2\text{O}$. F. W. Clarke says that it is possibly a metasilicate, *monohydrated calcium dialuminium hexametasilicate*, $\text{Ca}_3\text{Al}_2(\text{SiO}_3)_6 \cdot \text{H}_2\text{O}$. The white

prismatic crystals are pseudorhombic; really monoclinic with axial ratios $a:b:c = 1.1751:1:0.7845$, and $\beta = 89^\circ 17' 19''$. The sp. gr. is 2.72, the hardness $5\frac{1}{2}$; the optic axial angle, $2E = 78^\circ 31'$; and the mean index of refraction, $\beta = 1.580$. E. S. Larsen gave $\alpha = 1.578$; $\beta = 1.579$, and $\gamma = 1.452$.

Z. Weyberg⁸³ reported the formation of crystals of complex barium and strontium aluminosilicates, $RO:Al_2O_3:SiO_2 = 4:4:7$. If these substances are chemical individuals they may represent **tetrabarium octoaluminylheptametasilicate**, and **tetrastrontium octoaluminylheptametasilicate**.

cate, and **tetrastrontium octoaluminylheptametasilicate**. These substances are obtained by the prolonged fusion of mixtures of china clay with barium or strontium chloride. The crystals are hexagonal and hemimorphic, and are optically uniaxial and negative like nephelite.

In 1807, L. N. Vauquelin⁸⁴ analyzed flesh-red crystals of a mineral he found at Montecchio Maggiore, and called *sarcolite du Vicentin*—from *σαρκός*, flesh—the mineral was labelled *hydrolite* in E. de Drée's collection—in allusion to the contained water. H. J. Brooke and D. Brewster called a specimen from Vesuvius **gmelinite**—after C. G. Gmelin. R. J. Haüy regarded sarcolite as analcite; and A. Breithaupt identified it with melilite. F. de Fonseca considered sarcolite to be a distinct species of zeolite. F. W. Clarke gave a constitutional formula for this variety of chabazite, and C. F. Rammelsberg called it *natron-chabazite*. A. Streng, F. Tamnau, J. F. L. Hausmann, and P. Groth favoured the view that chabazite, levyne, and gmelinite are varieties of one mineral species; while A. des Cloizeaux, and C. Doelter, and J. D. Dana supposed them to be different.

C. T. Jackson applied the term *ledererite*—after C. Lederer—to a variety which A. des Cloizeaux, and O. C. Marsh showed was probably gmelinite. A. Arzruni applied the term *groddeckite*—after M. von Groddeck—to a zeolite from Andreasberg, Harz. The rhombohedral crystals have a hardness 3–4. The mineral closely resembles gmelinite in form and composition, but with magnesium and ferrous iron as impurities. G. Tschermak called it impure gmelinite.

The mineral was analyzed by L. N. Vauquelin,⁸⁵ A. Connell, C. F. Rammelsberg, A. A. Hayes, A. Arzruni, W. T. H. Howe, A. Damour, F. L. Walker, L. V. Pirsson, O. C. Marsh, and G. Tschermak. C. F. Rammelsberg⁸⁶ assumed that the composition of gmelinite is like that of chabazite, but with calcium largely replaced by sodium, hence he wrote $(Na_2Ca)Al_2Si_4O_{12} \cdot 6H_2O$, or simply $Na_2Al_2Si_4O_{12} \cdot 6H_2O$, that is, **hexahydrated sodium dialuminium tetrametasilicate**. F. W. Clarke gave a constitutional formula for gmelinite like that of chabazite, but with Na_2 in place of Ca. G. Tschermak gave $Na_2Al_2Si_5O_{14} \cdot 6H_2O$; but later suggested that it is a mixture of three aluminosilicates. L. V. Pirsson, and P. Groth regarded it as a mixture of two such silicates. G. F. H. Smith and co-workers regarded chabazite, gmelinite, levyne, and phacolite as belonging to the same family.

The crystals of gmelinite may be colourless or white and tinged green, yellow, or red. The crystals belong to the trigonal system, and, according to L. V. Pirsson⁸⁷ they have the axial ratio $a:c = 1:0.7345$. Rhohedral crystals appear hexagonal and are produced by a combination of the hexagonal prism with plus and minus rhombohedrons. G. Tschermak regarded the crystals as monoclinic with $a:b:c = 0.4571:1:0.3385$, and $\beta = 82^\circ 23'$. There are complex twinned forms as in the case of chabazite. The crystals have been studied by H. J. Brooke, D. Brewster, W. H. Miller, G. vom Rath, N. von Kokscharoff, F. Hessenburg, C. F. Rammelsberg,

E. Artini, A. des Cloizeaux, G. Rose, H. Guthe, R. P. Greg and W. G. Lettsom, etc. The cleavage parallel to (10 $\bar{1}$ 0) is fair; and that parallel to (0001) is sometimes distinct: L. V. Pirsson noted feeble optical anomalies; and F. Grandjean the optical axial angle $2V=0^{\circ}-30^{\circ}$. The sp. gr. ranges from 2.0-2.2. A. Breithaupt gave 2.083; H. J. Brooke, 2.05; G. B. Negri, 2.04; T. L. Walker, 2.135; and A. Fersmann, 2.08. The hardness is 4-5. G. Tamman measured the vap. press. by finding the partial press. p mm. of the water vap. in equilibrium with crystals originally containing 21.51 per cent. of water, but for equilibrium lost the following percentage amounts of water:

p	15.72	12.48	9.11	6.05	2.93	1.23	0.39	0.11 mm.
Loss	0.05	0.18	0.42	0.75	1.40	2.48	3.81	4.58 per cent.

The appearance of the crystals was not changed by the loss of water. L. V. Pirsson gave for the indices of refraction $\omega=1.4646-1.4770$, and $\epsilon=1.4637-1.4674$ for Na-light; and G. B. Negri obtained $\omega=1.48031$, and $\epsilon=1.47852$. L. V. Pirsson gave $\omega-\epsilon=0.0033$ for the birefringence; G. B. Negri, 0.0018; and F. Grandjean, 0.002. A. des Cloizeaux found that the optical character of crystals from some localities is negative, and from other localities positive. F. Grandjean found that the crystals of a negative character become positive when dehydrated.

Gmelinite is decomposed by acids with the separation of silicic acid. F. Grandjean found that like chabazite (*q.v.*), dehydrated gmelinite absorbs a relatively large proportion of the vap. of iodine, bromine, mercury, calomel, cinnabar, and sulphur; and that the product is pleochroic. J. Lemberg found that the exchange of bases which occurs when gmelinite is digested with aq. soln. of potassium chloride or carbonate furnished what he called *potassium-gmelinite*. If this product be treated with a soln. of sodium chloride, *sodium-gmelinite* is formed. If digested with a 10 per cent. soln. of sodium carbonate for 24 hrs. at 200° , analcite is formed; and if with a soln. of potassium carbonate, leucite is produced. I. Zoch made observations on this subject.

D. Brewster⁸⁸ applied the term **levyne** to a mineral collected by H. Heuland. There has been some discussion as to whether gmelinite and levyne are distinct species or whether they are varieties of chabazite—*vide supra*, gmelinite. There is also a question whether the mesolin of J. J. Berzelius, here regarded as a variety of gmelinite, would be better classed as a variety of levyne. Analyses were reported by A. Damour, J. J. Berzelius, A. Connell, W. F. Hillebrand and W. C. Cross, and G. A. Kenngott. C. F. Rammelsberg inferred from the analyses that the ratios RO : Al_2O_3 : SiO_2 : H_2O are 1 : 1 : 3.2-3.8 : 4.6 : 5.0. J. D. Dana gave the formula $CaAl_2Si_3O_{10} \cdot 5H_2O$, making the compound **pentahydrated calcium dialuminium orthotrisilicate**. F. W. Clarke gave for the constitution $Ca_3Al_6(SiO_4)_3(Si_3O_8)_2 \cdot 15H_2O$. According to G. Tschermak, the constitution is best explained by assuming that it is formed by the isomorphous association of two silicates. G. F. H. Smith and co-workers grouped this mineral with the chabazite family. For the synthesis of levyne, *vide* chabazite.

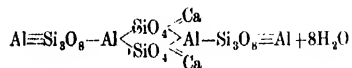

The crystals may be colourless or white, tinged grey, green, red, or yellow. According to W. Haidinger, the trigonal crystals of levyne have the axial ratio $a:c=1:0.8357$. G. Tschermak represents the crystals as monoclinic with the axial ratios $a:b:c=0.4704:1:0.3433$, and $\beta=84^{\circ}54'$. Twinning is common as in the case of chabazite. The cleavage (021) is indistinct. F. Grandjean gave for the optic axial angle $2V=0^{\circ}-30^{\circ}$. The sp. gr. is 2.09-2.16; and the hardness 4-4½. A. Damour found the crystals lose 4 per cent. of water in dry air, and regain it all in ordinary air. When heated, the loss of water begins at about 70° ; and 12-13 per cent. is lost at 225° ; the partially dehydrated crystals remain hygroscopic provided the temp. of dehydration does not exceed 360° . The loss of water is complete at a white heat, when the mineral furnishes a white blebby enamel. A. Lacroix gave 1.50 for the index of refraction; and for the birefringence, $\omega-\epsilon=0.002$; and F. Grandjean gave 0.0075. E. S. Larsen gave $\omega=1.496$, and

$\epsilon=1.491$. The optical character is negative, and F. Grandjean found that after heating to 400° and cooling, the optical character is positive. He also found that the dehydrated mineral behaves like chabazite towards the vap. of iodine, bromine, mercury, calomel, cinnabar, or sulphur. Levyne is decomposed by acids with the separation of gelatinous silicic acid.

F. C. Wernekinck⁸⁰ noted that some crystals associated with barytiferous harmotome at Annerød and Schiffenberge, Giessen, were different chemically and crystallographically. J. F. C. Hessel and L. Gmelin also showed the same thing with respect to the assumed harmotome from Marburg; which they called *calcium-harmotome*. A. Lévy proposed the name **phillipsite**—after W. Phillips. A. Breithaupt called the mineral *normaline*; and A. des Cloizeaux, *christianite*—after Christian, King of Denmark.

A zeolite from the lava of Capo di Bove, Rome, was imperfectly described by P. Mantovani, and named *spangite*—after N. Spang. J. D. Dana considers it to be a variety of phillipsite. F. Zambonini found some bluish crystals from the lava at Casal Brunori, Rome, and he called the mineral *pseudophillipsite*. G. Tschermak considers it to be a variety of gismondite; F. Zambonini, an intermediate form between gismondite and phillipsite proper. J. Schill found fibrous concretions of a zeolite near Sasbach, Kaiserstuhl, which he called *sasbachite*. According to A. Knop, it is phillipsite.

Analyses were made by F. C. Wernekinck, L. Gmelin, and many others.⁸⁰ There is a wide variation in the relative proportions of lime, soda, and potash. C. F. Rammelsberg⁸¹ first assumed phillipsite to be compounded of two silicates; and later he symbolized it $\text{RAl}_2\text{Si}_4\text{O}_{12}\cdot 4\text{H}_2\text{O}$, or **tetrahydrated calcium dialuminium tetrametasilicate**. W. Fresenius proposed a *Mischungshypothese* in which the mineral was supposed to be produced by the association of two silicates in various proportions. C. F. Rammelsberg did not favour W. Fresenius' hypothesis, but he assumed the existence of two *selbständigen Verbindungen*, with two *Zwischenstufen*. In harmony with W. Fresenius' hypothesis, F. Zambonini noted that the potash increased and the lime decreased as the silica increased. P. Groth employed two formulæ. G. Tschermak assumed that the phillipsites are solid soln. of five different silicates. With hypotheses of this character it should be possible to formulate the composition represented by any conceivable set of analyses. He cites in favour of the mixture-hypotheses that when treated with dil. acid, phillipsite usually furnishes pulverulent silicic acid; phillipsite from Aci Castello, gelatinous silicic acid; and phillipsite from Eulenberg gives both forms. He represents these two silicic acids by the formula $\text{H}_4\text{Si}_2\text{O}_6$ and $\text{H}_2\text{Si}_2\text{O}_5$. J. H. Pratt and H. W. Foote represented phillipsite by the formula $\text{RAl}_2\text{Si}_4\text{O}_{12}\cdot 4\frac{1}{2}\text{H}_2\text{O}$; C. Hintze, $(\text{Ca}, \text{K}_2)\text{Al}_2\text{Si}_5\text{O}_{14}\cdot 5\text{H}_2\text{O}$; and F. W. Clarke:

He added:

All phillipsites appear to be mixtures of orthosilicates and trisilicates, with the ratio $\text{Si}_2\text{O}_4 : \text{SiO}_4$ ranging between 3 : 1 and 1 : 3. Such a range and even a greater one is only to be expected when we remember that many zeolites are derivatives of plagioclase feldspars. The zeolites vary as the feldspars vary between end products, which may or may not be definitely known. Stilbite, for instance, represents a hydrated calcium albite or trisilicic anorthite, which in the anhydrous condition is yet to be discovered.

F. Zambonini⁸² showed that in all probability no part of the 14.30–18.86 per cent. of water reported in the analyses is constitutional water; rather is it usually regarded as absorbed or zeolitic water. A. Damour showed that the crystals lose 8 per cent. on exposure to dry air for a month, and regain it all in ordinary air in 24 hrs. When exposed for an hour at 50° , the mineral loses 12.3 per cent., and recovers nearly all when exposed to ordinary air for 24 hrs., but it thereby becomes opaque and pulverulent; at 150° , 16 per cent. of water is lost, and only 0.8 per cent.

recovered after exposure to ordinary air for 4 days; and at 250°, the loss is 18.5 per cent, and about half of this can be recovered by exposure to ordinary air. F. Zambonini found that phillipsite which had been heated to 250° soon recovered the lost water on exposure to moist air; but if heated to 275°, the recovery was very slow. W. Fresenius found phillipsite becomes pulverulent, and opaque at 150°; the amount of contained water gradually decreases as the temp. rises, and increases as it falls, so that a definite proportion is retained by the mineral at a definite temp. With a gram of phillipsite from Aci Castello, for example, the percentage amount of contained water at different temp. was:

	20°	50°	100°	150°	200°	Dark redness
Contained water	0.2183	0.2044	0.1738	0.1194	0.0645	0.0095

with pseudophillipsite, the percentage loss was:

	54°	75°	95°	126°	129°	159°	238°	Red heat
Loss	1.37	2.07	3.03	6.00	6.28	12.77	14.71	20.48 per cent.

There is a break in this curve at about 159°, and a break with phillipsite at 129°. The meaning of the break is not clear because all the water appears to be zeolitic. Phillipsite, in a stream of humid air, shows:

	115°	175°	215°	250°	275°	320°	380°
Loss	2.90	8.95	10.96	12.40	13.45	14.66	15.09 per cent.

Phillipsite is found in basalts, and various lavas. Minute crystalline aggregates and irregular crystalline groups were found in the deep-sea dredgings of the *Challenger* from the bottom of the central Pacific Ocean, south of the Hawaiian Islands. They are believed to have been formed at the bottom of the ocean by the decompositions of the augitic lavas of those islands. This subject has been discussed by J. Murray,⁹³ J. Murray and C. V. Leo, and A. Renard. A. Daubrée reported small transparent crystals of recent formation in the masonry of the thermal baths at Plombières; Bourbonne-les-Bains; Luxeuil, Haute Saône; and Oran, Algiers. H. St. C. Deville obtained a kind of potash-phillipsite by heating potassium aluminate, and silicate, silica, and water in a sealed glass tube at 200°. A little lime was derived from the glass.

The crystals of phillipsite are either isolated, or they occur in tufts or spherules with a radiating structure. The colour is white, may be with a reddish tinge. P. Groth⁹⁴ showed that the crystals belong to the monoclinic system, and A. Streng gave for the axial ratios $a : b : c = 0.70949 : 1 : 1.2563$, and $\beta = 55^\circ 37'$; G. Tschermak gave $0.5148 : 1 : 0.3547$, and $\beta = 90^\circ$. The subject was investigated by F. Köhler, P. Trippke, C. Stadtländer, W. Fresenius, and G. Cesaro. The crystals appear as penetration twins often simulating rhombic and tetragonal forms. The twins are sometimes simple and cruciform about a twinning plane (001). L. Langemann assumed that the individuals which form the complex twins of phillipsite are triclinic. F. Rinne found that heating did not change the character, and the twinning structure is retained, but the axial plane approaches (001) by some 10° , and the double refraction becomes weaker. The faces (010) are sometimes finely striated. The cleavage parallel to (001) and to (010) is rather distinct. The optic axial angle is large; A. des Cloizeaux gave $2H_a = 84^\circ 8\frac{1}{2}'$ for the red ray, and $84^\circ 51\frac{1}{2}'$ for the yellow ray. The angle is variable since for the red ray $2H_a$ ranged from $69^\circ 55' - 84^\circ 8\frac{1}{2}'$; $2H_0$ from $98^\circ 13' - 129^\circ 15'$; and $2V = 65^\circ 21' - 81^\circ$. The sp. gr. ranges from 2.15-2.20; and the hardness is just over 4. The action of heat has been previously discussed. A. des Cloizeaux found the index of refraction $\beta = 1.48 - 1.57$. The birefringence is low; A. Michel-Lévy and A. Lacroix gave $\gamma - \alpha = 0.003$. The optical character is positive. J. Königsberger⁹⁵ and W. J. Müller made observations on this subject. J. Lemberg studied the action of a soln. of potassium or sodium chloride or carbonate on phillipsite, and observed an interchange of bases. J. Roth, and C. R. van Hise discussed the transformation which phillipsite undergoes in nature—formation of albite, anorthite, and leucite. V. Goldschmidt said

dil. hydrochloric acid does not decompose the mineral; but with more conc. acid, flocculent and gelatinous silicic acid separates—*vide supra*.

J. H. Pratt and H. W. Foote⁹⁵ found crystals of a zeolite in the corundum mine of Buck Creek, North Carolina. They named the mineral **wellsite**—after H. L. Wells. The composition corresponds with $\text{RAl}_2\text{Si}_3\text{O}_{10}\cdot 3\text{H}_2\text{O}$, where R represents Ba:Ca:K₂=1:2:3. It may therefore be regarded as **trihydrated calcium dialuminium orthotrisilicate**, with some calcium replaced by potassium and barium. F. W. Clarke represents it by the formula:

The mineral is closely related to the phillipsite family, forming the isomorphous series:

		<i>a</i> : <i>b</i> : <i>c</i>	β
Wellsite	$\text{RAl}_2\text{Si}_3\text{O}_{10}\cdot 3\text{H}_2\text{O}$	0.768 : 1 : 1.2450	53° 27'
Phillipsite	$\text{RAl}_2\text{Si}_4\text{O}_{12}\cdot 4\text{H}_2\text{O}$	0.7095 : 1 : 1.2563	55° 37'
Harmotome	$\text{RAl}_2\text{Si}_5\text{O}_{14}\cdot 6\text{H}_2\text{O}$	0.7032 : 1 : 1.2310	55° 10'
Stilbite	$\text{RAl}_2\text{Si}_6\text{O}_{16}\cdot 6\text{H}_2\text{O}$	0.7623 : 1 : 1.1940	55° 50'

G. Tschermak had doubts whether this is a distinct mineral species. The monoclinic crystals have the axial ratios *a*:*b*:*c*=0.768:1:1.245 and $\beta=58^\circ 27'$. The small isolated crystals are invisible penetration twins closely resembling harmotome and stilbite. The crystals are colourless and transparent to white, and possess no cleavage. The optic axial angle is large, $2E=120^\circ\text{--}130^\circ$. E. S. Larsen found $2E=60^\circ$, and $2V=39^\circ$; the index of refraction $\alpha=1.498$ and $\gamma=1.503$, with the birefringence $\gamma-\alpha=0.005$. The optical character is negative. The sp. gr. is 2.278–2.366; and the hardness 4–4½. About one-third of the water is expelled between 100° and 200° ; another third between 200° and 300° ; and the remainder on ignition. Wellsite with 13.31 per cent. of water lost, at different temp.:

	100°	125°	175°	200°	260°	295°	Red heat
Loss	0	1.93	1.48	0.92	2.45	1.24	4.96 per cent.

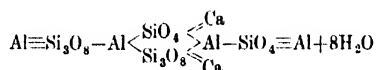

After being heated to 265° , nearly all the water is regained by exposure to moist air. The birefringence is low; and the optical character negative. The mineral is decomposed by hot hydrochloric acid with the separation of silicic acid in a granular form. A. Fersmann found a similar zeolite near Simferopol.

R. J. Häuy⁹⁶ mentioned a *zéolithe efflorescente* which he called **laumontite**—after Gillet de Laumont, who found the mineral in the lead-mines of Huelgoet, Brittany, in 1785. C. C. von Leonhard used a similar term; but A. G. Werner corrupted it to *lomonte*. It was analyzed by H. A. von Vogel in 1810.

The *zéolithe rouge d'Adelfors* of R. J. Häuy; the *ardforsite* of C. G. Retzius—*vide wollastonite*; the *meal zeolite* of W. Hisinger; the red zeolite of Upsala; and a white zeolite from Fahlun, are considered by N. J. Berlin, and A. Ewert to be impure laumontites. A zeolite at Schomnitz, Hungary, was called *leonhardite*—after C. C. von Leonhard—by J. R. Blum, and a few occurrences have been reported elsewhere. Similar zeolites have been analyzed by G. O. Barnes, G. Lewinstein, A. Sinita, J. Leinberg, A. E. Fersmann, and G. Tschermak. The mineral is very like laumontite in composition, and also furnishes monoclinic crystals. The sp. gr. is 2.25, and hardness 3–3½. N. Surgunoff distinguished three minerals belonging to one family—laumontite, $\text{Ca}_2\text{Al}_2\text{Si}_2\text{O}_8\cdot 8\text{H}_2\text{O}$; α -*leonhardite*, $(\text{Ca}, \text{K}_2, \text{Na}_2)_2\text{Al}_2\text{Si}_2\text{O}_8\cdot 7\text{H}_2\text{O}$, and β -*leonhardite*, $\text{Ca}_2\text{Al}_2\text{Si}_2\text{O}_8\cdot 7\text{H}_2\text{O}$. β -*leonhardite* was also described by A. Dwojtschenko; and α - and β -*leonhardite* by A. A. Twaltschrelidze. P. Savi, and L. Zilla described flesh-red monoclinic crystals of a zeolite which were found at Monte di Caporciano, and which P. Savi called *caporcianite*; its sp. gr. was 2.470, and hardness 2½. G. Meneghini said it resembled heulandite; J. J. Berzelius, and J. F. L. Hausmann, analcite; A. Breithaupt, crystalline chabasite; J. D. Dana, desmin; and E. F. Glocker, mesotype. It was analyzed by T. Anderson, and E. Bechi. According to G. A. Konngott, A. d'Achiardi, and C. F. Rammelsberg, *caporcianite* is like laumontite in composition and properties. A mine at Monte Catini furnished G. Meneghini with a zeolite which was called *schneiderite*—after the director of

the mine. The mineral appears to have been formed by the alteration of serpentine by magnesium waters, and it is considered to be a variety of laumontite. H. Traube reported masses of radiating fibres of a white or pale yellow zeolite found on the phillipsite crystals at Lauban, Silesia, and he called the mineral *laubantite*. Its composition corresponds with hexahydrated *dicalcium dialuminium pentametasilicate*, $\text{Ca}_2\text{Al}_2(\text{SiO}_3)_5 \cdot 6\text{H}_2\text{O}$; that is, $\text{Ca} = (\text{SiO}_3)_2 = \text{Al} - \text{SiO}_3 - \text{Al} = (\text{SiO}_3)_2 = \text{Ca} + 6\text{H}_2\text{O}$, the sp. gr. is 2.23, and its hardness 4½-5. A. E. Fersmann called a variety from Antipoff having 2.8 per cent. V_2O_5 , *ranadolaumontite*.

Analyses have been made by H. A. von Vogel,⁹⁷ C. G. Gmelin, P. A. Dufrenoy, I. Domeyko, A. Connell, L. von Babo and C. Delffs, F. J. Malaguti and J. Durocher, and many others. The formula of the idealized mineral, according to C. F. Rammeisberg,⁹⁸ is $\text{CaAl}_2\text{Si}_4\text{O}_{12} \cdot 4\text{H}_2\text{O}$. C. Hintze, and J. D. Dana regarded two of the four mols of water as constitutional, and wrote $\text{H}_4\text{CaAl}_2\text{Si}_4\text{O}_{12} \cdot 2\text{H}_2\text{O}$; and P. Groth wrote $\text{Ca}\{\text{Al}(\text{OH})_2\}_2(\text{Si}_2\text{O}_6)_2 \cdot 2\text{H}_2\text{O}$. The generalized formula $\text{CaAl}_2(\text{SiO}_3)_4 \cdot 4\text{H}_2\text{O}$ makes laumontite **tetrahydrated calcium dialuminium tetrametasilicate**. F. W. Clarke gave:

The assumption that two mols of water are chemically bound in the mol. is based on the observation of F. J. Malaguti and J. Durocher that when the crystals are kept in vacuo for a month, they lose 2.26 per cent. of water, and if kept over conc. sulphuric acid, 3.85 per cent. The crystals regain their lost water when exposed to moist air. These workers found that 3.17 per cent. of water is lost at 100°, 6.08 per cent. at 200°, 7.28 per cent. at 300°; and the whole 13-14 per cent. is lost at a red heat. G. Tammann, however, found that as with other zeolites, the vap. press. at different temp. is a continuous function; and that the vap. press. curve exhibits no breaks. With atm. in which the vap. press. of water was respectively 14.55 mm. and 0.11 mm., the percentage losses were respectively 0.25 and 2.58 with laumontite originally containing 17.87 per cent. of water. Similar results were obtained with leonhardtite. C. Doelter found that by slowly cooling molten laumontite he obtained a mixture of anorthite, a pyroxene, and a glassy matrix. C. Doelter, and G. Tschermak assumed that laumontite is really a mixture or solid soln. of anorthite and metasilicic acid: $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 2\text{SiO}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$. Later on, G. Tschermak obtained orthosilicic acid by treating laumontite with acids, and he represented it by the formula with orthosilicic acid as a nucleus: $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 2\text{H}_4\text{SiO}_4$.

Laumontite occurs in cavities in porphyry, gneiss, and syenite rocks, in veins traversing clay slate with calcite. It is a secondary mineral formed at a low temp. It has not been synthesized. It occurs in columnar or radiating masses, and crystals. The colour is white, may be tinged grey, yellow, or red. The crystals were described by R. J. Haüy,⁹⁹ A. des Cloizeaux, F. Mohs, etc. According to W. H. Miller, the monoclinic crystals have the axial ratios $a:b:c = 1.1451:1:0.5906$, and $\beta = 68^\circ 46'1''$; while P. Groth gave $1.0818:1:0.5896$, and $\beta = 99^\circ 18'$. The cleavage is complete on the (010) and (110) faces, and incomplete on the (100) and (201) faces. Twinning occurs on the composition plane (100). A. Michel-Lévy and A. Lacroix gave for the optic axial angle $2V = 30^\circ$; and A. des Cloizeaux, $2E = 52^\circ 24'$ for red light, and $56^\circ 15'$ for blue light; while raising the temp. to 75° made no perceptible change in the optic axial angles. The sp. gr. ranges from 2.3-2.4; and the hardness is in excess of 3. The action of heat on the water content has been previously discussed. As with other zeolites, when the mineral is heated before the blowpipe flame, it swells up and froths before settling down to a glassy enamel. For the vap. press. *vide supra*. As indicated above, laumontite decomposes when fused and cooled slowly. A. Michel-Lévy and A. Lacroix found the indices of refraction to be $\alpha = 1.513$, $\beta = 1.524$, and $\gamma = 1.525$; and the birefringence is weak, $\gamma - \alpha = 0.012$. The optical character is negative.

G. A. Kennigott¹⁰⁰ found that powdered and moistened laumontite gives an alkaline reaction with litmus; but F. W. Clarke was in doubt about the result with phenolphthalein. G. Steiger found that with water there is a slow decomposition and a little alkali passes into soln. J. Roth noted that the weathering of laumontite produces some calcium carbonate; G. Leonhard and C. R. van Hise observed the passage of laumontite into prehnite; and C. G. C. Bischof, M. F. Heddle, G. Jentsch, J. Roth, R. P. D. Graham, and C. R. van Hise, the passage of laumontite into orthoclase and albite. F. F. Grout applied the term *pseudolaumontite* to a product which was derived from diabase, and which was regarded as a laumontite with much of the lime replaced by potash and magnesia. J. Lemberg found that when laumontite is treated with sodium or potassium carbonate, much of the lime is replaced by the alkali, and a product resembling analcite is formed. Similar results were obtained with alkali chlorides. He called the product obtained with sodium carbonate soln., *soda-caporcianite*. F. W. Clarke and G. Steiger found that after exposure to the vap. of ammonium chloride, the mineral is decomposed, and some 3.95 per cent. of ammonia is taken up by the residue.

St. Epiphany,¹⁰¹ J. de Laet, and J. Beckmann have suggested that the *lyncurium* of Theophrastus' *Περὶ λίθων* and of Pliny's *Historia naturalis* (8. 38; 37. 3, 7) may have been hyacinth. W. Watson argued in favour of tourmaline; but J. Beckmann said that if so, Theophrastus would have referred to the fact that heat is necessary to make this mineral attract light bodies. G. Noya-Caraffa suggested that the *themedres* of the ancients was tourmaline; but A. B. de Boot, and J. Beckmann doubted this, and the latter has shown that Pliny's account of the *carbuncle* fits the known properties of tourmaline better than those of the other minerals named. Pliny said that this attracted chaff and light bodies after it had been heated by the beams of the sun, or by friction. J. Serapion the Arabian mentioned a red mineral resembling the hyacinth which "when strongly rubbed against the hair of the head, attracts chaff as the magnet does iron." As a matter of fact, this description would apply to most gem-stones.

The term **tourmaline** has been applied to a number of different silicates. It is a Singalese word first used for a reddish mineral brought to Europe from Ceylon by the Dutch Traders in 1703. A writer, "I. G. S.," at the beginning of the eighteenth century, said:

The stone called *tourmaline*, *turnale*, or *trip* has the property that it not only attracts the ashes from the warm or burning coals, as the magnet does iron, but also repels them again, which is very amusing; for as soon as a small quantity of ashes leaps upon it, and appears as if endeavouring to write itself by force into the stone, the ash, in a little, springs from it again, as if about to make a new effort; and on this account tourmaline was by the Dutch called *Aschentrecker*—ashes-drawer. When the turf coals are cold, it does not produce these effects. I have no doubt that, if heated, it would attract other things beside ashes.

Similar remarks were made by F. Maurer in 1713; and L. Leméry likewise described the mineral in 1717. C. Linnæus called it *lapis electricus*. I. S. R. I. Eques a Born, S. Rinman, and R. Kirwan called it tourmaline. A black variety of tourmaline had long been called *schörl*. This word is of uncertain origin. It was spelt *schurl* by J. Matthesius in 1562; *shirl* by U. Brückmann in 1727; and *skiörl* by J. C. Wallerius in 1747. It is also referred to by C. Gesner, L. Ercker, F. von Kobell, A. Cronstedt, J. B. L. Romé de l'Isle, and C. A. S. Hofmann.

It has been suggested that the word *schörl* is derived from the name of a German locality where the mineral occurred—Schorlau, meaning *schörl-village*; on the contrary, the word may be a miner's term of unknown origin, and that the village received its name because *schörl* was found near by. In the fifteenth century, the rejected material in auriferous and stanniferous ores was called *schurl* or *wolfram*. It has therefore been suggested that the word is derived from the old German word *schor*, meaning impurities or refuse.

J. B. L. Romé de l'Isle, A. Cronstedt, etc., regarded tourmaline and *schörl* as one species. Tourmaline is common in clay slates, crystalline schists, and in the

more siliceous rocks—*e.g.* the pegmatites. It is common in zones of contact metamorphism of schists and granites, and numerous kinds of rocks. H. B. Patton,¹⁰² for instance, regards the tourmaline in some schists in Colorado as having been formed at the expense of the biotite in the pegmatites of the adjoining contact zone. Tourmaline occurs as a pyrogenetic mineral in igneous rocks—*e.g.* granites, pegmatites, porphyries, and lavas. In igneous rocks it seems to have been produced by the fumarole action, and not as a direct separation from magma. Tourmaline has not been made artificially. C. Doelter made some unsuccessful experiments in this direction.

A red schörl from Siberia was called by R. Kirwan,¹⁰³ *rubellite*; by J. C. Delaméthérie, *daourite*—from Daurien; by C. Lermina, *siberite*; by R. J. Haüy, *tourmaline apyre*; and by J. F. L. Hausmann, *apgyrite*, in reference to its fire-resisting qualities. M. F. R d'Andrada called a black tourmaline from Kragerø, Norway, *apheizite*—from *αφίζω*, foam, in allusion to its behaviour in the blowpipe flame—and a blue tourmaline from Uto, Sweden, *indigolite* (also *indicolite*). R. Hermann called a colourless tourmaline from Elba, *achroite*—from *ἀ*, without; *χρῶς*, colour. I. Doneyko called a variety from Taltal, Chili, *taltalite*. G. L. Ulex, and F. Pisani showed that taltalite is a mixture of tourmaline and a copper earth. G. Tschermak called the magnesium tourmaline from Unterdrauburg, Drave district, Carinthia, *dravite*. T. Thomson found a brown mass of interwoven acicular prismatic crystals at Huel Unity, Cornwall, which he called *zeuzite*—from *ζεύς*, the act of writing—in allusion to the locality where it occurred. R. P. Greg, and A. des Cloizeaux found the crystals to be a ferri-ferrous tourmaline.

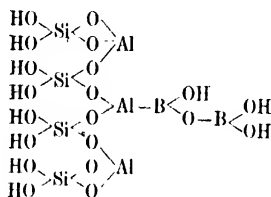

The first analysis of tourmaline is attributed to A. Wondraschek,¹⁰⁴ and analyses were soon afterwards reported by L. N. Vauquelin, R. J. Haüy, M. H. Klaproth, and C. F. Bucholz. The presence of boric oxide was discovered by H. A. von Vogel, and of lithium oxide by A. Arfvedson, W. Gruner, and C. G. Gmelin. An attempt was made by R. Hermann to show that carbon dioxide is an essential constituent; but C. F. Rammelsberg found no carbon dioxide in numerous samples. He did, however, find in some samples a little phosphoric oxide and fluorine. The constitution with inadequate data was discussed by J. D. Dana, C. F. Naumann, G. A. Kenngott, and A. Mitscherlich. The combined water, and the ferrous and ferric oxides were studied by C. F. Rammelsberg in 1869. On account of the imperfections in the analytical methods, analyses prior to 1870 are usually omitted in discussions on the chemical nature of the mineral. Numerous analyses have been made¹⁰⁵ since that time.

In spite of the excellent analyses of tourmaline which are available, there is no general agreement as to the composition of the idealized mineral stripped from the accidental constituents which so commonly contaminate the products produced in Nature's laboratory. It is almost certain that tourmaline is a mixed crystal or solid soln. of a number of different silicates. The tourmalines represent a group of isomorphous minerals whose chemical relations have not yet been elucidated. In the *alkali tourmalines*, the chief bases are lithium, sodium, and potassium; in the *magnesian tourmalines*, the chief base is magnesium—or, possibly, aluminium; and in the *iron tourmalines*, iron (ous) replaces much of the magnesium. E. T. Wherry showed that the replacement of Fe' by Li, and of Al by Mg, and the absence of calcium fit in well with the at. vol. theory of isomorphism. Before attempting to interpret the analyses, the imperfections to which analyses of complex silicates are liable must be taken into consideration. The main difficulties are (i) inaccurate determinations of the boron; (ii) the adsorption of water from the air during the fine-grinding of the mineral; and (iii) the ready oxidation of ferrous to ferric oxide during the fine-grinding which precedes analysis.

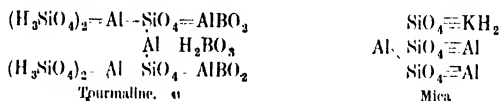

C. F. Rammelsberg,¹⁰⁶ in his paper: *Die chemische Natur der Turmaline* (Berlin, 1890), argued that tourmaline is a mixture of silicates of the types $R'_6SiO_5 : R''_3SiO_5 : R'''_2SiO_5$ in proportions between 1 : 2 : 6 and 15 : 1 : 90. He showed that the ratio R : Si in 64 good analyses ranges from 1 : 5.7–1 : 6.7. It is, however, necessary to consider the 8–10 per cent. of boric oxide in the mineral. The analyses discussed by R. B. Riggs, and E. A. Wülfing indicate that there

are three types with the group $3\text{B}_2\text{O}_3 \cdot 12\text{SiO}_2 \cdot 4\text{H}_2\text{O}$ constant, and in *lithium or alkali tourmaline*, $2(\text{Na}, \text{Li})_2\text{O} \cdot 0.8\text{Al}_2\text{O}_3 \cdot (3\text{B}_2\text{O}_3 \cdot 12\text{SiO}_2 \cdot 4\text{H}_2\text{O})$; *ferrous tourmaline*, $\text{Na}_2\text{O} \cdot 0.4\text{FeO} \cdot 7\text{Al}_2\text{O}_3 \cdot (3\text{B}_2\text{O}_3 \cdot 12\text{SiO}_2 \cdot 4\text{H}_2\text{O})$; and in *magnesium tourmaline*, $\frac{2}{3}\text{Na}_2\text{O} \cdot \frac{23}{3}\text{MgO} \cdot 5\text{Al}_2\text{O}_3 \cdot (3\text{B}_2\text{O}_3 \cdot 12\text{SiO}_2 \cdot 4\text{H}_2\text{O})$. There is, however, an excess of oxygen which is explained by assuming that AlO and HO groups are present. E. A. Wülfing inferred that the analyses are best summarized by regarding the tourmalines as solid soln. of the two silicates, $\text{H}_8\text{Na}_4\text{Al}_{16}\text{B}_6\text{Si}_{12}\text{O}_{63}$ and $\text{H}_6\text{Mg}_{12}\text{Al}_{10}\text{B}_6\text{Si}_{12}\text{O}_{63}$. P. Reiner bases his observations on these formulæ. R. B. Riggs, P. Jannasch and G. Kalb referred the analyses to the type $\text{R}_6\text{BO}_2(\text{SiO}_4)_2$, and P. Groth, $\text{R}_6(\text{AlO})\text{BO}(\text{SiO}_4)_2$. P. Jannasch and G. W. Kalb, W. and D. Asch, and G. Tschermak assume that there are three types of tourmalines, and V. Goldschmidt, two. H. Rheineck does not accept the view that the boric oxide and aluminium are in direct association.

S. L. Penfield and H. W. Foote argued that the tourmaline is a salt of a *tourmalinic acid*, $\text{H}_{11}\text{Al}_3\text{B}_2\text{Si}_4\text{O}_{21}$, or $(\text{H}_2\text{SiO}_4 : \text{Al} \cdot \text{H}_2\text{SiO}_4)_2 : \text{Al} \cdot \text{H}_3\text{B}_2\text{O}_5$ which contains the radicle $\text{H}_3\text{B}_2\text{O}_5$ of the acid $\text{H}_4\text{B}_2\text{O}_6$. Graphically, these formulæ become

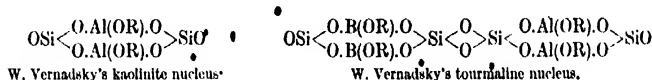

G. Cesaro regarded tourmaline as an orthosilicate with part of the silicon replaced by B_2O . F. W. Clarke has shown that although this formula fits most, but not all, the analyses of tourmaline, it does not harmonize with the characteristic change of the tourmalines into micas. W. T. Schaller, and P. Reiner avoid the difficulty by tripling the above formula. This gives the unwieldy and complicated tourmalinic acid, $\text{H}_{60}\text{Si}_{12}\text{B}_6\text{O}_{63}$. F. W. Clarke modified the type formula to

which would make the tourmalines *triboratotetraluminotetraorthosilicates*. He added that it is improbable that the boron is present partly as metaborate and partly as orthoborate; and as an alternative he said that it may be represented as B_3O_7 , the quinquevalent radicle of a hypothetical acid $\text{H}_5\text{B}_3\text{O}_7$. He added that fluorine may in part replace the metaborate radicle. By replacing various hydrogen atoms with the univalent elements, K, Na, Li, and F; bivalent elements, Ca, Mg, Mn, and Fe; and trivalent elements, B, Al, Fe, Mn, and Cr, and compounding different proportions of two or three mols of the above type, it is possible to represent the different analyses of tourmaline. The alkali tourmalines usually have a high proportion of aluminium, and the magnesian and iron (ous) tourmalines have a low proportion of aluminium. The above scheme provides for *ferric tourmalines* although the existence of such has not been unequivocally established in normal tourmalines. The ferric oxide appearing in some analyses may have been the result of oxidation. In a few cases, part of the aluminium is replaced by chromium, furnishing the so-called *chrome-tourmalines*. If a mol. of the type indicated by F. W. Clarke's, and H. W. Foote's formula loses its boric oxide and an atom of aluminium, and takes up potash, two mols. of mica are formed. P. Ereulisse represented the tourmalines as solid soln. of salts of different fluoaluminosilicic acids. J. Jakob applied the co-ordination theory and assumed tourmaline to be a

solid soln. of $4[\text{Al}(\text{SiO}_4)_3]\text{R}_9 + [\text{O}.\text{Al}(\text{OBO})_2]\text{Al}_2$. W. Vernadsky assumed that tourmaline is an additive substance containing the kaolinité ring, $\text{R}'\text{Al}_2\text{Si}_2\text{O}_3$, viz.

because tourmaline is formed by the weathering of feldspar, and it furnishes on weathering china clay or alkali-mica. He assumes that in tourmaline a similar ring is formed with boron in place of aluminium, and that the two rings are joined, furnishing the tourmaline nucleus $\text{R}'_4\text{Al}_2\text{B}_2\text{Si}_4\text{O}_{18}$. He postulates three groups: *kalbaite*, $\text{R}'_8\text{Al}_4\text{B}_2\text{Si}_4\text{O}_{21}$; *belbaite*, $\text{R}'_{14}\text{Al}_2\text{B}_2\text{SiO}_4\text{O}_{21}$; and *elbaite*, $\text{R}'_2\text{Al}_6\text{B}_2\text{Si}_4\text{O}_{21}$, one or more of which may form addition-compounds with the tourmaline nucleus. In this way it is possible to represent the composition of all the tourmalines. These hypotheses are to be regarded as tentative, though ingenious, attempts to solve the riddle—what is the chemical nature of tourmaline?

Tourmaline is rarely colourless or white; the colour may be red, blue, or green; and most commonly brownish-black, bluish-black, or black. Some specimens are red internally, and green externally; others are red at one extremity, and green, blue, or black at the other. Sometimes there are different colours in concentric layers. R. Scharizer,¹⁰⁷ and W. Vernadsky made some observations on the relation between the colour and composition. According to the former, the iron tourmalines containing little or no manganese are brown to brownish-black. The intensity of the brown colour produced by iron is increased by increasing the titanium content. As the proportion of manganese increases, the colour passes from blue to green and to red. He considers that the blue and green colours are the result of an admixture of green manganate and reddish-violet permanganate. The passage of manganate into permanganate explains the change of colour which occurs when the tourmaline is heated in oxygen. From his observations on the action of oxidizing and reducing gases on the heated mineral, W. Hermann inferred that chromium, manganese, and iron are concerned in the coloration of tourmaline. The mineral is sometimes massive and compact, or in columnar masses. The crystals are prismatic, slender or acicular, short and thick, and rarely flattened; they are often much rounded and barrel-shaped, and they are sometimes isolated, but more commonly in parallel radiating groups. Doubly terminated crystals are rare; usually the crystals are attached at one end. The crystals are commonly hemimorphic, and they furnish some of the most conspicuous examples of polar symmetry. The crystals belong to the trigonal system, and, according to V. von Worobieff, the axial ratio is $a:c=1:0.45181$. M. Jerofejeff gave $1:0.44805$ for this ratio; G. Seligmann, $1:0.4513005$; and A. Cossa and A. Arzruni, $1:0.45119$. Observations were also made by W. Ramsay, D. Brewster, J. D. Dana, A. T. Kupffer, W. E. Hidden, V. M. Goldschmidt, G. Rose, A. des Cloizeaux, A. d'Achiardi, W. H. Miller, A. N. Karmozhitzky, H. L. Ungemach, A. Lacroix, L. Duparc and co-workers, A. Ondrej, A. Krejci, C. M. Viola and E. Ferrari, W. P. Blake, P. Termier, E. Artini, O. B. Böggild, F. Slavik, A. Hamberg, W. Vernadsky, A. H. Westergard, and R. H. Solly. C. Hintze said that J. C. G. de Marignac's measurements more probably refer to phenacite than to tourmaline. W. T. Schaller said that the *c*-axis of red lithium tourmaline is largest for the ferruginous tourmalines. F. Rinne and M. Kemter, C. Kulaszewsky, H. Baumhauer, W. Ramsay, H. Traube, and T. L. Walker studied the corrosion figures. C. Kulaszewsky, and H. Haga and F. M. Jäger have studied the X-radiograms of tourmaline. The elementary parallelepiped is a prism of rhombic base, and 120° edge-angles; the edge-length of the rhomb is 16.23×10^{-8} cm., and the height 7.26×10^{-8} cm. The prismatic faces of the crystals are sometimes striated vertically. The cleavage is not noticeable, or is imperfect and parallel to (11 $\bar{2}$ 0) and (10 $\bar{1}$ 1). The alteration of analogous and antilogous patches on cross-sections indicates

supplementary **twinning** like that of hemimorphite. Juxtaposition twins or penetration twins with parallel axes are not common; cruciform twins are also very rare, but an example has been described by M. Bauer. A. E. Fersman found growths of feldspar with tourmaline at Mursinka, Ural. L. Duparc and co-workers found the **optic axial angle**, $2E$, of anomalous biaxial crystals varied from 0° – $14^\circ 5'$; and A. des Cloizeaux observed no change by raising the temp. from 12° – 186° . C. Doelter also made observations on this subject.

The **specific gravity** of tourmaline ranges from 3.0–3.2. Determinations were made by many of those who analyzed the mineral. J. Joly gave 3.104–3.139 at $14^\circ 4'$ for iron tourmalines, and 3.010 at $14^\circ 4'$ for a magnesian tourmaline. L. Duparc and co-workers obtained numbers ranging from 2.978–3.127. K. Becht found values from 3.066–3.144. E. A. Wülfing found the sp. gr. increased linearly with the proportion of heavy metal present with the magnesian tourmalines. W. T. Schaller obtained the smallest value 3.05 and the greatest, 3.20–3.25; and with the magnesium-free tourmalines, the smallest values 3.00–3.05 and the greatest, 3.20–3.25. He represented his observations on the effect of alumina by the curves, Fig. 179. The **hardness** is about 7. W. Voigt found the **compressibility** of tourmaline to be $\beta = 1.15 \times 10^{-6}$, and E. Madelung and R. Fuchs, 0.84×10^{-6} ($p = 125$ atm.). W. Voigt found the **modulus of elasticity** to be 15,560 kgrms. per sq. mm. at -45° ; 16,330 at 0° ; 17,160 at 45° ; and 25,570 at 90° . W. Lissauer measured the elastic modulus at the temp. of liquid air. F. Pfaff gave 0.0009369 for the coeff. of **thermal expansion**, between 0° and 100° , taken in the direction of the c -axis, and 0.0007732 in the direction of the a -axis. R. Scharizer found that it is possible to change the colour of tourmaline by heating the mineral in a flame charged with oxygen. K. Simon found a red

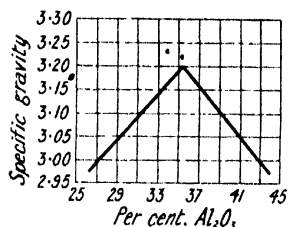

FIG. 179.—The Effect of Alumina on the Specific Gravity of Tourmaline.

tourmaline lost its colour at 670° when heated in a stream of hydrogen, but the colour is restored at room temp.; a dark red crystal became green at 500° , and remained pale green at room temp.; a reddish-violet tourmaline became brownish-green when heated and the colour disappeared at 500° , and it remained colourless when cold. Red tourmalines became green when heated between 500° – 800° in oxygen, and the green colour remained on cooling. R. Cusack gave 1012° – 1102° for the **melting point** of tourmaline; A. L. Fletcher gave 1062° – 1152° ; and C. Doelter, 1010° . The m.p. must obviously depend on the composition. The last-named found that on fusion tourmaline yields olivine and spinel. This decomposition must interfere with observations on the m.p. J. Joly found the **specific heat** of an iron tourmaline to be 0.2004 between 9.1° and 100° ; and 0.2111 for a magnesian tourmaline. S. P. Thomson and O. J. Lodge inferred that the **thermal conductivity** of tourmaline is probably unilateral, but F. Stenger found that it is not so. The ratio of the sq. roots of the conductivities in the direction of the a -axis and of the c -axis is 1.15–1.17. G. F. Fitzgerald made some observations on this subject.

A large number of observations have been made on the refractive indices of the tourmalines. A. des Cloizeaux found for a colourless tourmaline with Na-light, $\omega = 1.6366$, and $\epsilon = 1.6193$. Observations were made by M. Jerofejeff, P. H. Schwebel, A. Cossa and A. Arzruni, G. B. d'Achiardi, L. Duparc and co-workers, K. Becht, K. Zimanyi, etc. According to E. A. Wülfing, the lithium tourmalines have the lowest refraction; the magnesian tourmalines have intermediate values; and the iron tourmalines have the highest refraction. W. T. Schaller also found the ferruginous tourmalines have the highest refraction. The following is a selection of values from data furnished by the above-mentioned observers:

	Colourless.	Dark green.	Green.	Red.	Dark red.	Straw yellow.	Dark brown.	Black.
ω	1.6424	1.6424	1.6401	1.6394	1.6448	1.6430	1.6481	1.6525
ϵ	1.6223	1.6222	1.6220	1.6237	1.6251	1.6224	1.6260	1.6279
$\omega - \epsilon$	0.0201	0.0202	0.0181	0.0157	0.0197	0.0206	0.0231	0.0246

P. Reiner found for the refractive index with alkali tourmaline $\alpha=1.625$, $\gamma=1.646$; with magnesian tourmaline, $\alpha=1.628$, $\gamma=1.640$; and iron tourmaline, $\alpha=1.639$ and $\gamma=1.668$. The **birefringence** is strong. E. A. Wülfing also found the magnesian tourmalines have the lowest birefringence; the lithium tourmalines have intermediate values, and the iron tourmalines, the highest double refraction. The optical character is negative. All the coloured tourmalines have a well-marked **pleochroism**. This was noted by J. G. Wallerius in 1778, and observations have been recorded by A. des Cloizeaux, E. Bertrand, A. Beer, C. F. Rammelsberg, G. Spezia, A. von Lasaulx, R. Scharizer, A. Cossa and A. Arzruni, and A. C. Gill. In the black varieties, ω is green or blue, and ϵ is brown or red; in the green varieties, ω is green or greenish-brown, and ϵ is green of a different tint; in the red crystals, both rays are red but of a different tint. The dichroism with ultra-red waves was studied by E. Merritt, and V. Agafanoff. The effect of the colouring pigment on the pleochroism was also investigated by V. Agafanoff. E. Bertrand, and T. Liebisch observed the idiophanous figures of tourmaline. The absorption of the ordinary ray is much greater than that of the extraordinary ray. In some dark brown crystals the difference is so great that a section parallel to the optic axis, transmits virtually only the extraordinary rays, and can therefore be used as polarizer or analyzer—*e.g.* the so-called tourmaline tongs. Observations on the **absorption of light** by tourmaline plates were made by W. Pulfrich, J. Ehlers, A. Potier, E. Carvallo, and P. H. Schwebel. W. W. Coeblentz found the important bands on the **absorption spectrum** are at 1.28μ and 2.82μ ; and in the **reflection spectrum**, there are maxima at 7.5μ , 8.0μ , 9.2μ , 9.7μ , 10.2μ , and 10.7μ . A. Pfüger confirmed the law with respect to the proportionality of absorption and emission of light by tourmaline. E. Newbery and H. Lupton found that when green tourmaline is exposed to radium rays no visible effect is produced; a pink crystal became colourless when heated, but radium rays had no visible effect on the heated specimen, although the unheated crystal was slightly darkened in colour. Cathode rays did not change the colour of the heated or unheated mineral; the heated crystals alone have a fine orange glow. Colourless crystals assumed a faint pink colour by exposure to radium radiations. The **interference figures** are characteristic of uniaxial crystals, but sometimes the crystals are biaxial, may be as a result of press. strains. A. des Cloizeaux observed the biaxial interference figures about the boundary of differently coloured layers of a multi-coloured crystal. Observations on the **optical anomalies** of tourmaline crystals were made by E. Mallard, H. Bücking, L. Duparc, A. Madelung, etc. J. A. Anderson discussed the rotation of linearly polarized light by tourmaline crystals; and the motion of light in tourmaline crystals was investigated by C. Viola, E. A. Wülfing, and S. Nakamura.

K. Simon found that tourmaline which has been decolorized by heating in oxygen or hydrogen, has its colour restored by exposing the mineral to sunlight, or to **radium rays**. C. Doelter observed that a colourless tourmaline acquired a rose tint in radium rays; while other tourmalines were not changed. S. C. Lind and D. C. Bardwell found no change of colour, fluorescence, or thermoluminescence up to 300° with pink and green tourmalines. **Ultra-violet rays** act like radium rays, but more feebly. **Cathode rays** have but a slight action on colourless tourmaline. Tourmaline is either non-radioactive or it exhibits a feeble **radioactivity** which has been measured for a number of specimens by R. Piutti. F. Pockels investigated the influence of an **electrostatic field** on the optical properties of tourmaline; and J. Chaudier, the relation between the **electric double refraction** and the birefringence, and found that the former is smaller the less the value of the latter. The

pyroelectrification of minerals was first observed with tourmaline—*vide supra*. C. Linnæus stated that electricity is the cause of the property of attracting light bodies exhibited by warmed tourmaline. The phenomenon was studied by F. Äpinus, who showed that it was necessary to heat the mineral to between 37.5 and 100° in order to develop its attractive powers. The extremity of the crystal terminated by the six-sided prism then becomes positively electrified, and the other extremity negatively electrified. The chief axis of the crystal is thus an electrical axis. He added that when the crystal is large, flashes of light can be seen along its surface. J. Canton, and T. Bergman showed that the electrification is evoked by the change of temp. and is not produced when kept constantly in a heated condition. Observations were made by J. C. Wilcke, W. Watson, R. J. Haüy, M. Born, A. C. Becquerel, F. Köhler, J. D. Forbes, G. Rose, P. T. Riess and G. Rose, T. M. Gauguin, E. Riecke, H. Schedtler, and G. T. Techner. The relation between the electrical and morphological character of tourmaline was discussed by V. von Worobieff. Tourmaline exhibits **piezoelectrification**, and J. and P. Curie showed that by press. in the direction of the chief axis, the polar electrification is analogous to that which is developed by cooling the crystal. W. Lissauer studied the phenomenon at the temp. of liquid air. Observations on the piezoelectrification of tourmaline were made by E. Riecke and W. Voigt, D. H. Keys, and A. L. W. E. van der Veen. J. Curie found the **dielectric constant** in a direction parallel to the chief axis to be 6.05, and vertical to that axis, 7.10; R. von Fellingner gave the respective values 6.5382 and 7.12844; W. Schmidt, 5.65 and 6.75; and R. Cohn and A. Curs, 6.2 to 6.75. W. Lissauer found no change in the value of the dielectric constant in passing from room temp. to the temp. of liquid air. H. Saegusa measured the dielectric hysteresis of tourmaline. Tourmaline is paramagnetic. J. Königsberger measured the **magnetic susceptibility**; B. Bavink, the magnetic influence; and W. Voigt and S. Kinoshuto, the **magnetization numbers** parallel and vertical to the chief axis. B. Bavink studied the magnetic properties of tourmaline.

R. Piutti measured the occluded helium in some samples of tourmaline. H. Baumhauer studied the action of alkali hydroxide soln. J. Lemberg¹⁰⁸ investigated the action of soln. of sodium silicate at 200°, for 586 hrs., and obtained a product resembling analcite. E. C. Sullivan studied the basic exchange which occurs when tourmaline is placed in soln. of cupric sulphate. Some changes which occur in nature are produced by the addition of alkalis. The alteration of tourmaline to mica (lepidote), chlorite, cookeite, and steatite have been studied by G. Tschermak, W. T. Schaller, R. B. Rogers, C. R. van Hise, etc.

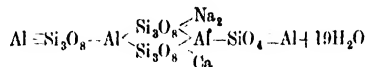

G. A. Kenngott¹⁰⁹ named a mineral erroneously thought to come from the Val Milar, Switzerland, **milarite**; it actually came from the Val Giuf, and hence J. Kuschel called it *giufite*. Analyses were made by R. Finkener, A. Frenzel, E. Ludwig, and F. P. Treadwell; and C. F. Rammelsberg calculated the formula $R'_6Ca_4Al_4Si_{24}O_{61}$; C. Hintze, $HKCa_2Al_2Si_{12}O_{30}$; P. Groth, $HKCa_2Al_2(Si_2O_5)_6$; and G. Cesaro, $K_2Ca_2Al_2(Si_2O_5)_6 \cdot H_2O$, or hemihydrated **potassium calcium aluminium trimesodisilicate**, $KCaAl(Si_2O_5)_3 \cdot \frac{1}{2}H_2O$. F. W. Clarke represents it by a constitutional formula analogous to that of beryl. The hexagonal prismatic crystals are colourless or pale green. In polarized light, the crystals are biaxial, and hence G. Tschermak, A. des Cloizeaux, and E. Mallard regarded them as pseudo-hexagonal; but F. Rinne showed that the anomalous characters are secondary, and that the crystals are hexagonal. W. Ramsay confirmed this, and found that the biaxial parts become uniaxial with rise of temp. F. Rinne gave for the axial ratio $a:c=1.06620$; and K. Busz, $1:0.66468$. E. Bertrand gave for the optic axial angle $2H_a=79^\circ$, and $2H_o=107\frac{1}{2}^\circ$. The sp. gr. is 2.5–2.6; and the hardness 5–6.

F. von Kobell¹¹⁰ found a massive, foliated, greyish-yellow mineral associated with the wollastonite and the edelforsite in the limestone of Gjellebäck, Norway; he called it **sphenoclase**—from *σφην*, a wedge; and *κλάω*, I break—in allusion to its breaking into wedge-shaped pieces. C. F. Rammelsberg calculated the formula

$R_6Al_2Si_6O_{12}$ from the analysis where $(Fe, Mn) : Mg : Ca = 1 : 1.4 : 4.2$. F. W. Clarke represents the idealized mineral as $Ca_6Al_2(Si_6O_7)_3$, analogous in structure with barylite and okenite, or **calcium dialuminium triorthosilicate**. The sp. gr. is 3.2, and the hardness 3½–6. Sphenoclase is slightly attacked by hydrochloric and sulphuric acids, but after ignition, the mineral is easily decomposed by hydrochloric acid with the separation of gelatinous silicic acid.

J. Söllner¹¹¹ reported a pale yellow or colourless mineral in the melilitic basalt of Kaiserstuhl, Baden, and he called it **dececkite**—after T. Dececk. The crystals are pseudomorphous after melilite. The analyses correspond with $(H, Na, K)_2(Mg, Ca)(Al, Fe)_2(Si_2O_6)_5 \cdot 9H_2O$, or **potassium calcium dialuminium pentamesodisilicate**, $K_2CaAl_2(Si_2O_5)_5 \cdot 9H_2O$. The crystals are apparently uniaxial with an index of refraction about 1.47, a weak birefringence, and optically negative. The sp. gr. is 2.1. The mineral becomes opaque when heated, and it is not attacked by hydrochloric acid.

A. Damour¹¹² described a zeolite which he obtained from Sasbach, Baden, and named **faujasite**—after Faujas de Saint Fond. Analyses were made by A. Damour, and C. C. Hoffmann. The mineral has 22.49–27.02 per cent. of water. V. Goldschmidt found 27.5 per cent. The analyses were summarized by C. F. Rammelsberg, in the formula $H_{12}Na_2CaAl_4Si_9O_{32} \cdot 12H_2O$; J. D. Dana, and C. Hintze, $H_7Na_2CaAl_4(SiO_3)_{10} \cdot 18H_2O$; P. Groth, $H_2(Na_2Ca)Al_2(SiO_3)_5 \cdot 9H_2O$; and F. W. Clarke:

It is more probable that the sodium and calcium of faujasite belong to different mols. which form an isomorphous mixture of sodium and calcium aluminosilicates, say $CaAl_2(SiO_3)_5 \cdot 10H_2O$, and $Na_2Al_2(SiO_3)_5 \cdot 10H_2O$. This makes the idealized mineral **decahydrated calcium dialuminium pentametasilicate**; and **decahydrated sodium dialuminium pentametasilicate**. G. Tschermak believed that faujasite is an isomorphous mixture of sodium and calcium aluminium silicates, each of which is combined with a silicic acid: $CaAl_2Si_2O_8 \cdot H_4O_2 \cdot H_8Si_4O_{12} + 4Aq$, and $Na_2Al_2Si_2O_8 \cdot H_4O_2 \cdot 2H_8Si_2O_8 + 4Aq$. Whatever view is finally adopted will depend on the mode of association of the water. A. Damour found faujasite loses 15 per cent. of water when exposed to dry air for a month, but regains almost all during 24 hrs. exposure to ordinary air. When heated to 50°–55° for one hour, it loses 15.2 per cent.; at 60°–65°, it loses 10.4 per cent., and at 70°–75°, 19.5 per cent. Almost all is regained by exposure to moist air for a few weeks. P. Jannasch found that at 100° the mineral lost 18.66 per cent. of water; at 200°–205°, 20.41 per cent., at 250°–260°, 22.67 per cent.; over a gas-burner, 27.02 per cent.; and over a blast-flame, 27.59 per cent. P. Jannasch also found that after being confined for 24 and 48 hrs. over calcium chloride, the losses were respectively 1.72 and 1.83 per cent.; 65 and 100 hrs. over conc. sulphuric acid, respectively 4.60 and 6.52 per cent.; and 118 and 190 hrs. over phosphorus pentoxide, respectively 7.44 and 10.88 per cent. The weight thereafter remained constant. The crystals usually occur in octahedra, and sometimes trisoctahedra. They are colourless, white, or brown. A. des Cloizeaux showed that the crystals are isotropic and belong to the cubic system. Twinning is common. The cleavage parallel to the (111) plane is clear. As with many other zeolites, the double refraction is anomalous. According to F. Rinne, the crystals, normally isotropic, are changed by the loss of a little water and form eight uniaxial individuals which are optically positive. The crystals at 150°, after losing 12 mols of water, become isotropic; a further loss of water makes the crystals uniaxial and negative. When water is resorbed, the crystals again become uniaxial and positive. The sp. gr. is 1.923; and the hardness 5. The crystals are decomposed by hydrochloric acid, and only a fraction of the separated acid is gelatinous.

W. Cross and L. G. Eakins¹¹³ found a zeolite on the Table Mts., and Silver Cliff, Colorado, which they named **ptilolite**—from *πιλον*, wing down—in allusion to the light downy nature of the aggregates of the fine acicular crystals. It has also been found at Teplitz Bay by L. Colomba; San Piero, Elba, by G. d'Achiardi; and Teigarhorn, Iceland, by G. Lindström. K. Callisen described a mineral from Iceland which he called *flokite*. O. B. Böggild, however, showed that it is essentially the same as ptilolite—*vide infra*. Analyses of these specimens correspond with $\text{CaAl}_2\text{Si}_4\text{O}_{24}\cdot 5\text{H}_2\text{O}$ mixed with the isomorphous silicates $\text{K}_2\text{Al}_2\text{Si}_4\text{O}_{24}\cdot 5\text{H}_2\text{O}$, and $\text{Na}_2\text{Al}_2\text{Si}_4\text{O}_{24}\cdot 5\text{H}_2\text{O}$. F. W. Clarke represented this mineral by $\text{H}_2\text{CaAl}_2(\text{Si}_2\text{O}_5)_5\cdot 6\text{H}_2\text{O}$, etc. This corresponds with **hexahydrated calcium dialuminium dihydropentamesodisilicate**; similarly with the **hexahydrated potassium dialuminium dihydropentamesodisilicate**, and **hexahydrated sodium dialuminium dihydropentamesodisilicate**. Or, neglecting the $6\text{H}_2\text{O}$:

According to W. Cross and L. G. Eakins, a sample of ptilolite with 13.44 per cent. of water lost 3.84 per cent. of water when confined over sulphuric acid, and at

	110°	125°	300°	Red heat
Loss	2.61	1.31	2.41	3.10 per cent.

L. Colomba found 0.81 per cent. loss over calcium chloride; 4.28 per cent. was lost at 85°, and 5.46 per cent. at 105°–110°. The mineral can reabsorb this water from moist air; but if heated to a high temp., the resorption is incomplete. The crystals are isotropic at ordinary temp., and doubly refracting at 120°–125°. L. H. Koch gave $\alpha=1.574$, $\beta=1.477$, and $\gamma=1.478$. The optical character is negative. The sp. gr. is 2.30. The crystals are insoluble in hydrochloric acid, and slowly decomposed by sulphuric acid.

H. How¹¹⁴ obtained a zeolite from Morden, Nova Scotia, which he named **mordenite**; L. V. Pirsson obtained the same mineral from the Noodoo, Wyoming. The analyses correspond with the formula $3\text{RAl}_2\text{Si}_2\text{O}_{24}\cdot 20\text{H}_2\text{O}$, where R represents $\text{K}_2:\text{Na}_2:\text{Ca}=1:1:1$. C. S. Ross and E. V. Shannon gave $(\text{Ca},\text{Na}_2)\text{O}\cdot \text{Al}_2\text{O}_3\cdot 9\text{SiO}_2\cdot 6\text{H}_2\text{O}$. F. W. Clarke represents the constitution as an isomorphous mixture of three silicates associated with ptilolite. According to S. J. Thugutt, the so-called *comptonite* from the Swiss Alps is the same mineral. The tabular crystals are white, may be tinged yellow or pink. The crystals may occur in concretions with a fibrous texture. They resemble heulandite in habit and angles. L. V. Pirsson gave for the axial ratios of the monoclinic crystals $a:b:c=0.40099:1:0.42792$, and $\beta=88^\circ 29\frac{1}{2}'$. The cleavage parallel to (010) is perfect. The axial angle is large. The sp. gr. is 2.08–2.15; L. H. Hoch gave 2.30. The hardness is 3–4. The powdered mineral loses 3–6 per cent. of water when kept for an hour at 100°. O. B. Böggild found the index of refraction is about 1.480; L. H. Koch gave $\alpha=1.475$, $\beta=1.477$, and $\gamma=1.478$. C. S. Ross and E. V. Shannon gave $\alpha=1.470$ – 1.475 ; $\beta=1.473$ – 1.477 ; and $\gamma=1.475$ – 1.478 . The double refraction is weak, 0.002–0.003, and negative; and the extinction inclined at about 15°. O. B. Böggild said the extinction of ptilolite is parallel. The mineral is completely decomposed by acids. W. T. Schaller considers *flokite* to be the same as mordenite. T. L. Walker and A. L. Parsons regard ptilolite to be identical with mordenite; but W. T. Schaller regards mordenite, ptilolite, and *clinoptilolite*—crystallized mordenite—as distinct mineral species.

H. How found reddish, pink, or chalk-white balls in a red clay from Cape Split, Nova Scotia. He considered this mineral to be partially altered mordenite which he called

scolecite—after J. Steele. A zeolite found in British Columbia by R. P. D. Graham was named *ferrierite*. It is related to mordenite and ptilolite, and has the composition $(\text{Mg}, \text{Na}, \text{H})_2\text{Al}_2(\text{Si}_2\text{O}_6)_2 \cdot 6\text{H}_2\text{O}$. The crystals are rhombic, the indices of refraction $\alpha=1.478$, $\beta=1.479$, and $\gamma=1.482$; and $\gamma-\alpha=0.004$; the optic axial angle $2V=50^\circ 25'$. When heated to 100° , water begins to be evolved; at 205° , 6.5 per cent. is lost; and at 275° , another one per cent. is given off.

R. J. Haüy¹¹⁵ referred to a fibrous zeolite analyzed by L. N. Vauquelin as *mesotype*—from μέσος, middle; and τυπός, type—in allusion to form of the crystals whose square prisms were considered to be intermediate between the forms of stilbite and analcite. The fibrous zeolites were afterwards investigated by J. N. von Fuchs and A. F. Gehlen. They called natrolite, soda-mesotype, and lime-mesotype was called *scolecite*—from σκώληξ, a worm—in reference to the way some specimens curl up when heated before the blowpipe; mesotype, between scolecite and natrolite in composition, was called *mesolite*. H. J. Brooke called a specimen of scolecite from Poonah, India, *poonalite*. The two minerals from Antrim, Ireland, a fibrous variety named *antrimolite* and a massive chalk-like variety named *harringtonite*, were shown by G. A. Kenngott, and A. Lacroix to be scolecites; and A. and R. Brauns showed that harringtonite and faröelite are the same minerals.

Several analyses of scolecite have been made.¹¹⁶ The results were represented by C. F. Rammelsberg,¹¹⁷ $\text{CaAl}_2\text{Si}_3\text{O}_{10} \cdot 3\text{H}_2\text{O}$, calcium dialuminum orthotrisilicate, in which the water was represented as being eq. to water of crystallization. A. Damour found the eq. of about a mol of water was lost at nearly 230° , and the bulk of the water was driven off at a temp. approaching redness. F. Rinne hence concluded that there are two scolecites, one a rhombic form with a mol less water than the other; the one with the higher water-content he called *metascolecite*—vide *infra*. The fact that one-third of the water is more easily expelled than the rest was considered by J. Lemberg to have some bearing on the constitutional formula. The dehydration curve of scolecite was also investigated by F. W. Clarke and G. Steiger, and C. Hersch. F. Zambonini obtained the following results with moist air:

	120°	217°	240°	275°	305°	365°	445°
Water lost	1.03	4.22	5.33	6.52	7.23	11.16	11.99 per cent.

There is said to be a break between 275° and 330° ; with dry air, the loss at 275° is greater, being about 7.20 per cent. A. Damour found that the water is resorbed by the mineral dehydrated at 300° , but after it had been heated to redness, it was no longer hygroscopic. F. Zambonini also studied the resorption of moisture by the dehydrated mineral, and he compared the state of the water in scolecite with that in silica hydrogel. G. Stoklossa said that the water is in a combined state, and he reported that there are really six different hydrates shown by breaks in the rehydration curve of scolecite dehydrated between 17° and 390° . Hence, he doubled C. F. Rammelsberg's formula, and wrote: $\text{Ca}_2\text{Al}_4\text{Si}_6\text{O}_{20} \cdot 6\text{H}_2\text{O}$. P. Groth regarded scolecite as a metasilicate, $\text{CaAl}\{\text{Al}(\text{OH})_2\}(\text{SiO}_3)_3 \cdot 2\text{H}_2\text{O}$. G. Tschermak assumed that orthosilicic acid is associated with an aluminosilicate, and wrote the formula $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot \text{H}_4\text{SiO}_4$. He said no water of crystallization is present, but a mol of water is an intrinsic part of the mol. F. W. Clarke represented the constitutional formula like that of natrolite (*q.v.*) with Ca in place of Na_2 , and $6\text{H}_2\text{O}$ in place of $4\text{H}_2\text{O}$. The water in mesolite was studied by G. Friedel, and E. T. Allen and J. K. Clement.

A. Daubrée¹¹⁸ found crystals of scolecite in the masonry of the baths of the thermal springs at Plombières, and Bourboigne; and R. Hermann noted that crystals of scolecite are forming in the plastic mass between the basaltic columns of Stolpen, Saxony. C. Doelter did not obtain scolecite from soln. containing the theoretical proportions of silicic acid, alumina, and lime; but prismatic crystals were formed when powdered scolecite was heated in a closed tube at 150° as indicated in connection with natrolite. This, in conjunction with A. Daubrée's experiment, shows that a low temp. is needed for the formation of this silicate. Scolecite occurs

massive and in nodules; fibrous and radiating; and in slender prismatic crystals. The crystals were measured by W. Phillips,¹¹⁹ W. H. Miller, S. Kreutz, A. des Cloizeaux, R. Köchlin, J. Königsberger, Ö. Luëdecke, V. von Zepharovich, etc. J. Brewster, and G. Rose showed that the crystals are monoclinic; and G. Flink gave for the axial ratios $a:b:c=0.9764:1:0.3434$, and $\beta=90^\circ 42'$; while S. Kreutz gave $0.97636:1:0.34338$, and $\beta=89^\circ 18'$. The monoclinic crystals of scolecite are stated to be isomorphous with those of natrolite. F. Rinne, and H. Haga and P. M. Jäger have studied the X-radiogram of scolecite. G. Tschermak made observations on the relations between the crystals of various zeolites. G. Flink, and F. Rinne made observations on the corrosion figures. The prismatic cleavage parallel to the (110)-face is nearly perfect. The twinning plane is (100). J. Luëdecke, G. Wyruboff, and C. Schmidt made observations on the twinning of the crystals of scolecite. The optic axial angle is medium; A. des Cloizeaux found for the red ray, $2E=53^\circ 41'$; for the blue ray, $2E=59^\circ 37'$; and for the red ray, $2H_a=35^\circ 57'$, $2H_o=156^\circ 4'$, and $2V=35^\circ 1'$. G. Flink gave $2E=16^\circ 48'$ for white light. Observations were also made by G. Schmidt, V. von Zepharovich, and J. Luëdecke. A. des Cloizeaux found the optical axial angle $2E=60^\circ 28'$ at 8.8° , and $59^\circ 46'$ at 146.5° . The sp. gr. was determined on many of the samples analyzed; the results range from 2.2–2.4; and the hardness 5–5½. G. Tammann found that in an atm. with the vap. press. of water p mm., the percentage amount of water lost by p sample of scolecite was:

p	15.7	14.6	12.3	9.1	6.1	2.9	1.2	0.11 mm.
Loss	0	0.004	0.013	0.017	0.029	0.042	0.079	0.105 per cent.

F. Rinne found a marked change in the optical properties when the mineral is heated; and scolecite which has been strongly heated is rhombic *metascolecite*. O. B. Böggild said the extinction is oblique up to about 17° . The refraction is like that of cedar oil. A. des Cloizeaux gave for the index of refraction 1.502 for red light; and C. Schmidt, 1.6470 for Li-light, 1.6570 for Na-light, and 1.6675 for TI-light. H. Michel gave $\alpha=1.509$, $\beta=1.515$. A. Lacroix found for the birefringence $\gamma-\alpha=0.0083$, and O. B. Böggild, 0.007. The optical character is negative. W. W. Coblentz found that the ultra-red transmission spectrum shows the absorption bands of water up to 5μ , where it becomes opaque. The 3μ water-band is complex. Observations on the pyroelectric behaviour of scolecite were made by R. J. Haüy, D. Brewster, P. Riess and G. Ross, G. W. Hankel, C. Schmidt, G. Friedel and A. de Grammont, and F. Rinne. O. Weigel studied the electrical conductivity of scolecite.

The mineral first described by H. Michel¹²⁰ as *okenito* was later called *metascolecite* because its composition, $\text{CaO} : \text{Al}_2\text{O}_3 : \text{SiO}_2 : \text{H}_2\text{O}=0.93021 : 1.0323 : 3 : 2.9941$, so closely resembles that of scolecite while the physical properties are different. It belongs to the rhombic system. The sp. gr. is 2.244; the indices of refraction, $\alpha=1.504$ –1.512, $\gamma=1.508$ –1.515.

C. Doelter¹²¹ found scolecite to be partially soluble in carbonated water. J. Lemberg found that when digested with soln. of potassium or sodium carbonate, the calcium is nearly all replaced by the alkali metal; similarly with soln. of potassium or sodium chloride; and with a soln. of sodium sulphate. G. Steiger also found that much of the calcium in scolecite can be replaced by silver, when the mineral is digested with a soln. of silver nitrate. The product was called *silver-scolecite*. F. W. Clarke and G. Steiger studied the action of ammonium chloride in a sealed tube at 350° , when some lime is replaced by ammonium, forming *ammonium-scolecite*. I. Zoch experimented with soln. of ammonium chloride and likewise found an exchange of bases. The subject was investigated by R. Gans, and G. Tschermak. Scolecite is decomposed by acids with the separation of gelatinous silica in the form, according to G. Tschermak, of orthosilicic acid. J. M. Theile studied the nature of the silicic acid so obtained. M. F. Heddle, and C. R. van Hise studied the transformation of scolecite in nature.

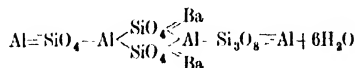

Several analyses of mesolite have been reported.¹²² C. F. Rammelsberg¹²³

found that the composition could be represented as a mixture of natrolite and scolecite. C. Hintze, V. Goldschmidt, H. L. Bowman, and G. Tschermak also regarded mesolite as variable mixtures of these two minerals; while R. Gorgey and J. N. von Fuchs and A. F. Gehlen supposed it to be a double salt. Mesolite occurs massive with radiating and interlaced fibres sometimes called *cotton-stone*. A. des Cloizeaux, on optical grounds, regarded the crystals as triclinic with penetration twinning. E. Hussak also found complex twinning in the apparently triclinic crystals from Brazil. O. Luedecke attempted to prove that mesolite is trimorphous — A. des Cloizeaux's triclinic variety, rhombic galactite (*q.v.*), and the monoclinic form from Iceland. R. Gorgey represented the axial ratios of the triclinic crystals as $a : b : c = 0.9747 : 1 : 0.3122$, and $\beta = 92^\circ$. C. Schmidt argued that the triclinic form is really monoclinic like scolecite. S. Kreutz gave for the axial ratios of the monoclinic crystals:

	Natrolite.	Mesolite.	Scolecite.
$a : b : c$	0.97853 : 1 : 0.35362	0.9747 : 1 : 0.3122	0.97636 : 1 : 0.34338
β	90°	92°	89° 18'
α, β, γ	1.480, 1.482, 1.493	1.505, 1.505, 1.506	1.512, 1.519, 1.519
$\gamma - \alpha$	0.013	0.001	0.007

G. Flink regarded the three minerals as isomorphous. H. L. Bowman gave for the optic axial angles with Na-light $2E = 76.25^\circ$, $2V = 81.5^\circ$. The prismatic cleavage is perfect; the sp. gr. 2.2–2.4; and the hardness 5. P. E. W. Oberg found the sp. ht. to be 0.2464 between 14° and 99° . O. B. Boggild found the index of refraction very nearly 1.505. R. Gorgey gave for the index of refraction 1.5021 for Li-light, 1.505 for Na-light, and 1.5072 for Ti-light; and J. Konigsberger and W. J. Müller gave $\alpha = 1.5048$, $\beta = 1.5050$, and $\gamma = 1.5053$ with Na-light. E. T. Wherry gave the values indicated above. R. Gorgey gave for the birefringence, $\gamma - \alpha = 0.0005$; $\gamma - \beta = 0.00028$; and $\beta - \alpha = 0.00023$. O. B. Boggild said that there is no double refraction with thin needles of mesolite, in some cases the impure mineral has a weak positive or negative birefringence. J. Lemberg found that by treatment with a soln. of an alkali chloride the lime is replaced by alkali; and with a soln. of thallium nitrate, G. Steiger obtained *thallium-mesolite*. F. von Richthofen, C. R. van Hise, and K. D. Ghinka studied the effect of natural agents on mesolite.

W. Haidinger¹²⁴ described a zeolite which was obtained from Kilpatrick, Scotland, by A. Edington, and which was accordingly named **edingtonite**. A. Breithaupt named it *actedite* on account of its hemihedral crystals; and F. Mohs, *brachyspar* — from *βραχύς*, heavy. O. Nordenskjöld found it at Bohlet, Sweden. Analyses were reported by W. Haidinger, J. Lemberg, M. F. Heddle, and G. Lindström. C. F. Rammelsberg computed the formula $\text{BaAl}_2\text{Si}_3\text{O}_{10} \cdot 3\text{H}_2\text{O}$, or **tri-hydrated barium dialuminium orthotrisilicate**. P. Groth regarded it as a metasilicate, $\text{BaO} \cdot \{\text{Al}(\text{OH})_2(\text{SiO}_3)_3 \cdot 2\text{H}_2\text{O}\}$. G. Tschermak regarded it as a mixture, $\text{H}_4\text{SiO}_4 \cdot \text{H}_2\text{BaAl}_2\text{Si}_2\text{O}_9 \cdot \text{H}_2\text{O}$. F. W. Clarke represents it by:

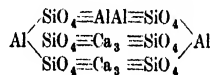

J. Lemberg obtained what he regarded as edingtonite by digesting artificial natrolite with a soln. of barium chloride for 12 days. The crystals are small and inconspicuous; and white with a grey or pink tinge. W. Haidinger regarded them as tetragonal with sphenoidal hemihedrism, with the axial ratio $a : c = 1 : 0.6725$; while O. Nordenskjöld represented them as rhombic with bisphenoidal hemihedrism, with axial ratios $a : b : c = 0.9872 : 1 : 0.6733$. The cleavage is complete when parallel to (110). O. Nordenskjöld gave for the optic axial angles with Li-, Na-, and Ti-light, $2E = 86^\circ 51'$, $87^\circ 17'$, and $88^\circ 8'$ respectively; and $2V = 52^\circ 17'$, $52^\circ 55'$, and $53^\circ 10'$ respectively. The sp. gr. is 2.694–2.776; and the hardness 4–4½. A. des Cloizeaux found the double refraction strong and negative.

O. Nordenskjöld gave for the indices of refraction respectively with Li-, Na-, and Tl-light, $\alpha=1.5344-1.5361$, $1.5370-1.5395$, $1.5401-1.5418$; $\beta=1.5466$, 1.5492 , and 1.5522 ; and $\gamma=1.5511$, 1.5540 , and 1.5566 . Edingtonite is decomposed by hydrochloric acid with the separation of gelatinous silicic acid.

T. Thomson found a mineral which he called *glottalite* near Port Glasgow, Scotland. It occurred in octahedral crystals belonging to the cubic system. M. F. Heddle said that it is probably edingtonite mixed with harmotome. R. P. Greg and W. G. Lettsom regarded it as a chabazite. A. Sigmund's *galactite* from Weitendorf, Steiermark, was considered to be a mixture of natrolite and scolecite.

Flesh-coloured crystals of a rare mineral were found by T. Thomson¹²⁵ in the ejected masses on Monte Somma, Vesuvius, and called **sarcolite**—from *σάρξ*, flesh, in allusion to the colour. This mineral is not the same as the zeolitic sarcolite from Vicentin—*vide* gmelinitz. R. J. Haüy seems to have considered these crystals to be analcite, and T. Monticelli and N. Covelli called it *analcime carnea*. A. Breithaupt regarded sarcolite as humboldtite or melilite; but A. des Cloizeaux, and F. de Fonseca showed that it is more probably a definite mineral species. The mineral was analyzed by A. Seacchi and M. del Lupo, C. F. Rammelsberg, and A. Pauly. C. F. Rammelsberg gave the formula $\text{Na}_6\text{Ca}_{27}\text{Al}_{20}\text{Si}_{30}\text{O}_{120}$; and P. Groth, $\text{Na}_2\text{Ca}_8\text{Al}_6\text{Si}_9\text{O}_{36}$. C. F. Rammelsberg supposed the mineral to be a complex of $\text{Na}_4\text{SiO}_4 : \text{Ca}_2\text{SiO}_4 : \text{Al}_4(\text{SiO}_4)_3 = 3 : 27 : 10$; or of $\text{Na}_6\text{Al}_2\text{Si}_3\text{O}_{12} + 9\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}$. W. T. Schaller also favoured the hypothesis that in sarcolite, lime-sarcolite is in isomorphous admixture with soda-sarcolite, $3\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$; or **calcium dialuminylo-orthotrisilicate**, $\text{Ca}_3(\text{AlO})_2\text{Si}_3\text{O}_{10}$, and **sodium dialuminylo-orthotrisilicate**, $\text{Na}_3(\text{AlO})_2\text{Si}_3\text{O}_{10}$. The alternative view is to regard the one as **calcium dialuminium triorthosilicate**, $\text{Ca}_3\text{Al}_2(\text{SiO}_4)_3$, and the other as the corresponding sodium salt. F. W. Clarke takes this view and writes:

The mineral has not been prepared artificially, although it is possible that some of the reported syntheses of meionite may really refer to sarcolite. N. L. Bowen suggested that it has been formed in nature by the rapid cooling of a fused mixture of nephelite and pyroxene. R. J. Haüy assumed that the cubo-octahedral crystals belonged to the cubic system; but H. J. Brooke showed that the pseudo-cubic crystals are really tetragonal with pyramidal hemihedrism, and have the axial ratio $a : c = 1 : 0.88737$; F. Zambonini gave $1 : 0.9861$; and P. Groth, $1 : 0.4183$. The crystals were studied by G. vom Rath, N. von Kokscharoff, F. Hensenberg, G. Strüver, C. F. Rammelsberg, and W. H. Miller. The cleavage is not apparent. A. Breithaupt gave 2.936 for the sp. gr.; C. F. Rammelsberg, 2.932; and F. Zambonini, 2.920. The last-named said that H. J. Brooke's value 2.545 is erroneous. The optical character of the uniaxial crystals is positive; F. Zambonini gave for the indices of refraction for Li-, Na-, and Tl-light respectively $\omega=1.6000$, 1.6035 , and 1.6067 ; and $\epsilon=1.6111$, 1.6147 , and 1.6180 . He considers that A. Pauly's values $\omega=1.6404$ and $\epsilon=1.6566$ for Na-light must refer to some other mineral. The double refraction is strong and positive, $\epsilon-\omega$ being 0.0111 , 0.0112 , and 0.0113 respectively for Li-, Na-, and Tl-light.

In 1790, F. de Bellevue¹²⁶ discovered a yellow mineral at Capo di Bove, Rome, which J. C. Delaméthérie called **melilite**—from *μέλι*, honey—in allusion to the colour—*vide supra*. The crystals which occur at Somma were called **humboldtite**—after F. H. A. von Humboldt; **somervillite**, by H. J. Brooke; **zurite**—after S. Zurlo—by V. Ramondini. The first attempt at analysis was made by P. Carpi. The mineral was subsequently analyzed by F. von Kobell, A. Damour, and many others.¹²⁷

The selection of a formula for melilite has proved to be very difficult. The earlier analyses were not concordant. C. F. Rammelsberg¹²⁸ gave the

formula $(\text{Na}, \text{K})_2(\text{Ca}, \text{Mg})_{11}(\text{Fe}, \text{Al})_4\text{Si}_9\text{O}_{36}$; A. des Cloizeaux gave the analogous formula $12\text{RO} \cdot 2\text{R}_2\text{O}_3 \cdot 9\text{SiO}_2$; W. Stahl, $\text{R}_2\text{O} \cdot 29\text{RO} \cdot 3\text{R}_2\text{O}_3 \cdot 20\text{SiO}_2$; C. Hintze, $(\text{Ca}, \text{Mg}, \text{Fe})_6(\text{Al}, \text{Fe})_2\text{Si}_5\text{O}_{19}$; and P. Groth, $(\text{Ca}, \text{Mg})_6(\text{Al}, \text{Fe})_2\text{Si}_5\text{O}_{19}$. J. H. L. Vogt suggested that the natural melilites are mixtures of gehlenite, $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, and what he called akermanite, $4\text{CaO} \cdot 3\text{SiO}_2$ —*vide* akermanite. This hypothesis failed, because, as W. T. Schaller expressed it, the end-member gehlenite is not a distinct and definite species, but is itself a variable mixture of definite end-members; and the other end-member akermanite was given a wrong formula—it should have been $4\text{MgO} \cdot 8\text{CaO} \cdot 9\text{SiO}_2$. F. Zambonini suggested three possible explanations of the composition of melilites: (i) they may be mixtures of the two types of compounds $\text{R}''\text{SiO}_3$ and $\text{R}''_3\text{R}'''\text{Si}_2\text{O}_{10}$; (ii) they may have the general composition $\text{R}''\text{R}'''\text{Si}_2\text{O}_8 \cdot n\text{R}''_2\text{SiO}_4$; and (iii), as G. Bödländer suggested, the optically negative melilites may be mixtures of $\text{R}''\text{SiO}_3$ and $\text{R}''\text{R}'''\text{Si}_2\text{O}_4$; and the optically positive melilites, of $\text{R}''\text{SiO}_3$ and $\text{R}''_3\text{R}'''\text{Si}_2\text{O}_6$. He considered that G. Bödländer's theory agreed well with the facts. W. Vernadsky gave $\text{R}''\text{R}'''\text{Si}_2\text{O}_8 \cdot 5\text{R}_2\text{SiO}_4$. K. Busz and F. W. Rüsberg suggested that melilite is a mixture either of gehlenite and $\text{R}''_3\text{Si}_2\text{O}_7$, or of gehlenite, Ca_2SiO_4 , and CaSiO_3 . F. W. Clarke suggested that the melilites are mixtures of $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ and $9\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$. A. F. Buddington made a number of mixtures of akermanite, $\text{Ca}_2\text{MgSi}_2\text{O}_7$, gehlenite, $\text{Ca}_2\text{Al}_2\text{SiO}_7$, and $3\text{R}'\text{O} \cdot \text{R}_2\text{O}_3 \cdot 3\text{SiO}_2$, where $\text{R}' = \text{Na}$ or Ca ; and $\text{R} = \text{Fe}$ or Al and found all types of melilite minerals as solid soln. of these constituents. A. N. Winchell represented the melilite minerals by R_5O_7 , where R includes the silicon; gehlenite and akermanite are considered to be the dominant members of the series; and the alkalies assigned to $\text{Na}_2\text{Si}_3\text{O}_7$ or $\text{NaAl}_3\text{SiO}_7$. He said that unlike W. T. Schaller, and A. F. Buddington, he found grossular and andradite are not miscible with the melilites. An excess of silica may exist in the interatomic spaces in the molecules.

In nearly all these cases there is little evidence to show that the calcium meta- and ortho-silicates can be united in isomorphous mixture with the alleged end-members of the melilite group. The assumed end-members are in most cases quite imaginary compounds. It is generally admitted that the melilites are isomorphous mixtures of a certain number of end-products; and W. T. Schaller added that these products must satisfy the requirements of isomorphism; they must be related chemically; they must have a similar crystal form; they must form mixtures with the same crystal forms as the end-members themselves; and it must be possible to represent the composition of all natural melilites as mixtures of these end-members. He claimed that these conditions are satisfied by assuming that all members of the melilite and gehlenite series, including fuggenite, can be represented as isomorphous mixtures of the four primary compounds: sarcosite, $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$; soda-sarcosite, $3\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$; velardenite, $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{SiO}_2$; and akermanite, $4\text{MgO} \cdot 8\text{CaO} \cdot 9\text{SiO}_2$. These have been discussed individually elsewhere. See also gehlenite.

Melilite is always of pyrogenetic origin; but it is found only in the younger eruptive rocks; never in the plutonic rocks or crystalline schists. It is usually associated with nephelite, and leucite, and it sometimes takes the place of feldspar.¹²⁰ This subject has been discussed by F. D. Adams, F. W. Clarke, E. S. Larsen and F. J. Hunter, C. H. Smyth, A. Stelzner, and A. E. Torneböhm. Melilite has been reported in slags by L. Bourgeois,¹³⁰ F. Fouqué, J. S. Dittler, P. Heberdey, J. H. L. Vogt, J. Percy, F. Bothe, C. J. B. Karsten, P. Berthier, K. Busz and F. W. Rüsberg, D. Forbes, A. Gurlt, F. Zambonini, G. Bödländer, A. Firket, etc. G. Bödländer observed it in portland cement; and L. Appert and J. Henrivaux found it to be produced in the melting of ordinary glass. L. Bourgeois prepared melilite by fusing a mixture of silica, lime, and alumina in the required proportions provided a salt of iron, magnesium, or manganese was present. It also forms more readily if some soda is present; and all natural melilites contain soda. Melilite was also produced by J. Morozewicz, and F. Fouqué and A. Michel-Lévy, by cooling

basaltic, augitic, and other rock magmas. Other minerals—olivine, plagioclase, augite, corundum, and spinel—were produced at the same time. F. Fouqué obtained it by crystallization from a fused mixture of lime and augitic andesine, or basalt. C. Doelter and E. Hussak found melilite among the products obtained by cooling fused garnet or vesuvianite. C. Doelter synthesized melilite by fusing tourmaline with calcium chloride and sodium fluoride; K. Bauer, by fusing mica-schist, nepheline, or andesine mixed with lithium chloride, and sodium and calcium fluorides; R. Medanich, by fusing a mixture of garnet, sodium hydrophosphate, sodium vanadate, and lithium chloride; and C. F. W. A. Oetling, by fusing a mixture of silica, alumina, iron oxide, magnesia, lime, alkali carbonate, and calcium fluoride. H. Buddington's work on the synthesis of the melilites is indicated above.

Melilite occurs in euhedral crystals and anhedral grains. The euhedral crystals are short square or octagonal prisms, or tetragonal plates. The colour is white, pale yellow, greenish-yellow, reddish-brown, or brown. The crystals belong to the tetragonal system, and A. des Cloizeaux¹³¹ gave for the axial ratio $a : c = 1 : 0.45483$. The crystals may be cruciform twins with the vertical axes only slightly inclined, or nearly at right angles. The cleavage parallel to (001) is distinct, and indistinct parallel to (100). The crystals show some optical anomalies. The sp. gr. ranges from 2.9–3.1, and the hardness is 5. V. S. Deleano and E. Dittler gave 1180° for the m.p.; and J. H. L. Vogt, 1100° . The last-named estimated the latent heat of fusion to be 90 cal., and the total heat of fusion 390 cal. E. Jannetaz found the square root of the ratio of the thermal conductivities in the direction of the base and of the chief axis to be 1.19. The indices of refraction are moderately high. H. Rosenbusch reported for red light, $\omega = 1.6312$, and $\epsilon = 1.6262$; and for yellow light, $\omega = 1.6339$, and $\epsilon = 1.6291$. Values were also measured by E. S. Larsen and J. F. Hunter, and K. Busz and F. W. Rüsberg. The birefringence is weak. H. Rosenbusch reported for Li-light $\epsilon - \omega = 0.00530$; for Na-light, 0.00517; and for Ti-light, 0.00591. The double birefringence is weakest for yellow light and increases towards both ends of the spectrum. The optical character is positive or negative. The opposite characters appear in different parts of the same crystal, and are sometimes arranged concentrically in zones with intermediate isotropic portions. The two end-members sarcolite and akermanite are optically positive, whereas melilite is generally negative although positive varieties are known. W. T. Schaller¹³² suggests two explanatory hypotheses. In one, a true compound of sarcolite and akermanite is formed which is optically negative; the melilites are solid soln. of this compound with smaller proportions of akermanite, sarcolite, and velardenite. If the indices of refraction ϵ and ω are not linear functions of the composition, as illustrated diagrammatically in Fig. 180, then the negative melilites may be isomorphous mixtures of two

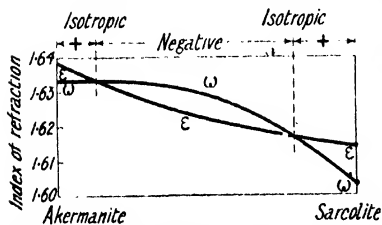

FIG. 180.—Possible Relation between the Refractive Indices of Mixtures of Sarcolite and Akermanite.

positive minerals. A. Stelzner studied the pleochroism of the crystals. Conc. hydrochloric acid decomposes the melilites with the separation of gelatinous silicic acid.

An alteration product of melilite from Cebolla Creek, Colorado, was reported by E. S. Larsen and W. T. Schaller, and named *cebolite*. The analysis corresponds with $\text{Ca}_2\text{H}_2\text{Al}_2\text{Si}_2\text{O}_{12}$. If, as F. W. Clarke suggested, the absence of the alkaline reaction with phenolphthalein when the powdered mineral is moistened with water indicates that CaOH -groups are absent, the graphic formula can be represented $\text{Ca}=\text{SiO}_4=[\text{Ca}.\text{SiO}_4 \equiv \text{Ca}\{\text{Al}(\text{OH})_2\}_2]$, calcium dihydroxyaluminium triorthosilicate. The crystals are probably

rhombic, biaxial, positive, $\alpha=1.595$, $\beta=1.600$, and $\gamma=1.628$. The sp. gr. is 2.96, and the hardness 5. The mineral gelatinizes with acids, and resembles the zeolites in its general properties.

The early observations on the distinction between heulandite and stilbite are indicated in connection with the latter. **Heulandite** is the *stilbite anamorphe* of R. J. Haüy,¹³³ and the *euzoile* of A. Breithaupt.

The *beaumontite* of A. Levy—named after E. de Beaumont—was found in yellow crystals at Jones' Fall, Baltimore, and was considered by F. Alger, J. D. Dana, A. des Cloizeaux, J. J. Berzelius, A. Schmidt, E. Mallard, G. H. Williams, and W. Klein to be identical with heulandite. G. Rose did not agree that the two minerals are identical; but E. V. Shannon found the crystallographic and optical properties, and the chemical composition to be in such close agreement that beaumontite could be regarded only as a variety of heulandite. E. Hitchcock reported a mineral which he called *incaluite* from Deerfield; but J. J. Berzelius, and A. des Cloizeaux showed that it is heulandite. Monoclinic crystals of a mineral from the granite blocks of Fonte del Prete, Elba, were named *oryzite*—from *ὄρυζα*, rice—by G. Grattarola, in allusion to the shape of the crystals. A. Arzruni, and P. Groth suggested that it is identical with heulandite. He also obtained minute acicular crystals of a mineral from the granite of San Piero, Elba, which he named *pseudonatroite* on account of its resemblance to natroite. He later showed that it more closely resembles heulandite. F. W. Clarke said that pseudo-natroite has nearly the same composition as stellerite, but with 2 mols less water. G. d'Achard suggests it is a variety of pilolite. A variety called *metakeulandite* was studied by G. Stoklossa, O. Weigel, K. H. Scheumann, and F. Rinne.

The old analyses of J. C. F. Meyer,¹³⁴ and L. N. Vauquelin gave a very good approximation of the composition of heulandite. Many analyses have been made since then; and it is not always clear whether heulandite or stilbite was under examination. The bases are lime, and small proportions of soda and potash; a little lithia is sometimes present. P. Jannasch, F. Zambonini, B. Mauritz, O. Weigel, and F. W. Clarke and G. Steiger found samples with up to 3.65 per cent. of strontia; and D. Lovisato, a sample with 2.55 per cent. of baryta. C. F. Rammelsberg¹³⁵ first summarized the analyses by the formula $\text{CaAl}_2\text{Si}_6\text{O}_{18} \cdot 5\text{H}_2\text{O}$. P. Jannasch, and F. Rinne used somewhat similar formulae. This is used to-day as the best representative formula; it makes heulandite **pentahydrated calcium dialuminium dimesotrisilicate**, $\text{CaAl}_2(\text{Si}_3\text{O}_8)_2 \cdot 5\text{H}_2\text{O}$. C. F. Rammelsberg later modified the formula to $\text{H}_4\text{CaAl}_2\text{Si}_6\text{O}_{18} \cdot 3\text{H}_2\text{O}$, which C. Bodewig wrote $\text{H}_4\text{CaAl}_2(\text{SiO}_3)_6 \cdot 3\text{H}_2\text{O}$. G. Tschermak used a similar formula. Later still, C. F. Rammelsberg considered the mineral to be a mixture of two such silicates. H. S. Washington used the formula $(\text{CaSi}_2)(\text{AlSi}_2\text{O}_8)_2 \cdot 5\text{H}_2\text{O}$, regarding heulandite as a salt of the aluminosilicic acid, $\text{H}_5\text{AlSi}_2\text{O}_8$. C. S. Ross and E. V. Shannon gave $(\text{Ca}, \text{K}_2, \text{Na}_2)\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 7\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. C. Doelter represented heulandite as a mixture of silicic acid and a silicate: $\text{CaAl}_2\text{Si}_4\text{O}_{12} \cdot 2\text{H}_2\text{SiO}_3 \cdot 3\text{H}_2\text{O}$. S. Hillebrand, and E. Baschieri separated from heulandite what he called *heulanditic acid*, $\text{H}_{10}\text{Si}_6\text{O}_{17}$; and assumed that heulandite is a salt of this acid. G. Tschermak later said that the mineral is a complex of four calcium dialuminium silicates. F. W. Clarke represented heulandite by a formula like that employed for stilbite, but with a mol less water.

A. Damour¹³⁶ found that heulandite from Farøe loses part of its water in dry air, and regains it in ordinary air; at 100°, the mineral loses 2.1 per cent. of water, and 8.7 per cent. between 100° and 150°; the lost water is regained by exposure to air for 24 hrs. At 190°, the mineral loses 12.3 per cent. of water, and all but 2.1 per cent. is regained by two months' exposure to ordinary air. P. Jannasch found the loss with the fine-grained mineral was greater (or faster) than with the coarse-grained mineral. A. A. Ferro, C. Bodewig, and C. Hersch made observations on this subject. F. Rinne found the loss greater (or faster) in vacuo than in air dried by sulphuric acid; and F. Zambonini found the loss over sulphuric acid in vacuo to be:

Time	3	5	24	48	72	118	190	310	550 hrs.
Loss	2.36	2.62	4.86	5.25	5.44	5.63	5.83	6.08	6.08 per cent

The losses in dry air at different temp. were :

	61°	101°	230°	303°	375°	412°
Loss	2.99	4.70	12.04	13.9	14.30	14.80 per cent.

and in moist air :

	61°	101°	151°	234°	272°	284°	309°	420°
Loss	1.63	3.02	5.08	8.20	11.08	12.00	13.92	14.74 per cent.

Although there is a break in the curves, there is nothing to show that any part of the contained water is constitutional. The lost water is rapidly regained if the temp. of calcination has not exceeded 300°. G. Stoklossa found that at 17°, in air sat. with moisture, heulandite is in equilibrium with the atm. when it contains about 16 per cent.—eq. to 5.5 mols.—of moisture, and therefore assumes that the ordinary formula should be doubled, $\text{Ca}_2\text{Al}_4\text{Si}_{12}\text{O}_{32} \cdot 11\text{H}_2\text{O}$. While the dehydration curve is continuous, he found that the rehydration curve of heulandite, which has been heated to a series of temp. between 17° and 380°, shows a number of breaks. A. Beutell also said that there are 11 mols. of water in heulandite, and all are present as water of hydration. O. Weigel inferred that the zeolites are neither adsorption products nor colloids of the nature of gels. Contrary to A. Beutell, O. Weigel maintained that the hydration and dehydration curves are practically reversible at temp. below 180°; and in agreement with K. H. Schumann, no permanent changes caused by dehydration up to a content of $3\text{H}_2\text{O}$; the dehydration curve is almost continuous; the breaks at higher temp. would not occur with integral mols if any considerable decomposition occurred; the curves of O. Weigel, and K. H. Schumann are concordant up to 200°; and optical observations give no evidence of decomposition. Hence, A. Beutell's hypothesis is not proven. O. Weigel considered the water to form a special kind of solid soln. which, as a result of the directing forces of the relatively rigid silicate lattice on the easily mobile water mols. shows some analogy to true hydrates. He added :

The water in zeolites possesses the property of mobility to a high degree whilst the silicate space-lattice must be considered as relatively rigid. The water mols. entering into the mesh cavities of this lattice will tend, according to their thermal press., to become uniformly distributed; on the other hand, the silicate mols. (or portions thereof) in the crystal lattice will tend to hold by attraction the water mols., or a portion thereof, in position in entire conformity with the symmetry of the lattice. Both tendencies can be simultaneously satisfied only if the number of water mols. is a complete multiple of the number of silicate mols., for only under these conditions can the water mols. arrange themselves in identical formation round each of the other mols. of the silicate lattice. It is only exceptionally favourable mixtures such as these that give the straight line in the dehydration curve. All other mixtures correspond to points on the irregular curves. The zeolites are therefore considered to be solid soln., but it is an open question whether the water in this soln. reacts with the solvent, i.e. forms an intimate compound with the silicate, or whether it enters the lattice as a mol. dissociated into its atoms, or into ions.

U. Panichi found that dehydrated zeolites absorb air and the absorbed air is richer in oxygen than is ordinary air; thus a gram of zeolite previously heated to 240° absorbed 1.093 c.c. of air which contained 28 per cent. of oxygen. G. Tammann, K. H. Schumann, and E. Löwenstein measured the vap. press. of heulandite and some of its substitution products—potassium-heulandite, and calcium-heulandite. The vap. press. is a continuous function of the combined water so that no breaks appear in the curve. The latter found that when in equilibrium with an atm. where the partial press. of the water-vap. was p mm., the mineral lost :

p	21.58	19.60	17.63	13.45	8.82	4.41	1.75	0.56	0.18 mm.
Loss	0.06	0.12	0.24	0.35	0.50	0.79	1.15	1.56	3.70 per cent

Similar measurements were made with calcium- and potassium-heulandites.

Heulandite occurs principally in basaltic rocks associated with other zeolites, it also occurs in gneiss and occasionally in metalliferous veins. C. Doelter¹³⁷ recrystallized the powdered mineral by digesting it in water sat. with carbon dioxide,

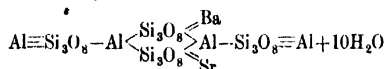

in a sealed tube at 170° for 14 days. He also made it by digesting a mixture of powdered anorthite, freshly precipitated silica, and carbonated water in a sealed tube for 14 days at 200°.

Heulandite occurs in globular forms and granular; in flattened euhedral crystals; and in groups of subparallel crystals producing curved surfaces. The colour is various shades of white passing into grey, red, and brown. A. Breithaupt¹³⁸ considered heulandite belonged to the triclinic system; and G. vom Rath and F. Hessenberg obtained triclinic varieties from Elba and Iceland. A. des Cloizeaux showed that the crystals belong to the monoclinic system, and have axial ratios $a:b:c=0.4035:1:0.4788$ and $\beta=63^\circ 40'$; recalculating the axial ratios to the pseudorhombic from $a:b:c=0.40347:1:0.8586$, and $\beta=88^\circ 34\frac{1}{2}'$. The crystals were studied by F. Rinne, A. Sigmund, O. Tietze, and J. Königsberger. The twinning plane of the crystals is (100). The cleavage parallel to (010) is perfect. F. Rinne studied the corrosion figures; and also the X-radiograms. According to A. des Cloizeaux, the optic angles vary from $0^\circ-92^\circ$, usually $2E=52^\circ$ for the red ray, and 53° for the blue ray. P. Gaubert gave $2V=31^\circ 22'$. E. Artini found $2E=81^\circ 14'-94^\circ 27'$ in yellow light, and $103^\circ 50'$ in white light at 150° . O. Tietze gave $2E=51^\circ 49'$. F. Rinne, A. des Cloizeaux, E. Mallard, W. Klein, and G. B. Negri, measured the influence of temp. on the optic angles and the planes of the optic axes. E. Mallard found that raising the temp. to 150° changes the axial angles and plane, but the original condition is restored when the crystals regain their water; but if heated to 180° the sections become opaque, and the change is permanent. F. Rinne said that the various changes which occur are due to the loss of water; the high temp. form is called *metaheulandite*. The sp. gr. of heulandite is between 2.17 and 2.22; V. Goldschmidt found a sample of sp. gr. 2.202; and E. Billows, one, 2.17. F. Cornu has drawn attention to the quartz inclusions sometimes found in heulandite vitiating these determinations. P. Gaubert measured the sp. gr. of the mineral. After being heated to different temp. the hardness is between $3\frac{1}{2}$ and 4. The action of heat on heulandite is indicated above. C. Doelter obtained a pyroxenic mineral, anorthite, and a glassy matrix by slowly cooling molten heulandite. P. E. W. Oeberg gave for the sp. ht. of heulandite 0.2682. O. Mulert found the heat of soln. in dil. hydrofluoric acid to be 0.5501 Cal. per gram; and he calculated the heat of formation to be $\text{CaO} + \text{Al}_2\text{O}_3 + 6\text{SiO}_2 + \text{Aq.} = \text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot \text{cryst.} + 59.44 \text{ Cals.}$, or 0.141 Cal. per gram. R. Brauns, and F. Rinne have discussed the optical anomalies. According to A. Michel-Lévy and A. Lacroix, the indices of refraction are $\alpha=1.498$, $\beta=1.499$, and $\gamma=1.505$; P. Gaubert obtained $\alpha=1.4996-1.4998$; $\beta=1.5002-1.5008$, and $\gamma=1.5069-1.5070$. C. S. Ross and E. V. Shannon gave $\alpha=1.482$; $\beta=1.485$; and $\gamma=1.489$. P. Gaubert measured the change in the indices of refraction on heating to 200° ; α changed from 1.5004-1.4651; β , from 1.5015-1.4651; and γ , from 1.5078-1.4747. The birefringence is low; A. Michel-Lévy and A. Lacroix gave $\gamma-\alpha=0.0066$. The optical character is positive. O. Weigel studied the electrical conductivity of heulandite.

According to P. Gaubert,¹³⁹ the coloration of heulandite by coloured liquids is due to the adsorption of the coloured liquid itself. F. W. Clarke found that powdered and moistened heulandite reacts feebly alkaline to phenolphthalein; and G. A. Kennigott, alkaline to litmus. G. Steiger, S. Hillebrand, and C. Doelter found that heulandite is perceptibly soluble in water; and the solubility in carbonated water or in soln. of sodium carbonate was found by C. Doelter to be greater. J. Lemberg digested heulandite with soln. of sodium and potassium chlorides for about a week; the lime was displaced by the alkali, forming respectively *sodium-heulandite*, and *potassium-heulandite*. He also studied the action of soln. of sodium silicate, borate, and phosphate. F. W. Clarke and G. Steiger heated heulandite with ammonium chloride in sealed tubes at 350° , and obtained an *ammonium-heulandite*. When heulandite is digested with hot hydrochloric acid, a granular to a gelatinous silicic acid may be formed; with conc. acid, E. Löwenstein obtained

finely powdered silicic acid. S. Hillebrand said that the air-dried acid is coloured pale blue by methylene-blue. F. Rinne, and F. Cornu also studied the action of acids on heulandite.

H. J. Brooke¹⁴⁰ found a zeolite mineral at Strontain, Scotland, and named it **brewsterite**—after D. Brewster. It has been found in a number of other localities. A. Breithaupt called it *diagonite*. Analyses were reported by A. Connell, T. Thomson, F. Rinne, and J. W. Mallet. C. F. Rammelsberg studied the relation of brewsterite to heulandite and to epistilbite and finally represented it by the formula $R_2Al_4Si_{11}O_{30} \cdot 10H_2O$; and F. Rinne gave $R_2Al_4Si_{12}O_{32} \cdot 11H_2O$, where R represented (Sr, Ba, Ca, Na, K). C. Hintze gave a somewhat similar formula; and P. Groth gave $(Sr, Ba)Al_2Si_4O_{16} \cdot 5H_2O$; that is, **pentahydrated barium (and strontium) dialuminium dimesotrisilicate**, $BaAl_2(Si_3O_8)_2 \cdot 5H_2O$, and $SrAl_2(Si_3O_8)_2 \cdot 5H_2O$. F. W. Clarke represented it by

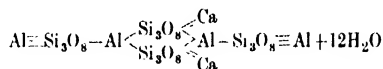

analogous with the formula for heulandite. It may possibly be a solid soln. of barium, strontium, calcium, and alkali salts. G. Tschermak considered it to be a solid soln. of two type silicates as in the case of heulandite.

The colour of brewsterite is grey, green, yellow, or brown. The crystals were measured by W. Haidinger, J. W. Mallet, W. H. Miller, etc. H. J. Brooke's data show that the prismatic crystals are monoclinic, with the axial ratios $a:b:c = 0.40482:1:0.42042$, and $\beta = 86^\circ 20'$. The cleavage parallel to (010) is perfect, and traces of cleavage are found parallel to (100). A. des Cloizeaux gave for the optic axial angle $2E = 94^\circ$ for the red ray, and 93° for the blue ray; A. Lacroix and A. Michel-Lévy gave $2V = 65^\circ$. A. des Cloizeaux found that raising the temp. from $8.8^\circ - 105.5^\circ$, altered $2E$ from $93^\circ 43' - 95^\circ 26'$. W. Klein, and F. Rinne made observations analogous with those obtained with heulandite. The sp. gr. is 2.1-2.5; and the hardness 5-5½. A. Damour reported that brewsterite loses 1.65 per cent. of water when exposed to dried air at ordinary temp. for a month. At 100° , 0.2 per cent. was lost in 2 hrs.; at 130° , 7 per cent. was lost, and all but 2.7 per cent. regained by exposure to ordinary air for 48 hrs. At 190° , the loss was 8.2 per cent., and all was regained after 48 hrs.' exposure to ordinary air; at 270° , 10 per cent. was lost, and all but 1.2 per cent. was regained after 8 days' exposure. At a dull red-heat the loss was 12.8 per cent., and, at a bright red-heat, 13.3 per cent. O. Weigel showed that the loss of water appears to be a continuous process—*vide* heulandite. A. Lacroix and A. Michel-Lévy gave for the mean index of refraction 1.45, and for the birefringence $\gamma - \alpha = 0.012$. A. Damour found the crystals to be pyroelectric. Brewsterite is decomposed by acids with the separation of granular silicic acid.

A. Cronstedt¹⁴¹ made references to *zeolites crystalli ad centrum tendentes* and *zeolites lummellaris*; and J. G. Wallerius, C. A. S. Hofmann, and J. C. F. Meyer regarded the latter as a foliated zeolite. A. G. Werner described four members of the zeolites and called them *Mehlzeolith* or *mealy zeolite*; *Faserzeolith* or *fibrous zeolite*; *Strahlzeolith* or *radiated zeolite*; and *Blatterzeolith* or *foliated zeolite*. J. C. Delamétherie called radiated zeolite, *zeolite nacrée* or *stilbite*; and R. J. Haüy regarded this zeolite as the type member of a species which he called **stilbite**—from $\sigma\tau\iota\lambda\beta\eta$, lustre—and foliated zeolite was considered to be a variety which he called *stilbite anamorphe*. A. Breithaupt supposed radiated and foliated zeolite to be distinct species, and called the former *desmine*—from $\delta\epsilon\sigma\mu\eta$, a bundle—and the latter *euzolite*. H. J. Brooke followed R. J. Haüy and called radiated zeolite stilbite, and foliated zeolite, heulandite—after H. Heuland—in this H. J. Brooke has been followed by the French and British mineralogists; the Germans call H. J. Brooke's stilbite, *desmine*; and sometimes they call heulandite, *stilbite*.

F. S. Beudant studied two varieties of stilbite which he designated *hypostilbite* and *sphaerostilbite*—the hypodesmine and sphaerodesmine of A. Breithaupt. These varieties were discussed by E. F. Glocker, J. F. L. Hausmann, A. des Cloizeaux, and S. Haughton. J. D. Dana regarded hypostilbite as a separate species, but J. D. Dana later included it with stilbite with a rather low percentage of silica. L. Liebener and J. Vorhauser, and F. Bukeisen described a mineral from Pufferloch, Tyrol, which he called *pufferite*. G. A. Kenngott regarded it as a stilbite. J. W. Mallot regarded laumontites from Skye, and Bombay as hypostilbites. G. vom Rath called crystals of a mineral lining cavities in the granite of San Piero, Elba, *foresite*—after G. F. Forresi. It was analyzed by A. d'Achiardi, and F. Sansoni; and these analyses were recalculated by C. F. Rammelsberg. A. des Cloizeaux showing that it is a variety of stilbite. The *syhedrite* of C. U. Shepard is stilbite. V. Rosicky and S. J. Flügge described a mineral which they called *epidamine*. Its chemical composition is near that of stilbite, $3\text{Ca}(\text{Na},\text{K})_2\text{Al}_2\text{Si}_6\text{O}_{18}\cdot 20\text{H}_2\text{O}$; it furnishes rhombic crystals of sp. gr. 2.16.

The oldest analyses of stilbite are by W. Hisinger,¹⁴² J. N. Fuchs and C. G. Retzius; numerous others have since been made. C. F. Rammelsberg¹⁴³ deduced the formula $\text{CaAl}_2\text{Si}_6\text{O}_{16}\cdot 6\text{H}_2\text{O}$, and assumed that this silicate was associated with $\text{Na}_2\text{Al}_2\text{Si}_6\text{O}_{16}\cdot 6\text{H}_2\text{O}$. This makes stilbite **hexahydrated calcium dialuminium dimesotrisilicate**, $\text{CaAl}_2(\text{Si}_3\text{O}_8)_2\cdot 6\text{H}_2\text{O}$. W. Fresenius postulated that stilbite is a mixture of two silicates. C. Doelter inferred from his observation on the formation of anorthite during the cooling of molten stilbite, and A. Damour's observations that two mols of combined water are present, that stilbite contains two mols of silicic acid in solid soln., viz. $\text{CaAl}_2\text{Si}_6\text{O}_{12}\cdot 2\text{H}_2\text{SiO}_3\cdot 4\text{H}_2\text{O}$. P. Groth used C. F. Rammelsberg's formula, $(\text{Ca},\text{Na}_2,\text{K}_2)\text{Al}_2\text{Si}_6\text{O}_{16}\cdot 6\text{H}_2\text{O}$, but assumed that in some cases another silicate, $\text{CaAl}_2\text{Si}_2\text{O}_8\cdot 3\text{H}_2\text{O}$, is present. G. Tschermak first gave $\text{H}_2\text{CaAl}_2\text{Si}_6\text{O}_{18}\cdot 4\text{H}_2\text{O}$; later, he added another mol. of water; and later still, he assumed that the stilbites are really associations of four different calcium aluminium silicates. F. W. Clarke gave $\text{CaAl}_6(\text{Si}_3\text{O}_8)_6\cdot 18\text{H}_2\text{O}$, and later, he gave :

E. Manasse used a graphic formula in which it was assumed that stilbite is a mixed orthosilicate and mesotrisilicate. C. Hersch also set up a constitutional formula for this substance.

A. Damour¹⁴⁴ found that stilbite loses 1.3 per cent. of water at 100° ; 13 per cent. between 100° and 150° , and all but 3 per cent. of the lost water is regained by 5 days' exposure to ordinary air; at 170° , 16 per cent. of water was lost, and rather less than half of this is regained by 15 days' exposure to ordinary air. C. Hersch found the loss of water after two hours' heating at different temp. amounted to :

Loss	104°	150°	210°	250°	290°	Red heat
	3.84	8.71	12.16	13.60	14.78	18.63 per cent.

F. Rinne's observations agreed better with A. Damour's than with C. Hersch's. E. Manasse concluded that the water given off below 250° is zeolitic water, and that given off above that temp. is constitutional water. F. Zambonini measured the loss of water in dry and moist air suffered by stilbite with 18.61 per cent. of water; and found for dry air :

Loss	112°	175°	210°	265°	328°	385°	440°
	7.88	11.51	13.56	14.68	15.66	15.97	17.56 per cent.

and he inferred that the dehydration process is greatly dependent on the humidity of the air, because for moist air he found :

Loss	118°	173°	215°	260°	310°	380°
	3.71	9.69	12.59	13.85	14.65	15.75 per cent.

E. Löwenstein found that when in equilibrium with water vap. at a partial press. p mm., stilbite had lost the following proportions of water at 25° :

p	21.58	19.60	17.63	13.45	8.52	4.41	1.75	0.56	0.18 mm
Loss	0.11	0.20	0.32	0.43	0.63	0.92	1.32	1.98	4.21 per cent.

Similar measurements were made with calcium-, potassium-, and ammonium-stilbites. A. Beutell and K. Blaschke also measured the rehydration of stilbite dehydrated at different temp. and inferred that the breaks in the curve indicate that 14 hydrates are formed.

Stilbite occurs in cavities in amygdaloidal, basaltic, and other rocks. The high degree of hydration of the mineral favours the view that it is not a high temp. product. It is apparently being formed by the action of the thermal waters at Olette on the granite. E. Manasse discussed its formation from orthoclase at San Piero. E. Baur and F. Becke noted the formation of a stilbitic substance when a mixture of silica, alumina, lime, alkali hydroxide, and water is heated for 12-16 hrs. at 350°. E. Tischler found that when a mixture of 96 parts of kaolinite, 80 of silica, and 20 of lime is repeatedly exposed to the action of steam, after grinding, a silicate of the composition $\text{CaAl}_2\text{Si}_6\text{O}_{18} \cdot 6\text{H}_2\text{O}$ is formed, and the crystals are sometimes found in sand-lime bricks.

The crystals of stilbite are often grouped in nearly parallel positions, forming sheaf-like aggregates; in divergent or radiated forms sometimes spherulitic; in thin lamellar prisms; and pseudo-rhombic pyramids; the colour is white, but may be tinged grey, yellow, brown, or red. R. J. Haüy¹⁴⁵ described the crystals as rhombic pyramids; but A. Breithaupt showed that like harmotome they belong to the monoclinic system and that the pseudo-rhombic form is produced by cruciform twinning. A. von Lasaulx found the axial ratios of the monoclinic crystals to be $a:b:c=0.76227:1:1.19401$ and $\beta=50^\circ 49\frac{3}{4}'$. G. Tschermak gave $a:b:c=0.4628:1:0.3811$, and $\beta=89^\circ 30'$. According to L. Langemann, the crystals are composed of triclinic individuals; and F. Rinne showed that when heated, the mol. structure becomes like that of a rhombic crystal. The crystals were studied by B. Jazek, and J. Königsberger. The crystals are always twinned, usually in thin tabular crystals parallel to (010), or else in cruciform penetration twins about the plane (001). The cleavage parallel to (010) is perfect. L. Langemann studied the corrosion figures which are best produced with hydrofluoric acid. A. Michel-Lévy and A. Lacroix found the optic axial angle $2V=33^\circ$; A. von Lasaulx, $2V=52^\circ-53^\circ$ in blue light; and A. des Cloizeaux, $2V=51^\circ 10'$ for red light and 52° for blue light. He also observed a small increase when the temp. is raised to 75° . The sp. gr. ranges from 2.094-2.205; and the hardness from $3\frac{1}{2}$ -4. J. Joly found the sp. ht. to be 0.2621. The action of heat has been discussed above. C. Doelter found that when melted and slowly cooled, stilbite furnishes clusters of acicular crystals of a pyroxene-like mineral, and often anorthite in a glass-like matrix. The index of refraction is low; A. Michel-Lévy and A. Lacroix gave $\alpha=1.494$, $\beta=1.498$, and $\gamma=1.500$. The birefringence is low. $\gamma-\alpha=0.0093$. J. Königsberger and W. J. Müller found the indices of refraction to be $\alpha=1.493$, $\beta=1.501$, and $\gamma=1.504$; and after treatment with a 25 per cent. soln. of potassium chloride, $\alpha=1.478$, $\beta=1.481$, and $\gamma=1.483$. W. W. Coblentz found the ultra-red transmission spectrum gave all the water-bands superposed; but no important bands peculiar to the mineral itself. O. Weigel studied the electrical conductivity of stilbite.

G. A. Kenngott¹⁴⁶ found that the moist powder reacts alkaline to litmus: F. W. Clarke and G. Steiger confirmed this observation, and found that water extracts a little alkali from the mineral at 70° . J. Lemberg found that there is an exchange of bases when stilbite is treated with soln. of potassium or sodium chloride, forming respectively *potassium-stilbite* and *sodium-stilbite*; and with a soln. of barium chloride all the calcium is displaced by barium, forming *barium-stilbite*. F. W. Clarke and G. Steiger heated stilbite and ammonium chloride in a sealed tube and obtained a complex ammonia-derivative. J. Königsberger and W. J. Müller, A. Beutell and K. Blasche, R. Gans, H. Eichhorn, and I. Zoch studied the action of soln. of ammonium chloride on stilbite and concluded that an *ammonium-stilbite* is formed. The transformations of stilbite in nature into albite, orthoclase, sand quartz, were studied by M. F. Heddle, J. R. Blum, and C. R. van Hise.

Hydrochloric acid decomposes the mineral with the separation of granular and gelatinous silicic acid. F. Rinne heated the silica-gel from stilbite and obtained a pseudomorph of silica after stilbite.

In 1826, A. Breithaupt¹⁴⁷ described a *neue Species der Zeolithordnung* from Iceland and the Farøe Islands which he named *monophane*—*μονοφάνης*, appearance—in allusion to the lustre of the fractured surface. In a priority claim, G. Rose pointed out that he had named the same mineral *epistilbite* in two mineral collections. W. S. von Waltershausen named a specimen from Bogarfjord, Iceland, *parastilbite*; and F. Hesseberg refers to a specimen from Santorin, named *reissite*—after W. Reiss. C. A. Tenne identified parastilbite, and O. Luedcke, *reissite*, with epistilbite.

A number of analyses has been reported, and from these, C. F. Rammeisberg¹⁴⁸ computed the formula $(\text{Ca}, \text{Na}_2)\text{Al}_2\text{Si}_6\text{O}_{16} \cdot 5\text{H}_2\text{O}$; or $\text{CaAl}_2\text{Si}_6\text{O}_{16} \cdot 5\text{H}_2\text{O}$, making epistilbite into **pentahydrated calcium dialuminium dimesotrisilicate**, $\text{CaAl}_2(\text{Si}_3\text{O}_8)_2 \cdot 5\text{H}_2\text{O}$. C. Bodewig, and C. Hintze gave $\text{H}_3\text{CaAl}_2\text{Si}_6\text{O}_{18} \cdot 3\text{H}_2\text{O}$; G. Tschermak, $\text{CaAl}_2\text{Si}_6\text{O}_{16} \cdot 5\text{H}_2\text{O}$; V. Rosicky and S. J. Thuggitt, $3\text{Ca}(\text{K}, \text{Na})_2\text{Al}_2\text{Si}_6\text{O}_{16} \cdot 20\text{H}_2\text{O}$; P. Jannasch, $\text{H}_2\text{CaAl}_2\text{Si}_6\text{O}_{17} \cdot 4\text{H}_2\text{O}$; F. Rinne, $\text{CaAl}_2\text{Si}_6\text{O}_{16} \cdot 5\frac{1}{2}\text{H}_2\text{O}$; and P. Groth, $\text{H}_2\text{Ca}_2\text{Al}_4(\text{SiO}_3)_{11} \cdot 7\text{H}_2\text{O}$. F. W. Clarke regarded heulandite (*g.n.*) and epistilbite as dimorphous forms of one silicate. F. A. Quenstedt, C. A. Tenne, P. Groth, and F. Rinne emphasized the relationship between epistilbite and heulandite. The second approximation to the formula is therefore largely dependent on which view is taken of the combined water. The amount of water in the reported analysis ranges from 12.52 to 15.68 per cent. V. Goldschmidt gave 15.5 per cent. C. Bodewig found samples containing 15.40 and 15.15 per cent. of water which retained 14.72 per cent. when dried over calcium chloride. P. Jannasch found that when epistilbite is confined over concentrated sulphuric acid it lost 1.04 and 1.97 per cent. respectively in 5 and 48 hrs.; over phosphorus pentoxide, it lost in weight 1.03 and 2.14 per cent. respectively in 3 and 48 hrs.; over calcium chloride, it lost 0.54 per cent. in 5 hrs.; and over dry sand, 0.10 per cent. in 5 hrs. F. Zambonini found that when heated in a stream of moist air, epistilbite with 15.11 per cent. of water lost at:

	120°	172°	210°	248°	308°	377°	455°
Loss .	2.06	4.70	7.31	10.33	12.69	13.27	14.09 per cent.

He concluded that epistilbite contains neither water of crystallization nor constitutional water; the water is adsorbed as zeolitic water.

Epistilbite occurs associated with stilbite in various localities, in isolated crystals, or in tufts or spherules with an internally radiated structure. The colour is white, may be with a reddish tinge. G. Rose¹⁴⁹ supposed the crystals to be rhombic, but A. des Cloizeaux, and C. A. Tenne found them to be monoclinic; and the latter from G. Rose's measurements, calculated the axial ratios $a:b:c=0.50430:1:0.58006$, and $\beta=54^\circ 53'$. Measurements were made by O. Luedcke, C. O. Trechmann, C. Hintze, and P. Jannasch. A. Levy emphasized the similarity between the crystals of heulandite and epistilbite. The twinning parallel to the (100) and (110) planes is common; there are also cruciform penetration twins. The cleavage parallel to (010) is perfect. The optic axial angle is large. A. des Cloizeaux gave $2E=67^\circ-77^\circ$ for the red ray, and $79^\circ-83^\circ$ for the blue ray. B. Mauritz gave $2E=70^\circ$. For the Li-, Na-, and Tl-rays, C. A. Tenne found respectively $2E=73^\circ 30'$, $75^\circ 35'$, and $76^\circ 40'$; L. Henniges, $2E=69^\circ 12'$, $70^\circ 45'$, and $71^\circ 55'$. S. G. Gordon gave $2E=40^\circ$ nearly. Raising the temp. from $12^\circ-121^\circ$, was found by A. des Cloizeaux to raise $2E$ from $70^\circ 25'-74^\circ 56'$. F. Rinne showed that when the temp. of the monoclinic twins is raised, the crystals become rhombic; if these crystals be exposed to air, the expelled water is readsorbed, and the original optical characters are resumed. This does not occur if the crystals are embedded in Canada balsam. The sp. gr. of epistilbite is near 2.25, and the hardness over 4. The index of refraction found by A. des Cloizeaux

is $\gamma=1.51$ for the red ray; A. Lacroix gave $\alpha=1.512$ and $\gamma=1.502$ for Na-light. S. G. Gordon gave $\alpha=1.435$, $\beta=1.495$, and $\gamma=1.500$, and $\gamma-\alpha=0.015$. A. Michel-Lévy and A. Lacroix found the birefringence is low, $\gamma-\alpha=0.010$. V. Rošický and S. J. Thugutt gave $\gamma-\alpha=0.015$, and $\beta-\alpha=0.010$. The optical character is negative. Epistilbite is almost completely decomposed by conc. hydrochloric acid with the separation of granular silicic acid.

A group of minerals called **scapolites** is analogous to the group of feldspars in that they form a series with a gradual variation in composition between two end-members which G. Tschermak,¹⁵⁰ in his memoir *Die Skapolithreihe*, regarded as *meionite*, $\text{Ca}_4\text{Al}_6\text{Si}_6\text{O}_{26}$, or *Me*, and *marialite*, $\text{Na}_4\text{Al}_3\text{Si}_9\text{O}_{24}\text{Cl}$, or *Ma*. There is no sharp line of demarcation in the series, but, as with the plagioclase feldspars, certain members of the series have received special names—wernerite, mizzonite, etc. His three subdivisions are:

1. *Me* to *Me*₂*Ma*₁ or 100-67 per cent. meionite, or 40-48 per cent. silica. *E.g.* meionite, and wernerite (paranthine, nuttallite, glaucolite, stroganovite, algerite, and wilsonite).

2. *Me*₂*Ma*₁ to *Me*₁*Ma*₂, or 67-34 per cent. meionite, or 48-56 per cent. silica. *E.g.* mizzonite, and scapolite (wernite, scapolite, ekebergite, porcelain spar, passauite, paralogite, and althysianite).

3. *Me*₁*Ma*₂ to *Ma*, or meionite 34-0 per cent., or silica 56-64 per cent. *E.g.* marialite, and riponite (dipyre, prehnitoid, and coeserite).

The following are given by J. D. Dana:

<i>Me</i> to <i>Me</i> ₂ <i>Ma</i> ₁	Meionite
<i>Me</i> ₂ <i>Ma</i> ₁ to <i>Me</i> ₁ <i>Ma</i> ₂	Wernerite
<i>Me</i> ₁ <i>Ma</i> ₂ to <i>Me</i> ₁ <i>Ma</i> ₃	Mizzonite
<i>Me</i> ₁ <i>Ma</i> ₃ to <i>Ma</i>	Marialite

The scapolites all crystallize in the tetragonal system, they have nearly the same optic axial ratio, and they exhibit pyramidal hemihedrism. A. Lacroix also showed that the birefringence of the members of the series decreases in passing from meionite to marialite. The subject has also been discussed by C. F. Rammelsberg, G. vom Rath, E. T. Wolff, A. Himmelbauer, A. N. Winchell, L. M. Borgström, N. Sundius, R. Brauns, H. Eekermann, and V. M. Goldschmidt.

The first member of the series was also the first scapolite to be definitely recognized. J. B. L. Romé de l'Isle¹⁵¹ described some crystals he obtained from geodes in the limestone at Monte Somma, Vesuvius, as *hyacinthe blanche de la Somma*; R. J. Haüy called the mineral **meionite**—from *μείων*, less—because the pyramid of the crystals was less acute than is the case with vesuvianite (idocrase), harmotome, or zircon. The last member of the series was also the last to be recognized. It was obtained from the volcanic rock called *piperno*, occurring at Pianura near Naples. G. vom Rath called it **marialite**—after Marie, the daughter of G. Rose.

It has been suggested that the *white schorl-spar* obtained by A. Cronstedt¹⁵² from Pargas, Finland, was a scapolite, although he regarded it as a lamellar pyroxene. M. F. R. d'Andrada applied the terms **wernerite**—after A. G. Werner—and **scapolite**—from *σκάπτος*, a glossed form of *κλάδος*, a branch—to specimens from Norway. R. J. Haüy at first used the same terms for what he assumed to be distinct minerals, but later he, and J. A. H. Lucas arbitrarily proposed to call scapolite *paranthine*—from *παρὰνθῆω*, to decay—in allusion to the inclination of the mineral to alter, and lose its lustre. J. A. Monteiro objected to the change, and showed that chemically and crystallographically, wernerite and scapolite were the same species, and he recommended applying the term wernerite to the species. P. C. Abildgaard called scapolite *rapidolite* (not *rapidolite*)—from *ῥαπίς*, a rod. A. G. Werner referred to a scaly grey variety of wernerite as *arctite*; J. J. Berzelius called wernerite *ekebergite*—after A. G. Ekeberg; A. G. Ekeberg called it *sodolite*; W. H. Wollaston, *natrolite*; C. F. Schumacher, *fuscite*—from *fuscus*, dusky; and C. von Leonhard, *gabbroite*—from its resemblance to gabbro—*vide* nephelite. C. C. von Leonhard regarded arctite, paranthine, scapolite, ekebergite, gabbroite, and fuscite as synonyms of wernerite; and believed meionite to be a variety of the same mineral. This was later shown to be the case by A. Breithaupt.

The bluish or greenish scapolite from the vicinity of Lake Baikal, Siberia, was called *glaucolite*—from *γλαυκός*, greenish-grey or sea-green—by Fischer von Waldheim, and

J. F. John, R. Hermann, and G. Rose showed that this glaucolite is a scapolite; but W. C. Brögger has shown that the so-called glaucolites from Norway and Lake Baikal are really scapolites (*q.v.*). A pink scapolite from Bolton, Mass., is similar to glaucolite. A glassy scapolite from Galway, Ontario, was called *ontariolite* by C. U. Shepard. H. J. Brooke called a smoky brown variety from Bolton, Mass., *nuttalite*—after T. Nuttall—A. Breithaupt showed that it is a scapolite. J. D. and S. L. Dana found a grey, green, and red variety at Chelmsford, Mass., and called it *chelmsfordite*. J. D. Dana showed that it is a scapolite. J. N. von Encls referred to a *Porzellanspath* from Obernzell, near Passau, which was later called *porzellanite* by F. von Kobell, and *passauite* by C. F. Naumann. A. des Cloizeaux showed that these three minerals are scapolites. R. Hermann named a mineral from Sljudjanka, *stroganovite*—after Count Stroganowit—and it was shown by N. von Kokscharoff to be scapolite. T. S. Hunt described a mineral from Franklin, New Jersey, and named it *algerite*—after M. Alger. It was shown by J. D. Dana, and J. D. Whitney to be a scapolite. P. C. Weibye described a mineral from Arendal which he called *athornastite*—from *athéparos*, neglected—and which was shown by J. F. L. Hausmann, G. A. Kenngott, and C. F. Rammelsberg to be a scapolite. The *wilsonite* of T. S. Hunt from Bathurst, Canada, was considered by E. J. Chapman to be a scapolite—*vide nua*. The *paralogite* of N. Nordenskjöld, obtained near Lake Baikal, was shown by N. von Kokscharoff to be a scapolite.

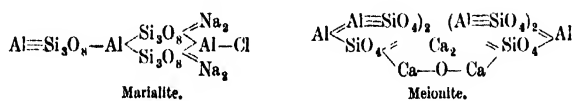

The *schorl blancheâtre de Mauléon* (Pyrenees) discovered by Gillet-Laumont in 1780, was called *leucolite*—from *leukós*, white—by J. C. Delaméthérie; *dipyre*—from *dis*, twice, and *πῦρ*, fire, in allusion to the two effects of heat, *viz.* fusion and thermoluminescence, while H. Steffens called it *Schmelzstein*. J. F. L. Hausmann showed that dipyre was identical with common scapolite. J. F. W. de Charpentier observed two kinds of dipyre; one of these had a dark colour and was infusible at the fusion temp. of ordinary dipyre; and he called it *cousserante*—from Cousserans or Conserans (Latin *Conseranni*), an old name for Ariège—where it occurs as a black schist. The work of A. des Cloizeaux, P. A. Dufrénoy, G. A. Kenngott, and F. Zirkel showed that coussite is a more or less altered form of dipyre. W. Salomon has recounted the history of dipyre and coussite. C. W. Blomstrand described a mineral from the vicinity of Solberg, Sweden, which he called *prehnitoid* owing to its resemblance to prehnite. G. A. Kenngott, and A. des Cloizeaux showed that it is a variety of scapolite. The *riponite* of G. Tschermak is a scapolite from Ripon, Canada. A. Seacchi called the crystals of a variety of scapolite he found in cavities in the trachyte of Monte Somma, Vesuvius, *mizzonite* (*mizonite*, or *meizonite*) from *μείζων*, greater—because the axis of the prism is a little longer than that of meionite—N. Nordenskjöld found a water-free scapolite or scapolite at Ersby, Finland, which was harder than ordinary scapolite, and called by F. S. Beudant *scodzerose*; A. E. Nordenskjöld called it *ersbyite*. M. L. Frankenhelm regarded ersbyite as a variety of labradorite, and C. F. Rammelsberg called it *Kalk-labrador*. A. des Cloizeaux, G. vom Rath, and E. T. Wolff showed that ersbyite is a variety of scapolite. N. Nordenskjöld's *pseudoscapolite* from Simonsby, Finland, was a mixture of scapolite and augite.

The oldest analysis of scapolite is that of a dipyre by L. N. Vauquelin; 153 more recent analyses of dipyre were made by A. Damour, V. Goldschmidt, A. des Cloizeaux, W. Salomon, A. E. Delesse, G. vom Rath, F. D. Adams, A. Lacroix, and A. Michel-Lévy; of meionite, by L. Gmelin, F. Stromeyer, E. T. Wolff, A. Damour, and G. vom Rath; of wernerite, by M. F. Heddle, P. C. Weibye, V. Hartvall, J. F. John, P. L. Simon, F. J. Wink, P. Schafhautl, L. Sipöcz, F. Becke, G. vom Rath, F. von Kobell, C. F. Rammelsberg, F. A. Genth, and A. Lacroix; of scapolite, by E. T. Wolff, G. vom Rath, F. J. Wink, T. Tschernytscheff, A. Laugier, J. J. Berzelius, L. M. Berg, N. Nordenskjöld, L. Stadtmüller, R. Hermann, O. O. Baklund, H. Wurtz, T. S. Hunt, and A. Himmelbauer; of ekebergite, by E. T. Wolff, A. G. Ekeberg, and V. Hartvall; of glaucolite, by C. Bergemann, M. Giwartowsky, and G. vom Rath; of paralogite, by N. Nordenskjöld, E. T. Wolff, and C. F. Rammelsberg; of prehnitoid, by C. W. Blomstrand; of porcelain spar, by J. N. Fuchs, and F. von Kobell; of nuttalite, by T. Thomson; of paranthite, by F. P. Dunnington; of algerite, by T. S. Hunt, and W. Crossley; of wilsonite, by T. S. Hunt, and C. F. Rammelsberg; of stroganovite, by R. Hermann; of riponite, by F. D. Adams; of cousserite, by A. des Cloizeaux, P. A. Dufrénoy, and B. Grandea; of mizzonite, by G. vom Rath; and of marialite, by G. vom Rath, and C. F. Rammelsberg. Analyses of samples with carbon dioxide were made by E. T. Wolff, G. vom Rath, R. Hermann, E. Neminar, L. Sipöcz, F. Becke, P. von Susschinsky, F. A. Genth, V. Goldschmidt, and J. D. Dana; of samples with chlorine, but without carbon dioxide, were made by C. F. Rammelsberg, F. D. Adams, J. Lemberg, V. Goldschmidt, H. Lenk, and

J. Eyer mann; of samples with chlorine and sulphur trioxide were made by L. Sipőcz, H. Wulf, R. Brauns, and N. Sundius; and of samples with chlorine, carbon dioxide, and sulphur trioxide were made by L. Sipőcz, and L. H. Borgström. R. Brauns called the scapolite containing the sulphate radicle *silvialite*—after Silvia Hillebrand.

C. F. Rammelsberg showed that the composition of the scapolites is very variable, due, in part, to the partial alteration of the mineral. J. N. von Fuchs, P. Schafhäutl, E. Neminar, L. Sipőcz, N. Sundius, F. Becke, and F. D. Adams established the presence of chlorine as a constituent of most scapolites, and, after showing that the proportion of sodium increases as that of chlorine increases, he devised the mixture hypothesis indicated above, and assumed that all the scapolites can be represented as mixtures containing the primary constituents *meionite*, $\text{Ca}_4\text{Al}_6\text{Si}_6\text{O}_{25}$; and *marialite*, $\text{Na}_4\text{Al}_3\text{Si}_6\text{O}_{24}\text{Cl}$. L. M. Borgström emphasized the part played by carbonate and sulphate as well as the chloride radicles, and he said that the composition of the scapolites can be explained as isomorphous mixtures of marialite or *chloromarialite*, $\text{Na}_3\text{Al}_3\text{Si}_6\text{O}_{24}\cdot\text{NaCl}$; *sulphatomarialite*, $\text{Na}_3\text{Al}_3\text{Si}_6\text{O}_{24}\cdot\text{Na}_2\text{SO}_4$; and *carbonatomarialite*, $\text{Na}_3\text{Al}_3\text{Si}_6\text{O}_{24}\cdot\text{Na}_2\text{CO}_3$; along with *sulphatomeionite*, $\text{Ca}_3\text{Al}_6\text{Si}_6\text{O}_{24}\cdot\text{CaSO}_4$, and *carbonatomeionite*, $\text{Ca}_3\text{Al}_6\text{Si}_6\text{O}_{24}\cdot\text{CaCO}_3$. In each of these cases, the nucleus of the marialites, so to speak, corresponds with three mols of $\text{NaAlSi}_3\text{O}_8$, and that of the meionites with three mols of $\text{CaAl}_2\text{Si}_2\text{O}_8$. The compound $\text{Ca}_4\text{Al}_6\text{Si}_6\text{O}_{25}$, or $3\text{CaAl}_2\text{Si}_2\text{O}_8\cdot\text{CaO}$, is regarded as *oxy-meionite*. E. T. Wherry found that the at. vol. hypothesis of isomorphism fits in well with the various replacements or substitutions in the scapolite group. C. F. Rammelsberg assumed the different scapolites to be addition compounds of a metasilicate, a complex metaorthosilicate, and a complex metasilicate and disilicate. G. A. Kenngott¹⁵⁴ calculated for meionite $\text{Ca}_7\text{Al}_{10}\text{Si}_{11}\text{O}_{44}$. P. Groth gave for meionite $\text{Ca}_4(\text{AlO})\text{Al}_2(\text{AlSi}_2\text{O}_3)_3$, **calcium oxytrialuminium tri-monaluminodisilicate**; and for marialite, $\text{Na}_4(\text{AlCl})\text{Al}_2(\text{Si}_3\text{O}_8)_3$, **calcium chlorotrialuminium mesotrisilicate**. He gave graphic formulæ for both these two compounds, and A. C. Brown also represented oxy-meionite by a graphic formula. A. Himmelbauer considered meionite to be a complex of $2\text{CaAl}_2\text{Si}_2\text{O}_8 + \text{Ca}_2\text{Al}_2\text{Si}_2\text{O}_9$; and marialite, a complex of $2\text{NaAlSi}_3\text{O}_8 + \text{Na}_2\text{AlSi}_3\text{O}_8\text{Cl}$. H. S. Washington regarded the scapolites as complexes of the acid $\text{H}_{10}\text{AlSi}_3\text{O}_{12}$; and A. Himmelbauer obtained a metasilicic acid by treating meionite with dil. hydrochloric acid, and from marialite, *marialitic acid*, $\text{H}_{10}\text{Si}_6\text{O}_{23}$. W. and D. Asch applied their cumbrous hexite-pentite hypothesis to the scapolites.

F. W. Clarke emphasized the parallelism of the feldspars and scapolites. He said: "Both groups of minerals are easily alterable, and both yield kaolinite as a final product of the change. Furthermore, both alter to muscovite, or to pinite, which is only an impure pseudomorphous mica." Crystallographically, kaolinite has close relations with the mica family as illustrated by the empirical and structural formulæ which he employed. F. W. Clarke gave:

where marialite is like sodalite, but with quadrivalent Si_3O_8 in place of quadrivalent SiO_4 ; and meionite is like anorthite, but with the bivalent $\text{Ca}\cdot\text{O}\cdot\text{Ca}$ -group in place of Ca^{++} .

The scapolites occur in the volcanic rocks such as the ejected masses on Monte Somma. They principally occur in crystalline schists, gneisses, amphibolites, and altered limestones. They occur in crystallized limestones as a direct result of contact action. They also appear to be formed as alteration products of plagioclase feldspars. This subject has been discussed by J. W. Judd,¹⁵⁵ A. Cathrein, A. Lacroix, H. Lenk, F. D. Adams and A. C. Lawson, F. Zirkel, W. Salomon, W. C. Brögger and H. H. Reusch, F. Becke, and A. E. Törnebohm.

L. Bourgeois¹⁵⁶ attempted to make meionite by fusing a mixture of its constituent oxides, but the product was anorthite; but he did obtain crystals of what was considered to be meionite by fusing a mixture of marble and a basaltic glass. K. B. Schmidt also prepared an artificial rock containing scapolite; and he obtained the same mineral from fused eclogite. C. Doelter fused epidote with calcium and sodium fluorides and recognized meionite in the products; he also observed meionite in a fused mixture of calcium oxide, silica, and alumina, and in a fused mixture of anorthite and sodium chloride. E. S. Shepherd and G. A. Rankin obtained crystals of meionite by heating a glass of that composition in contact with a soln. of sodium chloride in a bomb.

The scapolites occur in clear glassy or milk-white crystals; in crystal grains, and massive. Wernerite and mizzonite may be coloured white, with a grey, blue, green, or red tinge. The crystals belong to the tetragonal system and the different members have nearly the same axial ratio. N. von Kokscharoff¹⁵⁷ gave for meionite $a:c=1:0.43925$; G. Tschermak for wernerite, $1:0.4384$; N. von Kokscharoff for mizzonite, $1:0.44235$; and G. vom Rath for marialite, $1:0.4417$. Observations on the crystals of the scapolites were made by F. X. M. Zippe, A. Brezina, V. Goldschmidt, A. von Lasaulx, H. Fischer, etc. The crystals are characterized by pyramidal hemihedrism. The prismatic faces sometimes show vicinal prominences corresponding with the hemihedrism of the crystals. The corrosion figures also agree with the hemihedral character of the crystals. The cleavage parallel to (100) is perfect, and that parallel to (110) rather less so. Optical anomalies are rare, but are occasionally shown in the biaxial character of the interference figure, and a small angle between the optic axes.

The sp. gr. of many of the specimens analyzed were also determined. G. Tschermak calculated from the law of mixtures that the sp. gr. of the end-members is 2.815 for meionite, and 2.560 for marialite. The highest observed value is 2.737 for the meionite of Vesuvius, with its 12 per cent. of marialite. A. Himmelbauer, and N. Sundius have compiled sp. gr. tables of the scapolites from different localities. The mixture rule is in the main applicable, but there are disturbances due to the influence of potassium, the presence of sulphates and carbonates in place of chlorides, etc. The hardness is between 5 and 6. A. Brun found the m.p. of meionite to be 1138° – 1130° ; M. L. Fletcher, 1331° for meionite; and A. Himmelbauer, 1125° – 1238° for various scapolites, and 1088° – 1233° for marialite. J. Joly gave 0.2003 for the sp. ht. of wernerite. E. Jannettaz gave 0.845 for the sq. root of the ratio of the thermal conductivity in the direction of the base to that in the direction of the chief axis. A. Dannholm found the sp. ht. of scapolite. The indices of refraction are determined by the chemical composition and vary from $\omega=1.594$ – 1.5545 , and $\epsilon=1.557$ – 1.5417 respectively for meionite and marialite. There is some confusion in the data, for the effects of variation in the proportions of meionite and marialite are affected by the presence of sulphates and carbonates. Similar remarks apply to the birefringence. Scapolite is optically negative. Observations have been recorded by H. Rosenbusch, A. Lacroix, L. M. Borgström, R. Brauns, P. Franco, A. Laitakari, N. Sundius, K. Zimanyi, O. O. Baklund, H. Preiswerk, etc. A. Himmelbauer gave for scapolites with different proportions of meionite, Me.

	4	31	32	54	55	72	85 per cent.

According to G. A. Kenngott,¹⁵⁸ powdered and moistened meionite reacts strongly alkaline to litmus. The chloriferous scapolites gave the reaction for chlorides when treated with silver nitrate. According to G. Tschermak, the scapolites with a high proportion of meionite—Me to Me_2Ma_1 —are completely or almost completely decomposed by hydrochloric acid; the Me_2Ma_1 to Me_1Ma_2 scapolites are incompletely decomposed; while the Me_1Ma_2 to Ma scapolites are not much affected by

the acid. The scapolites are very liable to change and particularly so towards the sodium or marialite end of the series. The introduction of water and carbon dioxide is a common change. By the substitution of potash, the mineral passes into pinite and potash-mica; with magnesia and potash, magnesia-mica is produced; with magnesia, steatite is formed; and with the acquisition of iron, epidote is produced. In some cases, a greenish chlorite is produced. By the loss of its bases, scapolite passes into kaolinite or china clay used in the manufacture of porcelain, etc. Hence, the name *porcelgin-spar* for the scapolite at Passau—*vide supra*. C. F. Rammelsberg, C. R. van Hise, C. W. von Gümbel, J. N. von Fuchs, G. Forchhammer, L. Knaffl, C. G. C. Bischof, V. Goldschmidt, G. vom Rath, etc., studied these transformations; and J. Lemberg, and H. Schneiderhöhn investigated the action of soln. of potassium hydroxide, carbonate, and chloride; and of soln. of sodium carbonate, chloride, and sulphate, at 215°–220°.

A zeolitic mineral from Andreasberg, Harz, seems to have attracted attention in the latter half of the eighteenth century, but it was not given any specific name. I. S. R. I. Eques a Born¹⁶⁹ described it as a *spatum calcarium*, but, added T. Bergman, the crystals are not calcareous but siliceous, and he referred to it as *figura hyacinthica*. J. Demeste referred to it as *hyacinthe blanche*; J. B. L. Romé de l'Isle, as *hyacinthe blanche cruciforme*; J. C. H. Heyer, and F. W. H. von Trebra, as *Kreuzkristalle*; A. G. Werner, D. L. G. Karsten, and L. A. Emmerling, as *Kreuzstein*, *Silex crucifer*, and *pierre de croix*; J. C. Delamétherie, as *andreasbergolite*, or *andrecolite*; R. Kirwan, *staurolite*; C. A. G. Napione, *ercinite*; and A. J. M. Brochant, as *pierre cruciforme*. R. J. Haüy's term **harmotome** has been adopted; it is from *ἄρμος*, joint; and *τέμνειν*, to cut—alluding to the fact that the pyramid made by the prismatic planes in the twinning position divides parallel to the plane that passes through the terminal edges. T. Thomas called some well-developed crystals from Strontian, Scotland, *morvenite*; but A. Damour and A. des Cloizeaux showed that morvenite is the same as harmotome. C. Stadtländer has revived the history of harmotome.

J. C. H. Heyer first analyzed harmotome in 1789, and found it contained 24 per cent. of baryta; A. H. L. Westrumb, in 1794, found 20 per cent. of baryta; H. M. Klaproth, in 1797, found 18 per cent. of baryta; and R. J. Haüy, quoting Q. M. Tassaert's analysis, gave 16 per cent. of baryta. To distinguish it from phillipsite, called *lime-harmotome*, harmotome proper was sometimes called baryta-harmotome. Numerous analyses¹⁶⁰ of harmotome have been made. C. F. Rammelsberg¹⁶¹ calculated from the analyses, $\text{BaAl}_2\text{Si}_5\text{O}_{14} \cdot 5\text{H}_2\text{O}$, naming harmotome **pentahydrated barium dialuminium mesopentasilicate**; C. F. Rammelsberg assumed that the corresponding isomorphous alkali salt, $\text{K}_2\text{Al}_2\text{Si}_5\text{O}_{14} \cdot 5\text{H}_2\text{O}$, is present. G. Stoklossa doubled C. F. Rammelsberg's formula. P. Groth assumed that harmotome is produced by the isomorphous association of two silicates; and G. Tschermak, four silicates. J. Buckmoser assumed that harmotome is a derivative of harmotomic acid, $\text{H}_8\text{Si}_5\text{O}_{14}$. F. W. Clarke, and C. Hersch used graphic symbolization. The former gave:

According to A. Damour, harmotome from Strontian loses 4.3 per cent. of water by six months' exposure to dry air; at 100° it loses 1.8 per cent.; between 100° and 150°, 9.9 per cent.; and between 150° and 190°, 13.5 per cent. After 24 hrs.' exposure to ordinary air, the lost water is resorbed. At a dull red-heat, 14.65 per cent. of water is lost, and the mineral is disaggregated. C. Hersch found that the following percentage losses attended the heating of the mineral to:

	100°	150°	203°	252°	295°	Red heat
Loss	2.74	5.74	9.23	10.67	12.42	15.29 per cent

W. Fresenius made some observations on this subject; and G. Stoklossa measured the resorption of water by harmotome, dehydrated at different temp. The breaks in the curve, he said, indicate eleven hydrates; and that the water is chemically united in the mol.

Harmotome occurs in basalt and similar eruptive rocks; in phonolyte; trachyte, and gneiss rocks; and in some metalliferous veins. It has not been recorded in barytiferous gangue. It is commonly associated with calcite and quartz. J. Lemberg assumed that it is like chabazite, and he found traces of baryta and strontia in chabazite. He assumed that harmotome is formed by the action of barytiferous waters on chabazite. Harmotome, however, has not been prepared artificially.

Harmotome occurs in various twinned forms coloured white or tinged grey, yellow, red, or brown. L. von Buch¹⁶² first described the crystals of harmotome in 1794. R. J. Haüy considered the fundamental form to be a tetragonal pyramid. A. Breithaupt assumed the crystals were triclinic. This was discussed by C. F. Rammelsberg, G. F. Naumann, and G. A. Kenngott. The morphological features of the twinned crystals were studied by F. Köhler, and A. des Cloizeaux investigated their optical properties, and assumed that the rhombic crystals have monoclinic symmetry. A. Gadolin explained the structure on the assumption that the individual members of the twinned system are monoclinic. This view was supported by A. des Cloizeaux, R. Brauns, E. Mallard, H. Baumhauer, etc. A. des Cloizeaux gave for the axial ratios of the monoclinic crystals $a:b:c = 0.70315:1:1.2310$, and $\beta = 55^\circ 10'$. G. Tschermak gave $a:b:c = 0.5053:1:0.3516$, and $\beta = 90^\circ$. The crystals occur in cruciform penetration twins united as simple or as double twins; the double twins may have the aspect of a square prism with a diagonal pyramid having feather-like striations from the median line. More complex twins—e.g. three double twins—are known. As in the case of phillipsite, L. Langemann assumed that the individuals are triclinic because they deviate optically from monoclinic crystals. F. Rinne showed that the optical characters which refer the crystals to the triclinic system are not changed by heat, though there is a movement of the axial plane, and an increase in the double refraction. The cleavage (010) is well marked, but the (001) less so. A. des Cloizeaux gave for the optic axial angles $2H_a = 86^\circ 31' 98'' 33'$; and $2V = 85^\circ 52'$ for red light. He also measured the change which occurs on raising the temp. The sp. gr. is 2.45–2.50; and the hardness 4–5. A. des Cloizeaux found $\beta = 1.516$ for the index of refraction with the red ray; and for Na-light. A. Michel-Lévy and A. Lacroix gave $\alpha = 1.503$, $\beta = 1.506$, and $\gamma = 1.508$.

G. A. Kenngott¹⁶³ found that the moistened powdered mineral reacts alkaline to litmus. Conc. hydrochloric acid attacks the mineral with the separation of pulverulent silicic acid; J. Bruckmoser obtained pseudomorphs of silica after harmotome, and the silicic acid has the composition $H_2Si_6O_{14}$, *harmotomic acid*. G. Friedel found that dehydrated harmotome absorbs ammonia so violently that it decrepitates. F. Grandjean found the vap. of iodine, bromine, mercury, calomel, cinnabar, and sulphur are absorbed by dehydrated harmotome, and he measured the corresponding changes in the optical properties. J. Lemberg found that only a little barium is displaced by six months' digestion with soln. of calcium sulphate and sodium chloride at 100° . He found that with a soln. of potassium chloride the barium is rapidly displaced, and a *potassium-harmotome* formed. By digesting the latter with a soln. of sodium chloride, a *sodium-harmotome* is produced.

A. Meister¹⁶⁴ analyzed the crystals of a dark grey mineral found near the Tatarka, Siberia. The mineral was called *didymolite*, or *didymolite*. Its composition corresponded with $2CaO.3Al_2O_3.9SiO_2$. A little ferric oxide may take the place of alumina; and a little magnesia, the place of lime. In view of the absence of any definite information of the mol. structure, a number of hypotheses could be suggested for its constitution, but this would be unprofitable until more evidence is available. The mineral belongs to the monoclinic system, and the axial ratios are $a:b:c = 0.6006:1:0.2867$, and $\beta = 106^\circ$. The sp. gr. is 2.71; the hardness 4½–5; the index of refraction $\beta = 1.5008$; the birefringence is negative, $\gamma - \alpha = 0.015$; and the optic axial angle $2V = 81^\circ 20'$. The mineral is not decomposed by acids other than hydrofluoric acid.

J. Morozewicz¹⁸⁵ found a zeolite in the diabase tuff on one of the Commanche Islands, and he called it *stellerite*—after W. Steller. Its analysis correspond with $\text{CaAl}_2\text{Si}_7\text{O}_{18} \cdot 7\text{H}_2\text{O}$, and F. W. Clarke represents it by the formula $\text{Al} : \text{Si}_3\text{O}_8 : \text{Al}(\text{Si}_2\text{O}_5)_2 : \text{Ca} : 7\text{H}_2\text{O}$. J. Morozewicz considers it to be a salt of the aluminosilicic acid, $\text{H}_2\text{Al}_2\text{Si}_n\text{O}_{2n+4}$. *Stellerite* occurs in rhombic crystals with axial ratios $a : b : c = 0.98 : 1 : 0.75$. G. Tschermak gave $0.49 : 1 : 0.40$, and $\beta = 90^\circ$. The cleavage parallel to (010) is complete; less complete parallel to (100). The optical axial angle $2V = 43.5^\circ$. The sp. gr. is 2.124 at 15° , and the hardness $3\frac{1}{2}$ –4. It loses 2 mols. of water at 125° , and 4 mols. at 200° . The water lost at 125° is regained on exposure to air. The index of refraction $\alpha = 1.484$, and $\gamma = 1.495$. *Pseudonatrolite* (q.v.) is considered by F. W. Clarke to be *stellerite*.

A. Lacroix¹⁸⁶ obtained a white, silky, fibrous mineral from cavities in the doleritic basalt of Gignat, Puy-de-Dôme, and named it *gonnardite*—after F. Gonnard. Its composition approximates $(\text{Ca}, \text{Na})_2\text{Al}_2\text{Si}_6\text{O}_{18} \cdot 5\frac{1}{2}\text{H}_2\text{O}$. It is probably rhombic. The sp. gr. is 2.246–2.260; and the hardness $4\frac{1}{2}$ –5. It is optically biaxial, acid positive. E. S. Larsen gave $2E = 83^\circ + 10^\circ$; $2V = 52^\circ \pm 6^\circ$; and the indices of refraction $\alpha = 1.514$, $\beta = 1.515$, and $\gamma = 1.520$.

A. S. Finkle¹⁸⁷ found slender white fibres of a mineral in the rhyolitic tuff at Du.kee, Oregon, and he named it *erionite*—from *ἑριον*, wool. Its composition approximates $\text{H}_2\text{CaK}_2\text{Na}_2\text{Al}_2\text{Si}_6\text{O}_{17} \cdot 8\text{H}_2\text{O}$. Its sp. gr. is 1.997. It is optically biaxial; and positive. The crystals belong to the rhombic system. E. S. Larsen gave for the indices of refraction $\alpha = 1.438$, and $\gamma = 1.452$. The birefringence is high. It readily dissolves in hydrochloric acid.

A. Cronstedt¹⁸⁸ referred to a mineral *Röt Magnesia*; C. A. G. Napione, to *manganèse rouge*; and R. J. Haüy, to *manganèse oxyde violet silicifère*. H. B. de Saussure also described the mineral, and L. Cordier showed that it was an *epidote manganésifère*. C. A. S. Hofmann called it *Piemontischer Braunstein*. The mineral from St. Marcel, Piedmont, was called *piemontite*, that is, **piemontite**, by G. A. Kennigott. Analyses of piemontite were made by E. Geffken, W. Eitel, B. Koto, V. Hartwall, A. Sobrero, H. St. C. Deville, C. F. Rammelsberg, H. Laspeyres, G. Flink, A. W. Tamm, L. J. Igelström, and N. Svensson. The composition corresponds with that of the epidotes with some manganese replacing aluminium, $\text{Ca}_2(\text{AlOH})(\text{Al}, \text{Fe})_2(\text{SiO}_4)_3$; presumably, the clinozoisite, $\text{Ca}_2(\text{AlOH})\text{Al}_2(\text{SiO}_4)_3$, is in solid soln. with the isomorphous *manganic-epidote*, $\text{Ca}_2(\text{AlOH})\text{Mn}_2(\text{SiO}_4)_3$, **calcium dimanganic aluminohydroxytriorthosilicate**. The general properties of piemontite resemble those of epidote, to which reference must be made. Piemontite does not occur so abundantly as epidote and zoisite; and it is mainly confined to crystalline schist. B. Koto found it to be quite common in the manganeseiferous schists of Japan. N. Yamaski, and G. H. Williams found it associated with rhyolite.

Piedmontite is reddish-brown or black. H. Laspeyres gave for the axial ratios of the monoclinic crystals $a : b : c = 1.6100 : 1 : 1.8326$, and $\beta = 64^\circ 39'$; G. Flink gave $1.5807 : 1 : 1.8657$, and $\beta = 64^\circ 36'$. The cleavage and twinning resemble those of epidote. A. des Cloizeaux gave for the optic axial angles, $2H_a = 82^\circ$ – 90° , and $2H_0 = 121^\circ$ – 126° . A. Breithaupt gave for the sp. gr. 3.404–3.518; and the hardness $6\frac{1}{2}$. The pleochroism is pronounced and characteristic. It has been investigated by H. Laspeyres, A. Lacroix, and B. Koto—*vide* epidote.

§ 45. Beryllium-Aluminium Silicates

R. Riecke¹ studied the fusibility of mixtures of beryllia and clay. In an early issue of his *Tableau méthodique de minéraux*, R. J. Haüy² referred to a mineral, brought to Europe from Brazil, which he named **eucrase**—from εὐ, easily; κλάσις, fracture—in allusion to its easy cleavage. J. C. Delamétherie also made some references to the mineral. The first analysis was made by L. N. Vauquelin, and other analyses were made by J. J. Berzelius, J. W. Mallet, and A. Damour. The last-named summarized the analysis by the formula HBeAlSiO_5 ; C. F. Rammelsberg gave $\text{H}_2\text{SiO}_3 \cdot 2\text{Be}_3\text{SiO}_5 \cdot 3\text{Al}_2\text{SiO}_5$; and P. Groth, $\text{Be}(\text{AlOH})\text{SiO}_4$, **beryllium aluminohydroxyorthosilicate**,

analogous to those employed by him for datolite, homilite, and gadolinite. Eucrase, said G. Cesaro, corresponds to datolite except that aluminium is present instead of boron, and beryllium instead of calcium. Eucrase occurs with topaz in the chloritic schist of Villa Rica, Brazil; with topaz, etc., in the auriferous sands of Orenburg, Ural; with pericline, etc., in the mica schist of Gramsgrube, Austrian Alps; and also with pericline at Möllthal. The association with pericline indicates that the

mode of formation of each has been similar. F. Kolbeck and M. Henglein found euclase associated with pegmatite. V. Dürrfeld argued that the fluorite which accompanies the mineral indicates that euclase has been formed by the action of fluoriferous vap. A. Daubrée's synthesis of the beryllium silicates by the action of silicon tetrachloride on beryllia, was questioned by H. St. C. Deville. C. Doelter heated a mixture of alumina, silica, and beryllia under a layer of sodium fluoride in a magnesite crucible and obtained crystals corresponding in composition with an anhydrous euclase; but the product was not euclase.

Euclase occurs only in crystals with a prismatic habit, and with a colour ranging from white, blue, or green. The crystals, according to J. Schabus, are monoclinic with the axial ratios $a : b : c = 0.32369 : 1 : 0.33324$, and $\beta = 79^\circ 44' 4''$. C. F. Rammelsberg gave $0.6303 : 1 : 0.6318$, and $\beta = 91^\circ 42'$. Observations on the crystals have been made by V. Dürrfeld, E. Hussak, R. Köchlin, A. Levy, P. von Jeremejeff, A. T. Kupffer, K. Zerrenner, N. von Kokscharoff, W. H. Miller, A. des Cloizeaux, P. Guyot, N. Kulibin, C. S. Weiss, L. J. Spencer, and V. Goldschmidt. C. F. Rammelsberg said that the euclase is isomorphous with datolite, homilite, and gadolinite. The cleavage parallel to (010) is perfect; but the cleavages parallel to (100) and to (001) are imperfect. A. des Cloizeaux gave for the optic axial angles $2V = 49^\circ 37'$; and $2E = 88^\circ 47'$ for the red ray, and $88^\circ 7'$ for the blue ray. Raising the temp. to 176° increased $2E$ by $2^\circ 18'$. A. des Cloizeaux found that a colourless variety of euclase had a sp. gr. 3.089, and a blue variety, 3.097. A. Breithaupt found the sp. gr. of Brazilian euclase ranged from 3.094–3.095. In general, the extremes are 3.051–3.111. The hardness ranges from 7–8. A. des Cloizeaux found the indices of refraction to be $\alpha = 1.6520$, $\beta = 1.6553$, and $\gamma = 1.6710$ for Na-light. A. Worobieff measured the indices with light of different wave-lengths. The optical character is negative. The coloured crystals are distinctly pleochroic. C. Doelter found the colourless euclase acquires a soft blue tint when exposed to radium rays; and pale green euclase became a shade darker. Exposure to ultra-violet light bleaches these colours. With the exception of hydrofluoric acid, the mineral is not affected by acids.

P. Hautefeuille and A. Perrey³ melted together a mixture of potassium hydroxide, beryllium oxide, silicic acid, and an excess of neutral potassium vanadate; washed the product well with water and dil. alkali-lye; and separated the crystalline constituents by flotation in soln. of cadmium borotungstate of different sp. gr. They thus obtained what has been called *beryllia-leucite*, $KBe(SiO_3)_2$, **potassium beryllium dimetasilicate**. They also claimed to have made other complex beryllium silicates with $K_2O : Be_2O : SiO_2 = 2 : 1 : 8$; $1 : 1 : 4$; $2 : 1 : 10$; and $1 : 1 : 5$. They also obtained icositetrahedral crystals of beryllia-leucite by rapidly heating the constituents to a high temp. and cooling slowly. They assumed that in these complex salts the beryllia can replace alumina and also ferric oxide, and that it is a sesquioxide; so that in some cases beryllium oxide functions as a monoxide like magnesia, and in other cases, as a sesquioxide like alumina. The evidence is not satisfactory.

The history of **beryl** in its bearing on the evolution of our knowledge of the element, beryllium has already been discussed—4, 28, 1—and various analyses of the mineral were indicated at the same time. T. Uemura⁴ found a Japanese beryl containing beryllium, calcium, sodium, magnesium, scandium, silicon, aluminium, and iron, but no chromium.

W. Vernadsky applied the term *vorobyevite*, *worobieffite* or *worobyewite*—after M. Vorobyey—to cassia-beryl. G. F. Kunz called rose-red beryl *morganite*—after J. P. Morgan. The terms *aquamarine*, *emerald*, and *emerald* applied to beryl have already been discussed. T. Thomson called a greenish-yellow beryl from Aberdeen, *daivsonite*; C. U. Shepard, a colourless or white beryl from Goshen, Mass., *goshenite*; A. Grattarola, a slightly altered rose-red variety from Elba, *rosterite*—after G. Roster; and A. Atterberg, and J. J. Bertzelius, an altered variety, *pseudomargarit* or *pseud'emerald*. A. Eppler investigated a yellow beryl called *heliodor* containing 0.58 per cent. of ferric oxide; it became luminous in the cathode rays.

C. F. Rammelsberg summarized the analyses by the formula $\text{BeAl}_2\text{Si}_6\text{O}_{18}$. E. T. Allen and J. Clement found the small proportion of water in beryl is expelled very slowly on calcination, and they assumed that the water is dissolved in the mineral. S. L. Penfield, however, argued that the, approximately, 2 per cent. of water is chemically combined, and wrote the formula $\text{H}_2\text{Be}_6\text{Al}_4\text{Si}_{12}\text{O}_{37}$. T. Uemura wrote the formula $4\text{BeO} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$. W. Vernadsky supposed that in beryl there is a nucleus of a mineral $m\text{BeAl}_2\text{Si}_4\text{O}_{12}$ associated with $n\text{BeSiO}_3$. F. W. Clarke considers some of the methods of synthesizing beryl, the alteration of beryl into mica, and the common changes which occur involving the replacement of beryllium, do not agree with the formula $\text{Be}_2(\text{Si}_3\text{O}_8)_2\text{Be}(\text{AlO})_2$; but rather with the metasilicate formula of **beryllium dialuminium hexametasilicate**, $\text{Be}_3\text{Al}_2(\text{SiO}_3)_6$:

Beryl is commonly found in pegmatite veins, and also in clay slate, and in mica schists. J. J. Ebelmen⁵ found that if beryl be dissolved in fused boric oxide, crystals of beryl separate out on cooling or on volatilization of the boric oxide. H. St. J. Deville treated a heated mixture of alumina and beryllia with silicon tetrachloride, and obtained, not beryl, but a silicate with the composition $6\text{BeO} \cdot 5\text{SiO}_2$. P. Hautefeuille obtained beryl by fusing a mixture of alumina, beryllia, and silica, using lithium molybdate as a flux and *agent minéralisateur*; with potassium vanadate as a flux, beryllia-leucite, $\text{K}_2\text{Be}_3\text{Si}_4\text{O}_{12}$, was formed. H. Traube treated a mixed soln. of aluminium and beryllium sulphates with sodium metasilicate; and crystallized the precipitate from a soln. of fused boric oxide. It is assumed above that since the start was made with a metasilicate, the same kind of silicate is obtained at the end.

Beryl usually occurs in long prismatic crystals, but rarely in tabular crystals. G. F. Kunz⁶ found a large crystal of aquamarine weighing 110.5 kgms., at Marabá, Brazil. A beryl from Grafton, Mass., weighed 2900 lbs., and measured 4 ft. 3 ins. in one direction, and transversely 32 ins.; and another weighed nearly $2\frac{1}{2}$ tons. A. Lacroix discussed the beryl crystals from Madagascar. Beryl occasionally occurs in compact, columnar, or granular masses. The **colour** may be emerald green, pale green, light blue, yellow, rose-red, or white. W. Hermann attributed the colour to iron oxide; and G. O. Wild and R. E. Liesegang found the emerald-green varieties owe their colour to chromium; but the other varieties have no chromium, but possess an iron content nearly proportional to the colour intensity. Rose-beryl is thought to be coloured by cerium—*vide* quartz. The **crystals** belong to the hexagonal system; and, according to N. von Kokscharoff, have the axial ratio $a : c = 1 : 0.498855$. The crystals were studied by R. Scharizer, H. Panebianco, C. Anderson, R. Fellingner, H. Rubens, H. Ungemach, P. Siedel, W. F. P. McLintock and T. C., F. Hall, H. Thiene, A. Lacroix, L. Duparc and co-workers, A. S. Finkle, O. Dreher, C. S. Middlemiss and L. J. Parshad, W. E. Ford, E. Kaiser, C. Anderson, E. Romanovsky, H. Reis, P. von Jeremejeff, E. S. Dana, O. Lehmann, G. A. Kenngott, F. Hessenberg, G. vom Rath, P. Groth, A. d'Achiardi, C. Busz, W. Müller, G. Strüver, A. Schrauf, M. Websky, P. von Jeremejeff, W. E. Hidden, and S. L. Penfield. The **cleavage** (0001) is imperfect and indistinct. The crystals are sometimes striated vertically, rarely transversely. P. von Jeremejeff has discussed the twinning of the crystals of beryl. Beryl is often optically anomalous and may appear to be biaxial. This subject has been investigated by D. Brewster, J. Babinet, W. F. Salm-Horstmar, A. Breithaupt, A. Madelung, A. des Cloizeaux, F. Pfaff, E. Mallard, E. Bertrand, F. J. Wiik, R. Brauns, B. Lévy, A. Schrauf, A. N. Karnojitzky, A. Grattarola, and J. Hirschwald. L. Duparc and co-workers found that a beryl from Madagascar had the **optic axial angle** $2V = 2^\circ 34'$, and $2E = 10^\circ 12'$ for Na-light. H. Bücking studied the effect of press. on the axial angle; C. Doelter, and A. Offret, the effect of heat; and F. Pockels, the effect of heat and press. The **corrosion**

figures were studied by F. J. Wiik, R. C. Hills, W. Pettersson, H. Traube, A. Arzruni, K. Vrba, W. Kohlmann, A. P. Hones, C. Anderson, and S. L. Penfield. The **X-radiogram** was investigated by F. Rinne. The **specific gravity** of beryl ranges from 2.6-2.9; L. Duparc and co-workers obtained numbers ranging from 2.7116-2.8808; and A. Piutti, numbers from 2.628-2.886. A. H. Church gave for aquamarine, 2.702. W. E. Ford studied the rise in the sp. gr. with increasing proportions of alkalis. The **hardness** is 7-8. According to H. Vater, the coeff. of **elasticity** increases with increasing load, but with an alternation of loading, there is a steady decrease. W. Voigt found in directions 0° , 45° , and 90° to the chief axis, the coeff. of elasticity 21650, 17960, and 23120 kgrms. per sq. mm. respectively; and the **modulus of torsion**, parallel and perpendicular to the chief axis, 6666 and 8830 kgrms. per sq. mm. He also found the coeff. of **compressibility** to be $\beta=0.0675$, or 70 times smaller than with water; E. Madelung and R. Fuchs gave $\beta=0.0657$ ($p=125$ atm.).

F. Pfaff found the coeff. of **thermal expansion** of beryl to be $\alpha=0.0000017214$ in the direction of the c-axis, and $\alpha=0.061316$ in the direction of the a-axis; or, for the coeff. of cubical expansion, 0.06105 . H. Fizeau gave at 40° parallel to the chief axis, $\alpha=0.06106$; and perpendicular to that axis, $\alpha=0.06137$; or, for the coeff. of cubical expansion at 40° , 0.06168 . The maximum density lies at -42° ; H. Panebianco gave -47° for this temp. A. Offret found that unit vol. at 0° became 1.000743 at 500° . According to R. Benoit, the coeff. of linear expansion at 0° is $\alpha=- (1304.9 - 8.06\theta)10^{-9}$ parallel to the chief axis, and $\alpha= (993.7 + 9.316\theta)10^{-9}$ perpendicular to that axis. H. de Sénarmont found elliptical melting figures were obtained by the experiment described 1. 11, 5, Fig. 18. According to E. Jannetaz, the ratio of the sq. roots of the **thermal conductivities** perpendicular and parallel to the chief axis is 1:0.92. J. Joly gave 0.2066-0.2127 for the **specific heat** of different samples of beryl; P. E. W. Oeberg gave 0.1979. A. Brun gave 1410° - 1430° for the **melting point** of beryl from Limoges. A. S. Watts gave the softening temp. of mixtures of ground microcline and beryl, and of orthoclase and beryl. J. Joly found that yellow and green beryls became colourless at 357° . C. Doelter found that a higher temp. was needed for aquamarine; green beryls became paler but were not decolorized by heating in oxygen or in reducing gases. E. Newbery and H. Lupton found that a green beryl became blue after it had been heated by the Bunsen flame.

The **index of refraction** of beryl has been measured by F. Kohlrausch, A. des Cloizeaux, J. C. Heusser, J. Danker, H. Dufet, B. Jezek, A. Offret, L. Duparc and co-workers, E. Rengade and A. Lacroix, and L. Maddalena. The results vary for Na-light from $\omega=1.571$ - 1.6033 ; and from $\epsilon=1.566$ - 1.5955 . W. E. Ford found that with increasing proportions of alkalis, the index of refraction of most minerals is reduced, but, with beryl, the converse rule obtains; caesia, on account of its high mol. wt., exerts an overpowering influence. A. Schrauf measured the effect with different spectral lines. L. Duparc and co-workers found that with Li-light, ϵ varied from 1.5728-1.5740, and ω from 1.5787-1.5865; with Na-light, ϵ varied from 1.5756-1.5831, and ω from 1.5818-1.5899; and with Tl-light, ϵ varied from 1.5791-1.5864, and ω from 1.5850-1.5931. A. Offret found the effect of temp. to be as follows:

			Li-ray.	Na-ray.	Green Cd-ray.	Blue Cd-ray.
20°	ω	.	1.570980	1.574043	1.576570	1.580448
	ϵ	.	1.566050	1.569027	1.571497	1.575348
320.4°	ω	.	1.575080	1.578219	1.580862	1.584904
	ϵ	.	1.569887	1.572936	1.575439	1.579306

H. Dufet represented the change which occurs by raising the temp. to θ° , $\delta\omega/\delta\theta \times 10^7 = 189.4 - 10.34\theta + 0.2735\theta^2$; and $\delta\epsilon/\delta\theta \times 10^7 = 180.3 - 10.314\theta + 0.2735\theta^2$. The **double refraction** is not strong; L. Duparc and co-workers obtained $\omega - \epsilon = 0.0081 - 0.0084$; and H. Dufet gave for the effect of temp., $\delta(\omega - \epsilon)/\delta\theta = 0.0691 - 0.026\theta$. The **optical character** is negative. W. E. Ford, and A. Lacroix studied

the effect of increasing proportions of alkalis on the optical properties. The crystals are **pleochroic**. This subject was discussed by G. Tschermak. F. M. Stapp found a beryl from West Africa showing a distinct **asterism**, and the so-called cat's-eye effect. W. Vernadsky found the crystals to be **triboluminescent**. According to L. Sohnke, the crystals are fluorescent, but J. Schincaşlia could not confirm this. E. Newbery and H. Lupton found that a crystal which had been exposed to radium rays gave a feeble bluish-white **thermoluminescence** which appeared only on the basal planes. S. C. Lind and D. C. Bardwell found no fluorescence or change of colour by exposing aquamarine or emerald to α -rays. A synthetic emerald which had been exposed to radium radiations for 10 days gave a faint green thermoluminescence at 200°. E. Engelhardt observed some crystals have a pale green fluorescence in ultra-violet light. C. Doelter observed no fluorescence in **radium rays**, but on exposure the colour darkens a little. He also found that beryl is opaque to the **X-rays**, and aquamarine was darkened a little by exposure to X-rays. C. Baskerville and G. F. Kunz found that a rose-coloured beryl became cherry-red by the action of X-rays. V. Goldschmidt and R. Brauns studied the origin of a circle of light found on aquamarine from Brazil. W. G. Hankel found the **pyroelectricity** of the crystals to be small. J. Curie found the **dielectric constant** to be 6.24 parallel to the optic axes and 7.58 perpendicular to that direction; W. Schmidt gave 5.55 and 6.05 respectively. The **paramagnetism** was investigated by J. Plücker; and W. Voigt and S. Kinoshuto investigated the **magnetic susceptibility**.

Beryl is insoluble in acids other than hydrofluoric acid. G. A. Kenngott⁷ found that the moistened and powdered mineral shows no reaction with litmus, but it reacts distinctly alkaline after calcination. According to J. Lemberg, when beryl is digested with a 12 per cent. soln. of sodium silicate at 200°, up to about 19 per cent. passes into sodium silicate decomposed by hydrochloric acid. The transformation of beryl into kaolinite and muscovite has been discussed by H. Müller, A. Grattarola, A. Damour, and A. Atterberg.

§ 46. Magnesium Aluminium, Thallium, and Rare Earth Silicates.

H. Abich¹ observed that one part of spinel intimately mixed with 1.2 parts of silica, fuses to a grey mass which does not adhere to the platinum crucible, and is not attacked by the strongest acids. It is decomposed by fusion with potassium carbonate. W. Heldt fused a mixture $\text{MgO} : \text{Al}_2\text{O}_3 : \text{SiO}_2 = 1 : 3 : 3$; P. Berthier, mixture 3 : 1 : 3, and 3 : 1 : 6; N. G. Sefström, 3 : 1 : 3; and L. Bourgeois, 12 : 2 : 9, and 2 : 1 : 5. J. Lemberg replaced part of the calcium in many calcium aluminium silicates with magnesium, by digesting them in a soln. of a magnesium salt. H. Mackler, A. E. Hottinger, L. E. Barringer, G. Flach, and R. Rieke studied the effect of heating mixtures of china clay and magnesia, with and without quartz

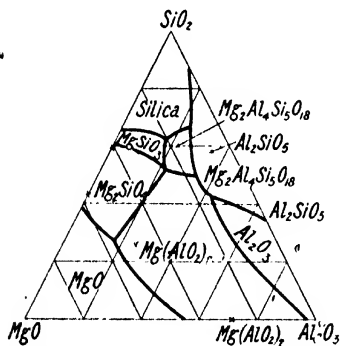

FIG. 181.—Equilibrium Diagram of the Ternary System: $\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$.

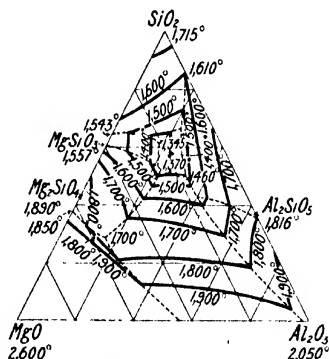

FIG. 182.—Melting-point Curves of the Ternary Mixtures: $\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$.

addition. The magnesium aluminium silicates are not so numerous as those of calcium. The ternary system $\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ for dry melts of the constituent oxides has been explored by G. A. Rankin and H. E. Merwin,² and the results are summarized in Figs. 181 and 182. The latter shows the m.p. of all ternary mixtures of these oxides. The binary compounds have been discussed elsewhere. The sole ternary compound is represented by cordierite, $2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$, now to be considered. A. Meissner, and P. Niggli described the ternary system.

E. von Schlotheim³ referred to a blue mineral from Cabo de Gata as *Spanish lazulite*. A. G. Werner, and D. L. G. Karsten called it *iolite*—from *iov*, violet—*lithos*, stone; L. Cordier called it *dichroïte*—*δίχροα*, double coloured—in allusion to its dichroism; J. Gadolin, *steinheilite*—after C. A. Steinheil; Y. Kikuchi, *cerasite*—from *κέρασος*, cherry—in allusion to the Japanese name of cherry-stone

for the rock containing the altered mineral; and C. A. S. Hofmann, *pelionite*—from $\pi\epsilon\lambda\acute{\iota}\varsigma$, livid—in allusion to its smoky-blue colour. J. A. H. Lucas, and R. J. Italy finally adopted the term **cordierite** because names derived from the colour are not always applicable, and dichroism is found in many other minerals. L. Cordier, and C. C. von Leonhard showed that *pelionite* and *dichroite* are identical; and F. Stromeyer⁴ that *stenheilite* and *cordierite* are the same.

Early analyses were made by C. G. Gmelin, R. Brandes, and F. Stromeyer. Numerous analyses have been since made, and from them C. F. Rammelsberg calculated the formulae $R''_2Al_4O_5O_{18}$ and $R''_3Al_6Si_8O_{28}$; O. C. Farrington, $(Mg,Fe)_4Al_8Si_{10}O_{38}.H_2O$; A. Osann, $(Mg,Fe)_3(Al,Fe)_6Si_8O_{28}$; W. E. Hidden and J. H. Pratt, $(Mg,Fe)_4Al_8Si_{10}O_{38}.H_2O$; P. Groth, $(Mg,Fe)_4(OH)_2Al_8(Si_2O_7)_6$; and E. A. Wülfing and L. Oppenheimer, $Mg_3Si_8Si_8O_{28}$. The best representative value is $Mg_2Al_4Si_5O_{18}$. The latter formula agrees with the work of G. A. Rankin and H. E. Merwin. Cordierite may then be represented as **magnesium dialumyl-aluminium orthopentasilicate**, $Mg_2Al_2(AlO)_2Si_5O_{18}$. The analyses of cordierite have up to 2.5 per cent. of water. Most observers consider that the water is due to the partial alteration of cordierite by weathering. M. Weibull found that the cordierite he investigated contained the hydrated silicates, muscovite, talc, and kaolinite, which could be detected microscopically; and he considers that the mineral itself is anhydrous. O. C. Farrington, and F. Zambonini observed the loss of water at different temp. The latter found with two different samples:

	125°	205°	255°	300°	350°	400°	480°
Loss . . .	0.35	0.45	0.56	0.65	0.66	0.75	0.95
Loss . . .	0.08	0.13	0.23	0.27	—	0.34	—

F. Zambonini, and F. W. Clarke think that the water is an intrinsic part of the mineral. F. W. Clarke writes the formula:

Since the proportion of water varies from sample to sample, and anhydrous cordierite can be obtained synthetically, it is assumed that cordierite itself is not a hydrated silicate.

Cordierite is found in a great variety of rocks—both eruptive and metamorphic—e.g. gneiss, granite, basalt, porphyry, trachyte, dacite, andesite, etc. It is thought to have been formed by crystallization from the fused magma after biotite but before the feldspars. This subject has been discussed by H. Bücking,⁵ E. Hussak, J. Szabo, A. Harker, E. O. Hovey, G. A. F. Molengraaff, A. Lacroix, A. E. Bergeat, K. Jimbo, etc. It has been found as a product of contact metamorphism. H. Bücking, and F. Zirkel, for instance, found it in sandstone vitrified in contact with basalt; A. Scott, in shale metamorphosed by contact with essexite; and Y. Kikuchi, in slate in contact with granite. R. Brauns, and A. Lacroix have also made observations on the formation of cordierite by pyrometamorphic actions. C. Doelter, E. Hussak, and L. Bourgeois made cordierite by fusing a mixture of silica, magnesia, and alumina in proper proportions. J. Morozewicz obtained it in his experiments on artificial magmas super-saturated with alumina. When magnesia and iron were present in magmas of the composition $RO.mR_2O_3.nSiO_2$, and n was greater than 6, cordierite was formed. G. A. Rankin and H. E. Merwin have shown the region of stability of this compound in the ternary system, $MgO-Al_2O_3-SiO_2$. Crystals are best obtained from melts in which it (or sillimanite) is the primary phase. This compound was found to be unstable at its m.p., and is considerably affected by solid soln. with the boundary compounds, Fig. 177. There are two forms. An unstable β -cordierite crystallizes from glasses at temp. below about 950°; and at somewhat higher temp., it passes into stable α -cordierite. The properties of both forms—but particularly those of

the α -form—are close to those of the mineral cordierite. G. A. Rankin and H. E. Merwin added:

Aggregates with the ternary compound as the chief constituent were prepared by heating for periods of 15 mins. to 5 hrs. at 900° – 1400° . While the glass was heating, the μ - or unstable form of the ternary compound began crystallizing at 900° or less as fine fibres which radiated from points on the surface of the grains. At temp. of 925° – 1150° this form inverted to the α -form. The inversion in different portions of the same charge, and in different aggregates from glasses of the same composition, had an extreme temp. range of about 200° . This range is mostly accounted for in a lag in the starting of the inversion. When once started in a grain the inversion proceeded so rapidly that only in a few instances was a grain found, after quenching, to contain both forms.

Cordierite occurs in short prismatic, six- or twelve-sided crystals, often with rounded edges; it also occurs massive, and in embedded grains. The colour is various shades of blue, grey, yellow. The transparent blue pebbles of Ceylon are cut as gem-stones so as to display the colour to the best advantage. As a gem-stone, pale blue cordierite is known as *saphir d'eau*, and the darker varieties as *lynx-sapphire*. Blue corundum is harder and possesses a higher sp. gr. than cordierite. L. Cordier,⁶ and R. J. Haüy assumed that the crystals are hexagonal; F. Mohs showed that they belong to the rhombic system, and W. H. Miller gave for the axial ratios $a:b:c=0.58709:1:0.55835$. Observations were made by V. Goldschmidt, A. des Cloizeaux, G. vom Rath, F. Tammann, A. Breithaupt, A. Lévy, J. F. L. Hausmann, etc. F. Rinne studied the X-radiograms of cordierite. G. A. Rankin and H. E. Merwin found that the artificial crystals are advantageously studied when they occur in melts of higher refractive index, say in melts with less than 55 per cent. silica. The crystals were usually stout six-sided prisms with basal termination, and negative elongation. The prism angle was 120° , and basal sections gave a nearly or quite uniaxial negative interference figure. In one case there was evidence of rhombic symmetry. These crystals had the 120° prism, and the side and basal pinacoids corresponding to the faces on the other crystals; they also had the front pinacoid and a second prism which bevels the edge between the side pinacoid and axial prism. Penetration twinning of cordierite is parallel to (110) and oft repeated, furnishing pseudohexagonal forms; the twinning parallel to (130) also furnishes pseudohexagonal forms. The faces (100) and (010) are sometimes vertically striated. The crystals often show a lamellar structure parallel to (001) especially when partially weathered. The cleavage parallel to (010) is distinct, and that parallel to (001) is indistinct. A. des Cloizeaux gave for the optic axial angle $2V=39^{\circ} 32' - 84^{\circ} 28'$; $2E=63^{\circ} 45' - 125^{\circ} 16'$; and $2H=82^{\circ} 21'$. L. Duparc and co-workers gave $2V=69^{\circ} 38' - 71^{\circ} 12'$; A. Offret gave $2E=115^{\circ} 38'$; A. Osann, $2E=85^{\circ} 50'$; and L. Oppenheimer, $2E=70^{\circ} 30' - 161^{\circ} 34'$, and $2V$ from $40^{\circ} 46' - 87^{\circ} 12'$ for Na-light. The axial angle was found to increase from $43^{\circ} 36' - 85^{\circ} 34'$ as the iron-content and sp. gr. decreased. A. des Cloizeaux found that raising the temp. increased the axial angle $2E$ from $63^{\circ} 56'$ at 8.8° to $71^{\circ} 40'$ at 150.8° with the red ray. W. Klein found that $2E$ passed from $68^{\circ} 9'$ at 16° to $77^{\circ} 43'$ at 200° . F. Rinne studied the X-radiograms of cordierite.

The sp. gr. is between 2.581 and 2.660; when iron is present, the sp. gr. is higher; thus, E. A. Wulffing and L. Oppenheimer obtained 2.625–2.628 with samples containing about 12 per cent. of iron oxide. The hardness is $7-7\frac{1}{2}$. A. Brun gave for the m.p. 1310° . In Figs. 181 and 182, the mixture corresponding with $Mg_2Al_4Si_5O_{18}$ is outside the region representing mixtures containing this compound. The compound dissociates when melted, and therefore has no definite m.p. C. Doelter and E. Hussak found that cordierite crystals were not changed when dipped in molten augite. G. A. Rankin and H. E. Merwin found a ferruginous cordierite after heating half an hour at 1440° , consisted of glass and sillimanite.

The indices of refraction have been measured by A. des Cloizeaux, K. Zimanyi, A. Offret, A. Osann, A. Michel-Lévy and A. Lacroix, etc., and the values range from $\alpha=1.5320-1.5918$; $\beta=1.5360-1.5970$; and $\gamma=1.5390-1.5992$, with Na-light. L. Duparc and co-workers found $\alpha=1.5359$, $\beta=1.5414$, and $\gamma=1.5440$ for

Li-light; $\alpha=1.5392$, $\beta=1.5443$, and $\gamma=1.5475$ for Na-light; and $\alpha=1.5423$, $\beta=1.5473$, and $\gamma=1.5506$ for Tl-light. I. Oppenheimer gave for Na-light $\alpha=1.5330$ – 1.5520 ; $\beta=1.5381$ – 1.5599 ; and $\gamma=1.5406$ – 1.5610 . A. Offret measured the effect of temp. and nature of light on the refractive index, and found:

	Li-ray. Red.	Cd-ray. Red.	Na-ray. Yellow.	Cd-ray. Grey.	Cd-ray. Blue.

G. A. Rankin and H. E. Merwin found that the refractive indices of the artificial crystals $\alpha=1.519$, β and $\gamma=1.522$; and $\alpha=1.524$, β and $\gamma=1.528$. The birefringence of cordierite is feeble, $\gamma-\alpha=0.0047$, $\gamma-\beta=0.0013$, and $\beta-\alpha=0.0058$. The range for $\gamma-\alpha$ is 0.011 – 0.0047 . The birefringence found by G. A. Rankin and H. E. Merwin for the artificial crystals $\gamma-\alpha=0.003$ – 0.004 . The optical character is negative. A. Beer investigated the absorption spectrum of cordierite with red light. The effect of polarized light was described by D. Brewster, W. Haidinger, A. Bertin, T. Liebisch, etc. A. Agafanoff measured the absorption spectrum of cordierite in ultra-violet light. The pleochroism of many coloured crystals of cordierite is strong. Observations were made by W. Haidinger, A. Osann, H. Rosenbusch, and A. Offret. Crystals from Ceylon gave α , light yellow; β , deep violet; γ , pale violet; from Bodenmais: α , yellowish-white; β , milk-white; γ , greenish-white; from Smitak: α , smoke-brown; β , leather-brown; γ , honey-yellow; and from Orijarfoi: α , clove-brown; β , dark Berlin blue; and γ , light Berlin blue. There are often pleochroic spots in cordierite in the zones of contact metamorphism. These are bright yellow with light vibrating parallel to the c -axis, and colourless with light vibrating parallel to either of the other two axes. The pleochroic haloes disappear when heated, and they are absent in cordierite from igneous rocks. They are thought to be produced by an organic pigment about the inclusions, but J. Joly has shown that in many cases, if not all, they are caused by the radioactive properties of a particle in the centre of the halo. O. Mügge produced colours of like tint by exposing cordierite to the rays from specks of radium—*vide mica*. O. Anschel confirmed the radioactive origin of these haloes by exposing the mineral to radium rays. M. Weber discussed the development of a pleochroic halo in zircon by contact with a cordierite crystal. G. Hövermann, and M. Weber made observations on the subject. E. Raymond studied the actions of chlorine and of hydrogen chloride on cordierite.

Cordierite is readily altered by exposure, so that the mineral is most commonly found in an altered state or surrounded by a crust of altered cordierite. The alteration of cordierite has been discussed by F. W. Clarke, A. Wichmann, W. Haidinger, C. R. van Hise, etc. The change may involve simple hydration as in the formation of fahlunite; some of the lime may be removed by carbon dioxide; and iron oxide or alkalis may be introduced. Mica in some of its forms is a common product of the change and a number of pseudomorphs after cordierite have received special names.

T. Scheerer reported a mineral from Karsgør, Norway, which he named *aspeniolite*—after *ἀσπείρα*, welcome—and it has been discovered by W. Haidinger, J. R. Blum, F. P. Möller, F. Zirkel, A. Wichmann, A. Lacroix, etc. The sp. gr. is 2.764. P. A. von Bonsdorff described a “hydrated iolite” from Abo, Finland. It was called *auralite*; and T. Thomson called it *bonsdorffite*. W. Haidinger, J. R. Blum, A. des Cloizeaux, H. J. Holmberg, A. Lacroix, and F. J. Wilk have made observations on the mineral. For *cataspilite*, *vide mica*. C. T. Jackson described a mineral which he named *chlorophyllite*—from *χλωρός*, green; *φύλλον*, leaf—and obtained from Unity, Maine. Its sp. gr. was 2.77. It was discussed by C. U. Shepard, W. Haidinger, P. Barbier, C. F. Rammelsberg, F. Gonard, C. Baret, M. F. Hedde, A. Wichmann, F. Zirkel, and G. A. Kenngott. A. Erdmann obtained a mineral which he named *esmarkite*, from Bräkke, Norway. F. Pisani regarded it as a scapolite; and W. Haidinger, F. P. Möller, A. Lacroix, J. J. Berzelius, and

J. R. Blum, as an altered cordierite. W. Hisinger obtained a mineral which he named *fahlunite* from Fahlun, Sweden; J. F. L. Hausmann called it *trichasite* in allusion to the three cleavages which are in part due to the original cordierite. It was described by R. J. Haiiy, J. R. Blum, F. J. Wiik, A. Wichmann, and W. Haidinger. The minerals *gignatolite* and *gongylite* are discussed in connection with mica. L. F. Svanberg found a mineral which he called *gropkite* at Gropptorf, Sweden. It was discussed by A. des Cloizeaux, G. Tschermak, and H. Fischer. T. Thomson described a mineral occurring near Lake Huron, and he called it *huronite*. J. D. Dana described it as an altered fahlunite; B. J. Harrington, as a decomposed feldspar. L. F. Svanberg's minerals, *iberite* and *oosite*, were described in connection with mica. C. P. Carlsson described a mineral *peplotite* from Ramsberg, Sweden, as an altered cordierite. The mineral *pinite* is described in connection with mica. P. C. Weibye described prismatic crystals of *polychroilite*—from *πολύς*, many; *χρῶς*, colour—obtained from the gneiss at Kragerø, Norway. It was described by J. D. Dana, and A. des Cloizeaux. A. Erdmann found a mineral in the granite at Brückke, Norway, and he called it *prasiolite*—from *πράσιος*, leek-green. It was also described by W. Haidinger, P. C. Möller, F. Zirkel, F. Gonnard, A. Wichmann, and J. R. Blum. N. Nordenskjöld found a mineral in the granite at Helsingfors, Finland; he named it *pyrrargillite*—from *πῦρ*, fire; *ἀργίλλος*, clay. It was described by L. F. Svanberg, J. R. Blum, A. Wichmann, F. J. Wiik, and A. Lacroix. P. A. von Bonsdorff obtained from Raumo, Finland, a mineral which he called *raumite*, and which A. E. Nordenskjöld showed to be like prasiolite. H. G. T. Wachtmeister found a mineral at Fahlun, Sweden, which he named *weissite*—after C. S. Weiss. It was discussed by W. Haidinger, S. Tennant, and J. D. Dana. A. Brusoni⁸ described a rhombic mineral from Volpedo, Piedmont, which he called *zobeduwite*, its composition is $5\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot 4\text{H}_2\text{O}$. A. N. Winchell described a mineral from Bingham, Utah, which he called *racewinite*. It is hydrated calcium ferric aluminium silicate of sp. gr. 1.94–1.98.

J. Lörenzen⁹ described a mineral from Fiskernäs, Greenland, which he called *körnerupine*—after M. Körnerup—and A. Sauer independently described a mineral from Waldheim, Saxony, which he called *prismatine*. The two descriptions are so much alike that N. V. Ussing said that it can hardly be doubted that they refer to the same mineral species. The analyses correspond approximately with the formula $\text{MgAl}_2\text{SiO}_6$, or **magnesium aluminium aluminatoorthosilicate**, $\text{Al} \cdot \text{SiO}_4 \cdot \text{MgAlO}_2$; although J. Uhlig's analysis corresponds better with $\text{NaH}_3\text{Mg}_6\text{Al}_{12}\text{Si}_4\text{O}_{40}$, which F. W. Clarke regards as a heptaorthosilicate; and for the simpler analysis, he gave $(\text{Al} \equiv \text{SiO}_4)_2 = \text{Al} - \text{SiO}_4 \equiv (\text{MgAlO}_2)_3$. It is assumed that augites (*q.v.*) are mixtures of silicates in isomorphous association with silicates of this type. A. Lacroix and A. de Gramont represented körnerupine as a boriferous mineral, $\text{Mg}_6(\text{Al}, \text{Fe}, \text{B})\text{O}_{12}(\text{SiO}_4)_7$. C. Doelter, and J. Morozewicz prepared pyroxenes (*q.v.*) containing 73 per cent. of $\text{MgAl}_2\text{SiO}_6$, but it was not found possible to isolate either $\text{MgAl}_2\text{SiO}_6$ or $\text{CaAl}_2\text{SiO}_6$, since both decompose in molten fluxes. C. Doelter and E. Dittler reported rhombic crystals of magnesium aluminium aluminato-orthosilicate, $\text{MgAl}_2\text{SiO}_6$, were produced by sintering a mixture of the constituent oxides. E. Fixek fused a mixture of magnesium metasilicate, diopside, alumina, and ferric oxide, and obtained mixed crystals containing 30 per cent. of the silicate in question. Vide Z. Weyberg's $\text{KAl}'_2\text{SiO}_6$. Körnerupine occurs in colourless, white, or yellowish-brown fibrous or columnar aggregates resembling sillimanite, and it shows prismatic zones (110), (100), and (010). The crystals belong to the rhombic system with the axial ratios $a:b:c = 0.862:1:-$, to $0.854:1:-$, according to N. V. Ussing. The cleavage is prismatic and well-defined. The optic axial angles are $2E = 65\frac{1}{2}$, $2V = 37^\circ 34' 37''$ for Na-light. According to N. V. Ussing, the sp. gr. is 3.273–3.341; and the hardness 6.5. The indices of refraction are $\alpha = 1.6691$, $\beta = 1.6805$, and $\gamma = 1.6818$ for Na-light. The coloured crystals are pleochroic. According to A. Sauer, prismatine alters into a fine fibrous mineral of a light green colour which he called *cryptotite*—from *κρυπτός*, hidden; *τίλαι*, fibre. According to P. Groth, the composition approximates HAlSiO_4 —vide *supra*.

C. d'Osson¹⁰ noted the occurrence of a granular honey-yellow mineral in the limestone of Pargas, Finland; and he called it *chondrodite*—from *χονδρός*, a grain. H. Seybert noted a similar mineral at Sparta, New Jersey, and he called it *maclureite*—after W. Maclure. The analyses of maclureite by H. Seybert, and W. Langstaff showed that it is a magnesium fluosilicate. The presence of fluorine was

overlooked by C. d'Ohsson. P. Cleaveland's suggestion to call the mineral *brucite*—after A. Bruce—was not adopted, since F. S. Beudant employed the term for native hydrate⁸ magnesite. J. L. de Bournon named some dark reddish-brown crystals from Monte Somma, *humite*—after A. Hume. T. Monticelli and N. Covelli regarded humite, maclureite, and *brucite* as synonyms of chondrodite. R. J. Haty showed that chondrodite is monoclinic, and W. Phillips, that humite is rhombic.⁹ The results of the studies of A. Lévy, J. C. G. de Marignac, C. F. Rammelsberg, J. F. L. Hausmann, A. Scacchi, W. H. Miller, J. D. and E. S. Dana, A. E. Norden-skjöld, N. von Kokscharoff, F. Hesseberg, G. vom Rath, M. Websky, E. S. Breidenbaugh, G. W. Hawes, C. Klein, and A. des Cloizeaux were thus summarized by P. Groth. There are three types of crystals of magnesium fluosilicate occurring in nature. The first type furnishes rhombic crystals which may be called *humite*; the second type furnishes monoclinic crystals which may be called *chondrodite*; and the third type also gives monoclinic crystals for which he proposed the name *clinohumite*. H. Sjögren found yet a fourth type furnishing monoclinic crystals which he called *prolectite*—from *προλέγειν*, to foretell—in allusion to the prediction of S. L. Penfield and W. T. H. Howe that a member of this family corresponding with this mineral remained to be discovered.

The axial ratios of members of the series were measured by G. vom Rath, A. Scacchi, E. S. Dana, H. Sjögren, etc. With the scale of reference employed by A. Scacchi, and E. S. Dana, the results can be summarized: •

		<i>a</i> : <i>b</i> : <i>c</i>
Prolectite, $\text{Mg}(\text{MgF})_2\text{SiO}_4$	Monoclinic	1.0803 : 1 : 2.3877 (or 0.7959 × 3)
Chondrodite, $\text{Mg}_3(\text{MgF})_2(\text{SiO}_4)_2$	Monoclinic	1.0803 : 1 : 3.1447 (or 0.6290 × 5)
Humite, $\text{Mg}_3(\text{MgF})_2(\text{SiO}_4)_3$	Rhombic	1.0802 : 1 : 4.4033 (or 0.6290 × 7)
Clinohumite, $\text{Mg}_2(\text{MgF})_2(\text{SiO}_4)_4$	Monoclinic	1.0803 : 1 : 5.6588 (or 0.6288 × 9)

This is a good example of P. Groth's *morphotropische Reihe*, where the addition of a Mg_2SiO_4 -mol. adds a certain length to the vertical axis, without affecting the other axes or the axial angle $\beta=90^\circ$, so that the vertical axis of prolectite is nearly $\frac{1}{3}$ ths, that of chondrodite $\frac{2}{5}$ ths, and that of humite $\frac{1}{7}$ ths of that of clinohumite. The relations of these minerals was also discussed by T. V. Barker.

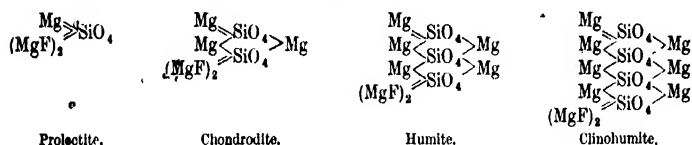

No analysis of prolectite is available; analyses of chondrodite were made by C. F. Rammelsberg, G. vom Rath, F. C. von Wingard, H. Sjögren, F. Berwerth, W. Fischer, G. W. Hawes, E. S. Breidenbaugh, N. von Kokscharoff, M. Siewert, and S. L. Penfield and W. T. H. Howe; analyses of humite by C. F. Rammelsberg, G. vom Rath, W. Langstaff, H. Seybert, W. Fischer, T. Thomson, F. C. von Wingard, H. Sjögren, and S. L. Penfield and W. T. H. Howe; and analyses of clinohumite by C. F. Rammelsberg, F. C. von Wingard, G. vom Rath, A. K. Coomaraswamy, and S. L. Penfield and W. T. H. Howe.

The analytical difficulties in the accurate determination of silica, fluorine, and small quantities of combined water prevented for a long time the establishment of the chemical relations of these minerals. A. Scacchi supposed that chondrodite, humite, and clinohumite represented three types of crystallization of one and the same chemical substance; C. F. Rammelsberg, and G. vom Rath suggested the formula $\text{Mg}_3\text{Si}_2\text{O}_9$ for the whole group provided part of the oxygen be replaced by fluorine. They noted that the percentages of silica varied in the different types. E. Mallard made a guess at the composition by assuming it to be a mixture of olivine, periclase, and sellaite. P. Groth suggested that part of the fluorine is replaced by hydroxyl; and F. C. von Wingard concluded that the three minerals have the same chemical composition, viz. $\text{Mg}_{19}\text{F}_4(\text{OH})_2\text{Si}_8\text{O}_{38}$. H. Sjögren recalculated the older analyses, and after a consideration of the neglected water, concluded that each of these minerals should be represented by a separate formula, and he emphasized the isomorphous replacement of fluorine by hydroxyl. S. L. Penfield and W. T. H. Howe employed specially selected materials purified by hand picking and the flotation of the powders. They showed that these minerals form a chemical

series progressing from proctectite to clinohumite by an increase of one mol of Mg_2SiO_4 . Thus:

	Magnesium.
Proctectite . . .	tetrafluorohydroxyorthosilicate, $Mg[Mg(F,OH)_2]_2SiO_4$
Chondrodite . . .	tetrafluorohydroxydiorthosilicate, $Mg_3[Mg(F,OH)_2]_2(SiO_4)_2$
Humite . . .	tetrafluorohydroxytriorthosilicate, $Mg_4[Mg(F,OH)_2]_2(SiO_4)_3$
Clinohumite . . .	tetrafluorohydroxytetraorthosilicate, $Mg_5[Mg(F,OH)_2]_2(SiO_4)_4$

The first member of this series was not known when S. L. Penfield and W. T. H. Howe published their work, but they said that it is "a possible and a most likely compound to occur," and it was discovered soon afterwards at Nordmark, Sweden, by H. Sjögren. See leucophenacite, and gageite. According to F. W. Clarke, the chondrodite group gives indications of the possible polymerization of fosterite, Mg_2SiO_4 . In the first member of the family, one bivalent magnesium atom is replaced by two univalent MgF -groups furnishing proctectite, $Mg(MgF)_2SiO_4$; a similar replacement in $(Mg_2SiO_4)_2$ furnishes chondrodite, $Mg_3(MgF)_2(SiO_4)_2$; likewise $(Mg_2SiO_4)_3$ furnishes humite, $Mg_4(MgF)_2(SiO_4)_3$; and $(Mg_2SiO_4)_4$ furnishes $Mg_5(MgF)_2(SiO_4)_4$. Structurally

where part of the fluorine may be replaced by HO-groups. Fosterite or chrysolite is closely related to the members of this group; and, as shown by G. vom Rath, a few of its forms are like those of humite— $a:b:c$ for clinohumite is 1.0803:1:0.6288, and $b:2a:c=1.0735:1:0.6296$ for chrysolite. Since the latter contains no fluorine or hydroxyl, it naturally deviates considerably in chemical type from the members of the humite group, and its crystal habit is also different.

The following remarks refer mainly to humite, chondrodite, and clinohumite. The colour of all three minerals is much the same—white, yellow, or chestnut-brown; chondrodite and clinohumite also appear hyacinth-red. The crystals of chondrodite vary in habit; they are often flattened parallel to (010). Chondrodite also occurs massive both compact and in embedded grains. The euhedral crystals of humite are rare. The anhedral crystals of all three minerals may be irregularly shaped, rounded, or ektipsoidal. Humite crystallizes in the rhombic system; the other members of the humite group are monoclinic. The axial ratios are indicated above. The crystals of chondrodite were investigated by A. Scacchi, G. vom Rath, A. des Cloizeaux, F. Hessenberg, H. Sjögren, A. E. Nordenskjöld, C. F. Rammelsberg, N. von Kokscharoff, J. D. Dana, and E. S. Dana; those of humite, by A. Scacchi, G. vom Rath, A. des Cloizeaux, F. Hessenberg, H. Sjögren, and E. S. Dana; and those of clinohumite, by A. Scacchi, E. Scacchi, G. vom Rath, F. Hessenberg, W. H. Miller, A. des Cloizeaux, and E. S. Dana. B. Jazek, and A. Ondrej gave for the axial ratios of chondrodite, $a:b:c=1.08506:1:3.13937$, and $\beta=90^\circ 0'$. Humite crystals usually show penetration twinnings, or lamellar polysynthetic twinnings. Trilling sometimes occurs. The twinning plane with humite crystals is (017) with the two c -axes at $60^\circ 26'$; also (037) with the c -axes at $59^\circ 34'$. Chondrodite and clinohumite show crossed and polysynthetic twinning with the lamellæ parallel to (001). The cleavage parallel to (001) is distinct in humite, and rather less so with chondrodite and clinohumite. The axial angle is large. H. Sjögren gave for red, yellow, and green rays respectively $2V=68^\circ 1'$, $67^\circ 54'$, and $67^\circ 44'$ for humite; $2V=79^\circ 40'$, $79^\circ 40'$, and $79^\circ 38'$ for chondrodite; and $2V=76^\circ 29'$, $76^\circ 27'$, and $76^\circ 24'$ for clinohumite. A. des Cloizeaux obtained $2H_a=78^\circ 18'$ for humite with the red ray. H. Sjögren also found for $2H_a$ with the red ray $85^\circ 53'$ – $86^\circ 8'$

and $85^{\circ} 41' - 86^{\circ} 8'$ for the blue ray with a yellow chondrodite; and with a brown chondrodite $89^{\circ} 8' - 89^{\circ} 20'$ for the red ray, and $88^{\circ} 28' - 89^{\circ} 14'$ for the blue ray. A. des Cloizeaux found for the red, yellow, and blue rays respectively $2H = 82^{\circ} 6' - 83^{\circ} 19'$, $82^{\circ} 9' - 83^{\circ} 27'$, and $82^{\circ} 31' - 84^{\circ} 7'$; and $2E = 148^{\circ} 38' - 154^{\circ} 2'$, $149^{\circ} 24' - 155^{\circ} 24'$, and $154^{\circ} 10' - 163^{\circ} 52'$. Observations were also made by A. Michel-Lévy and A. Lacroix, C. Klein, and E. S. Dana. The sp. gr. of humite is 3.1-3.2; and similar results apply to chondrodite and clinohumite. The observations of W. Barlow and W. J. Pope, and T. V. Barker on the valency vol. of the series has been discussed 1. 5, 18. P. E. W. Oeberg gave 0.2142 for the sp. ht. of chondrodite. The indices of refraction are moderate. A. Michel-Lévy and A. Lacroix gave $\beta = 1.643$ for humite, and $\alpha = 1.607$, $\beta = 1.619$, and $\gamma = 1.639$ for chondrodite, while H. Sjögren gave $\beta = 1.659$ for the same mineral. L. Brugnatelli gave $\beta = 1.638$ for chondrodite, and 1.670 for clinohumite. The birefringence is strong; A. Michel-Lévy and A. Lacroix gave $\gamma - \alpha = 0.032 - 0.028$ for humite, and 0.032 for chondrodite. The optical character of all three minerals is positive. Pleochroism is well marked particularly in the brown varieties. The minerals are all decomposed by acids with the separation of gelatinous silica. The transformation of the humites in nature has been discussed by E. S. Dana, and H. Sjögren.

According to F. Stromeyer,¹¹ K. L. Giesecke found a sapphire-blue mineral at Fiskernäs, Greenland, which was named **sapphirine**, a term wrongly applied by C. A. S. Hofmann to haüyne. Analyses were made by F. Stromeyer, A. Damour, E. Schluttig, J. Lorenzen, and N. V. Ussing. Formulae were given by J. F. A. Hausmann, N. von Kokscharoff, and G. A. Kenngott. The best representative formula is $Mg_5Al_{12}Si_2O_{27}$. F. W. Clarke represents it by the formula $(AlO_2)_2AlSiO_4 \equiv (MgAlO_2)_3$, **magnesium aluminium pentaluminate-orthosilicate**; and A. Lacroix and A. de Gramont, $9MgO.10(Al,Fe,B)_2O_3.4SiO_2$.

Sapphirine usually occurs in disseminated grains or granular aggregates, and in indistinct tabular crystals. The colour is pale blue or green. G. Forchhammer attributed the colour to the presence of ferrous phosphate. The monoclinic crystals, according to N. V. Ussing, have the axial ratios $a : b : c = 0.65 : 1 : 0.93$ and $\beta = 79^{\circ} 30'$. The cleavage is not distinct. The optical axial angles were found by N. V. Ussing to be $2H_a = 68^{\circ} 50'$, $2H_o = 111^{\circ} 13'$, and $2V_a = 68^{\circ} 49'$, for yellow light; A. des Cloizeaux gave for red, yellow, and green light, $2H_a = 77^{\circ} 50' - 83^{\circ} 29'$, $83^{\circ} 55'$, and $83^{\circ} 34'$. The sp. gr. is 3.420-3.486; and the hardness $7\frac{1}{2}$. A. des Cloizeaux gave for the indices of refraction $\alpha = 1.705$, $\beta = 1.709$, and $\gamma = 1.711$ for red light, and N. V. Ussing, $\alpha = 1.7055$, $\beta = 1.7088$, and $\gamma = 1.7112$. A. Michel-Lévy and A. Lacroix gave $\gamma - \alpha = 0.009$ for the birefringence. The optical character is negative. The crystals are pleochroic.

G. Agricola¹² referred to *carbunculi carchedonii* in *Boëmorum agris* which were called *Bohemian garnets* by A. G. Werner, and M. H. Klaproth. The former called the mineral **pyrope**—from *πυρρός*, fire-like—and A. Weisbach, *voesite*. Many analyses¹³ have been made. The composition calculated by C. F. Rammelsberg, and C. von John, approximates **magnesium dialuminium triorthosilicate**, $Mg_3Al_2(SiO_4)_3$. Calcium and iron are often present, and the mineral sometimes contains chromium. The work of C. F. Rammelsberg,¹⁴ E. Cohen, and C. von John agrees with the assumption that the chromium is present as sesquioxide in a **magnesium dichromium triorthosilicate**, $Mg_3Cr_2(SiO_4)_3$. H. E. Boeke found evidence that there is a continuous series of mixed crystals between pyrope and almandine—i.e. **magnesia-garnet** and **ferrous-garnet**.

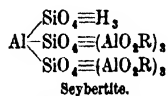

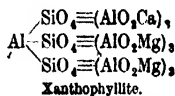

Pyrope is often found in peridotites and the serpentines derived from them. The colour of pyrope is various shades of red, brown, and black. When transparent, pyrope is prized as a gem; and it is the common red garnet of the jewellers. Pyrope does not appear on the ternary diagram, Fig. 177. The general crystallographic properties have been described in connection with grossular—lime-garnets (*q.v.*). The sp. gr. ranges from 2.69-2.78. W. E. Ford gave 3.150, the hardness is $7 - 7\frac{1}{2}$. P. E. W. Oeberg gave 0.1758 for the sp. ht. C. Doelter found the m.p.

to be 1185° , or rather fusion begins at that temp. He also found that the mineral decomposes when melted, forming spinel, etc., as indicated in connection with grossular. According to C. Doelter, when pyrope is heated in gases the colour is not changed. The indices of refraction given by H. Rosenbusch, P. A. Wagner, and M. Seebach are 1.7369-1.7422 for Li-light; 1.7412-1.7466 for Na-light; and 1.7451-1.7508 for Tl-light. W. E. Ford gave 1.705. B. Jezek found for different samples, 1.73721-1.73914 for Li-light; 1.74301-1.74606 for the D-line; 1.74696-1.75258 for Tl-light; and 1.75748-1.76134 for blue light. C. Doelter found the colour of pyrope is not changed by exposure to radium rays; but with some varieties the red colour is deepened both by radium rays and by X-rays. E. Reymond studied the action of chlorine and of hydrogen chloride on pyrope; and V. Iskyul, the action of hydrochloric acid, and the solubility of silica in pyrope.

The alterations which pyrope undergoes in nature have been discussed by A. Schrauf,¹⁵ A. E. Déleace, F. Becke, H. von Fouillon, G. Linck, J. S. Diller, A. von Lasaulx, J. Mrha, J. Lemberg, G. Tschermak, and C. R. van Hise. Pyrope changes into chlorite, serpentine, and various more or less indefinite substances; thus, A. Schrauf found near Krems, Bohemia, a substance which he called *kelyphite*—from *κελυφος*, a nut-shell—as a crust about a nucleus of pyrope. A. von Lasaulx found that it is not a homogeneous substance.

The minerals seymbertite, brandisite, and xanthophyllite belong to the clintonite family of brittle micas. They are complex calcium magnesium aluminosilicates. According to W. W. Mather,¹⁶ seymbertite was discovered at Amity, New York, in 1828, by J. Finch and co-workers; it was named *clintonite*, after W. Clinton; and in 1829, J. Finch described the mineral under the name *bronzite*. In 1832, J. G. Clemson described the mineral as *seymbertite*—after H. Seybert. A. Breithaupt called the mineral from Amity, *chrysophane*; T. Thomson, *holmite*; and G. Rose, *xanthophyllite*. A related clintonitic mineral from Fassathal, Tyrol, was called *brandisite*—after M. Brandis—by W. Haidinger, and *disterrite*—from *δύς*, twice; and *στερρός*, hard—by A. Breithaupt. Another clintonitic mineral from the Urals was called *xanthophyllite*—from *ξανθός*, yellow; and *φύλλον*, a leaf—by G. Rose, and *valuevite* or *valuevite*—after P. A. von Waluw—by N. von Kokscharoff.

Analyses of seymbertite have been reported by T. G. Clemson, G. J. Brush, G. Tschermak and L. Sipőcz, T. Thomson, and A. Breithaupt; of brandisite, by F. von Kobell, G. Tschermak and L. Sipőcz, and U. Panichi; and of xanthophyllite, by G. Rose, M. Meitzendorf, A. Knop, P. D. Nikolajeff, R. Schläpfer, and F. W. Clarke and E. A. Schneider. C. F. Rammelsberg calculated formulæ for these minerals from the analyses, and obtained for seymbertite $R''_5Al_4Si_2O_{15} \cdot 2H_2O$; for brandisite, $H_{10}R''_{24}Al_{12}Si_{10}O_{85}$; and for xanthophyllite, $R''_5Al_6Si_2O_{18} \cdot 2H_2O$, or $H_4R''_6Al_6Si_2O_{20}$. P. Groth gave for seymbertite, $H_6(Mg, Ca, Fe)_{10}Al_{10}Si_3O_{36}$; for brandisite, $H_8(Mg, Ca, Fe)_{12}(Al, Fe)_{12}Si_5O_{41}$; and for xanthophyllite: $H_8(Mg, Ca)_{14}(Al, Fe)_{16}Si_6O_{22}$. G. Tschermak considered these three minerals to be isomorphous mixtures of different proportions of an aluminate and a silicate. F. Zambonini considered these minerals to be hydrated mixtures of a disilicate, $H_2R_2Si_2O_7$, an aluminate, $R''Al_2O_4$, and water in the proportions 1 : 2.33 : 1; with brandisite 1 : 2.5 : 0.75; and with xanthophyllite, 1 : 3 : 1. V. Goldschmidt gave for brandisite, $Ca_4(Mg, Fe)_8Al_{12}Si_5O_{40} \cdot 4H_2O$. P. Erculisse regards the clintonites as solid soln. of the micas and spinels. F. W. Clarke regards these minerals as morphologically like biotite and having the univalent radicle AlO_2R'' , where R'' represents Mg, Ca, Fe, or Mn. Xanthophyllite is considered to be the most basic member of the series:

This makes xanthophyllite calcium magnesium ennealuminoxy-aluminotri-

orthosilicate; and seybertite, **calcium magnesium trihydrohexaluminoxy-aluminotriorthosilicate**.

The colour of seybertite is yellow, reddish-brown, or copper-red; that of brandisite is yellowish-green, leek-green, or reddish-grey; and that of xanthophyllite is usually leek- or bottle-green. These minerals all belong to the monoclinic system. Some measurements of the crystal constants have been made by G. Tschermak; and N. von Kokscharoff gave for xanthophyllite the axial ratios $a:b:c = 0.57736:1:1.62214$, and $\beta = 90^\circ 0'$. The crystals are usually tabular; those of seybertite are sometimes hexagonal in outline. The symmetry of xanthophyllite approximates to that of the rhombohedral system, and the forms simulate the octahedron. Complex twinning occurs as in the case of the other micas. The basal cleavage is perfect. The folia are brittle. Percussion and press. figures correspond to those of the micas. The corrosion figures of xanthophyllite and of seybertite have been studied by F. J. Wiik. G. Tschermak gave for the optic axial angle of seybertite, $2E = 3^\circ - 13^\circ$, and A. des Cloizeaux found that for the red ray, $2E = 20^\circ 23'$ at 21.5° ; $20^\circ 32'$ at 95.5° ; and $20^\circ 40'$ at 171° . For brandisite, G. Tschermak gave $2E = 18^\circ - 35^\circ$; and A. des Cloizeaux found in some cases $2E = 0^\circ$, in others $2E = 15^\circ - 20^\circ$, and in another case $2E = 28^\circ$, and increase of the angle with a rise of temp. was not unequivocally proved. For xanthophyllite, G. Tschermak found $2E = 17^\circ - 32^\circ$; H. Bücking, $2E = 20.5^\circ$; and A. des Cloizeaux, $2E = 20^\circ$, with a decrease of about 1° when the temp. rises $26.5^\circ - 146.5^\circ$. The sp. gr. of all three minerals is near 3.0-3.1; and the hardness between 4 and 5. According to F. W. Clarke, xanthophyllite decomposes when heated, forming a portion soluble and a portion insoluble in hydrochloric acid. The insoluble portion has the composition of spinel, $Mg(AlO_2)_2$. F. Zambonini investigated the dehydration of some xanthophyllite from the Urals, and found in a current of air:

	130°	210°	250°	350°	450°
Percentage loss	0.19	0.31	0.37	0.51	0.64

Only 1.98 per cent. was lost by heating the mineral in a porcelain crucible over a Bunsen's burner; and 5.10 per cent. in a platinum crucible over a gas blowpipe flame. Hence, he concluded that all the combined water is not to be regarded as constitutional water; a part is extrinsic. A. Knop made some observations on the dehydration of this mineral. A. Michel-Lévy and A. Lacroix found the indices of refraction of seybertite to be $\alpha = 1.646$, $\beta = 1.657$, and $\gamma = 1.658$. The crystals are optically negative. A. S. Eakle found the sp. gr. of xanthophyllite to be 3.081, and A. Laitakari, 3.093; for the indices of refraction, A. S. Eakle gave $\beta - \gamma = 1.660$, and A. Laitakari, $\gamma - \beta = 1.638$, and $\beta - \gamma = 0.0006$. The crystals are optically negative. The three minerals are pleochroic. Seybertite is readily and completely decomposed by hot conc. hydrochloric acid; brandisite is readily attacked by conc. sulphuric acid, but not so rapidly by conc. hydrochloric acid. F. W. Clarke and G. Steiger found that ammonium chloride vap. attacks xanthophyllite only feebly.

In connection with pyroxene and diopside, it was found convenient to apply the term **augites** to the monoclinic pyroxenes with sesquioxides—alumina, ferric oxide, &c., as essential constituents. The aluminous pyroxenes are also augites. A. G. Werner¹⁷ applied Pliny's term *augite*—from αἰγῆ, lustre—to the black volcanic schorl of the early writers—J. B. L. Romé de l'Isle, F. de la Fond, and J. Démește; A. G. Werner's term, and the *volcanite* of J. C. Delamétherie, included only the black igneous rocks; while L. A. Emmerling, and A. Estner did not clearly distinguish augite as a definite mineral species. R. J. Haüy included a number of species as pyroxenes (q.v.) as A. G. Werner did with augite.

The amphibole of H. Seybert was called *macluerite* by T. Nuttall; a variety of augite was called *basaltine* by R. Kirwan, and basaltic hornblende by A. G. Werner; a variety from Fassathal, Tyrol, was called *fassaite* by C. A. S. Hofmann, and *pyrgom*—from πύργωμα, a tower—by A. Breithaupt. V. Zsivny analyzed a sample of fassaite from Hodrusbanja (Comitat Hont). A white aluminous augite analyzed by T. S. Hunt was called *leucaugite*

—from *λευκός*, white—by J. D. Dana. L. Tokody studied the optical properties of *fassaite*, and V. Zivny, the composition. E. F. Glocker referred to needle-like crystals of augite in the porous lavas of Züfel and Laacher-See. It was named *porricine*, and described by H. Laspeyres, F. Sandberger, and A. des Cloizeaux.

R. J. Haüy¹⁸ applied the term *diallage* to a green or brown mineral which is found in gabbros and related rocks. The name—from *διαλλαγή*, difference—was intended to emphasize the dissimilar cleavages or planes of fracture. Typical augite exhibits schillerization, and closely resembles bronzite in appearance. There has been much discussion as to whether diallage is a distinct mineral species, or a variety of pyroxene. G. Tschermak regarded diallage as a member of the augite family, and it has a lamellar or thin foliated structure and parting. It resembles diopside in composition, but usually contains alumina. Analyses were made by G. vom Rath,¹⁹ H. Traube, M. F. Heddle, A. Hilger, T. Petersen, W. Wahl, A. Cossa, A. Cathrein, O. Luedecke, A. R. Leeds, D. Hummel, etc.

The earliest analyses of augite were made by L. N. Vauquelin, and W. Roux; and since then numerous others have been made. The mineral is essentially a metasilicate of calcium, magnesium, and ferrous iron plus ferric and aluminium silicates. Manganese and alkalis are often present, and up to 1.5 per cent. of titanic oxide is present in the so-called *titanic-augites* analysed by A. Knop, P. Merian, E. Lord, A. Streng, C. Becker, B. Mauritz, and F. Gonnard and P. Barbier. There are also pyroxenes with up to nearly 3 per cent. of chromic oxide—*chromic-diopside* and *chromic-augite*. These were analyzed by C. W. von Gümbel, A. Schrauf, R. Scharitzer, E. Jannettaz, A. Knop, F. P. Mennell, H. Lenk, C. F. Rammelsberg, K. Oebbecke, and R. Brauns. Here the chromium replaces part of the aluminium. The mineral *omphazite* or *omphacite* of C. A. S. Hofmann, and A. Breithaupt was named—after *ὄμφαξ*, an unripe grape—in allusion to the colour; it is a variety of chromic-augite. Analyses were made by L. Hezner, J. Ippen, and O. Luedecke. The character of omphacite was discussed by C. A. S. Hofmann,²⁰ C. C. von Leonhard, R. J. Haüy, F. Mohs, W. Haidinger, A. Breithaupt, A. des Cloizeaux, J. F. L. Hausmann, G. Tschermak, H. Rosenbusch, and P. T. Riess. A *vanadic-augite* with up to 3.65 per cent. of vanadic oxide was called *lavorovite*, or *lavoroffite*, or *lavroffite*—after N. von Lavroff—by N. von Kokscharoff; it was analyzed by K. von Schafhäütl, and P. Hermann—*vide* diopside.

The composition of augite as a mineral is so variable that it has not been possible to formulate the composition of an idealized augite. C. F. Ramélsberg²¹ regarded the augites as mixtures of diopside, $\text{CaMgSi}_2\text{O}_6$, with alumina. G. Tschermak at first supposed alumina-augite to be an isomorphous mixture of diopside with a silicate of the composition $\text{MgAl}_2\text{SiO}_6$, or $\text{R}''\text{Al}_2\text{SiO}_6$. This silicate is hypothetical, but its composition approximates to that of cornerupine or prismatine (*q.v.*). Here it is assumed that the proportion of calcium is less than that of magnesium. C. Doelter found that this is not always the case, and he assumed the augites to be isomorphous mixtures of diopside with one or more of the silicates $\text{MgAl}_2\text{SiO}_6$, $\text{MgFe}''_2\text{SiO}_6$, $\text{CaAl}_2\text{SiO}_6$, $\text{CaFe}''_2\text{SiO}_6$, and $\text{Fe}''\text{Fe}''_2\text{SiO}_6$. A. Knop regarded the augites as mixtures of RSiO_3 , $(\text{Al,Fe})_2\text{O}_3$, and $\text{Fe}_2\text{Si}_3\text{O}_9$. N. Parravano, A. Lèrian, J. Uhlig, A. Cathrein, J. Hampel, F. W. Clarke, J. Götz and E. Cohen, P. Mann, J. W. Retgers, W. Wahl, A. H. Phillips, and others also advocated the view that the augites are solid soln. of different silicates. In the augites which contain alkalis it is assumed that silicates analogous to acmite or jadeite are also in isomorphous association with the other silicates. E. T. Wherry found the at. vol. theory of isomorphism fits in with (i) the complete replaceability of Mg and Fe'' ; (ii) the slight tendency of Mg or Fe'' to replace Ca; (iii) the existence of Na and Li, and the absence of K pyroxenes; and (iv) the improbability of G. Tschermak's mol. $\text{R}''\text{R}''_2\text{SiO}_6$. H. S. Washington regards the pyroxenes as mixtures of jadeite, $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$; acmite, $\text{Na}_2\text{O} \cdot \text{Fe}_2\text{O}_3 \cdot 4\text{SiO}_2$; and diopside, $(\text{Ca,Mg,Fe})\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ mols. Augite and ægirite are composed of acmite and diopside with Fe_2O_3 and Al_2O_3 in solid soln. P. Erculisse regarded

the augites (and hornblendes) as solid soln. of derivatives of metasilicic acid and the aluminosilicic acid, $H_2Al_2SiO_6$.

Augite is a pyrogenetic mineral, and is commonly found in igneous rocks of all classes. Augite was found by F. Mohs,²² G. Rose, C. F. Rammelsberg, M. Jerošeff and P. Latschinoff, E. Ludwig, and G. Tschermak in meteorites. Crystals of augite have been reported in many slags by J. Percy,²³ E. Mäillard, N. S. Maskelyne, C. Gruner, G. J. Brush, J. F. L. Hausmann, E. Mitscherlich, J. Nöggerath, C. C. von Leonhard, F. Sandberger, C. F. Rammelsberg, F. von Kobell, C. Vélain, G. vom Rath, T. Scheerer, P. W. von Jeremejeff, J. H. L. Vogt, and E. Reynolds and V. Ball. Augite is readily obtained by simply fusing a mixture of the constituents. It was so obtained by P. Berthier,²⁴ H. J. Johnston-Lavis, F. Fouqué and A. Michel-Lévy, A. Daubrée, A. Lacroix, C. J. St. C. Deville, S. Mœunier, etc. J. Morözewicz found both ordinary augite and the alkaline augites in his work on artificial magmas, when over 50 per cent. silica was present, and when the alumina is in excess of that required for feldspar and mica. G. V. Wilson obtained it by the action of glass on fragments of lime. K. Bauer, J. Lenarcic, L. Bourgeois, and C. Doelter obtained augite among the products of the fusion rock magmas—e.g. garnet vesuvianite, epidote, biotite, and clinocllore; he also obtained augite by fusing diopside with alumina or ferric oxide. J. Lenarcic obtained augite by fusing a mixture of labradorite and magnetite; and B. Vucnik, by fusing hedenbergite with anorthite, albite, or corundum.

The general properties of the augites are like those of diopside (*q.v.*). The colour of the augites depends on the composition; usually it varies from a dark green to black, and in thin section, colourless to pale green. Augites with no iron may be white—e.g. the *leucaugite* of J. D. Dana²⁵—*vide supra*. Vesuvian augite is yellow. The titaniferous augites are often pale violet-brown. G. Becker made some observations of the colour of titaniferous augites. Manganese oxide introduces a violet or rose-red colour into the augites—e.g. the *violan* of A. Breithaupt, and A. des Cloizeaux. In general, augite crystals appear in short thick prisms, rarely tabular or bladed. The axial ratios of the monoclinic crystals vary but little with wide variations in composition. The change in form with varying amounts of ferrous and ferric oxides has been discussed by G. vom Rath, and G. Flink. Thus, a colourless diopside with 0.51 per cent. Al_2O_3 , 0.98 Fe_2O_3 , and 1.91 FeO had the axial ratios $a:b:c=1.09126:1:0.58949$, and $\beta=74^\circ 8'$; while an augite with 5.6 per cent. of Al_2O_3 , and 9.5 FeO had the ratios $1.09547:1:0.59035$, and $\beta=74^\circ 13'$. Diopside, augite, aegirite, aomite, and jadeite are probably isomorphous. H. Baumhauer, and G. Grein,

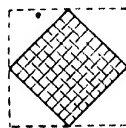

FIG. 183.—Transverse Section of a Prismatic Crystal of Augite.

studied the corrosion figures of the augites. The commonest form of twinning is on the composition plane (100); the twinning on the (001)-plane is usually repeated in thin lamellæ; the twinning on the (101)-plane furnishes cruciform twins; and the twinning on the (122)-plane furnishes stellate groups. The last two forms are rare. The cleavage parallel to (110) is often well-developed, but sometimes quite imperfect. In cross-section, the obtuse angles of the traces of this cleavage intersect at $92^\circ 50'$, and the acute angles at $87^\circ 5'$. This is shown diagrammatically in Fig. 183. The outer dotted lines represent the form of the primary; the continuous lines represent the cleavage-solids; and the broken lines represent the rhombic cleavage. A second cleavage parallel to (100) is highly developed in some augites, and the crystals then separate into thin plates. There may also be an imperfect cleavage parallel to (010). A parting parallel to (001) is well developed in many crystals twinned in lamellæ parallel to this plane. It is considered to be a result of multiple twinning, and not a true cleavage. E. A. Wülfing gave the optic axial angle $2V=61^\circ 12'$; and G. Tschermak, 68° . E. Goens examined the optic axial angle in the ultra-red. For the X-radiograms, *vide* diopside.

The sp. gr. ranges between the limits 3.15 and 3.60, and it naturally depends on the composition, e.g. the replacement of magnesium by sodium lowers the sp. gr., while calcium, iron, and manganese in place of magnesium raise the sp. gr. Similarly, the replacement of aluminium by ferric iron raises the sp. gr. The m.p. also depends on the composition. In general, the augites with sodium, aluminium, iron, and manganese have a lower m.p. than diopside. C. Doelter found for various augites 1090°–1260°; for diallage, 1160°–1180°; and for soda-augites, 1085°–1115°. A. Brun gave 1230° for the m.p. of an augite from Monte Rossi. R. Cusack gave 1187°–1199° for the m.p. of augite, and A. L. Fletcher, 1237°–1249°. R. Cusack gave 1264°–1300° for the m.p. of diallage; and A. L. Fletcher, 1328°–1350°. L. H. Adams and E. D. Williamson found the compressibility, β , of augite to be 2.34×10^{-6} at 0 megabar, 2.27×10^{-6} at 2000 megabars, and 1.04×10^{-6} at 10,000 megabars. F. E. Naumann obtained numbers between 0.1930 and 0.1950 for the sp. ht. of augite; P. E. W. Oeberg, 0.1830 between 15° and 99°; and R. Ulrich, 0.1931 between 19° and 98°. H. Fizeau gave for the coeff. of thermal expansion of the two axes in the plane of symmetry; 0.02730 and 0.027910, and for the axis at right angles to this plane, 0.0413856. This makes the coeff. of cubical expansion 0.025971. G. Tschermak gave $\beta=1.74$ for the index of refraction; E. A. Wülfing, $\alpha=1.6475$, $\beta=1.7039$, and $\gamma=1.7227$ for Na-light; and A. Michel-Lévy and A. Lacroix, $\alpha=1.706$ –1.712, $\beta=1.712$ –1.717, and $\gamma=1.728$ –1.733.* For the birefringence E. A. Wülfing gave $\gamma-\alpha=0.0252$, and A. Michel-Lévy and A. Lacroix 0.021–0.022. The optical character is positive. The more strongly coloured augites are often pleochroic; but ordinary augite is not perceptibly pleochroic. This subject has been discussed by G. Tschermak. According to L. van Werneke, A. Pelikan, J. Blumrich, and A. Scott, titaniferous augites are generally pleochroic and exhibit, in section, an hour-glass structure, the crystals consisting of a number of sectors. A. Scott showed that the extinction angles, indices of refraction, and optic axial angles differed in the various sectors. W. Vernadsky found augite to be triboluminescent. C. Doelter found that augites free from iron are as transparent as calcspar for the X-rays, while the ferruginous augites are less permeable. At ordinary temp., augite is a non-conductor of electricity, but it becomes a conductor at higher temp. Thus, with an augite with a m.p. 1225°, C. Doelter found the sp. electrical resistance of the compressed powder to be:

	1000°	1050°	1100°	1160°	1200°	1270°
Ohms	8315	5361	2936	1119	28.88	5.4

and for the cooling of molten augite:

	1215°	1206°	1160°	1115°	1050°	1000°
Ohms	7.54	9.45	17.7	172.0	493.4	669.0

B. Bavink studied the magnetic properties of crystals of augite.

G. A. Kenngott²⁸ found green and black augites powdered and moistened with water react markedly alkaline; F. Sestini found that powdered and moistened Vesuvian augite behaves similarly. Water dissolved 0.057 per cent., and water sat. with carbon dioxide dissolved 0.095 per cent. in 50 hrs. It was assumed that water breaks augite into two parts, the calcium and magnesium silicates appear in the soluble part, the aluminium and iron silicates in the insoluble part. A. Daubrée observed that the augites are not so readily decomposed by steam at 400° as diopside. C. Simmonds found that augite does not show any definite reduction by hydrogen at a red heat. Acids have but a slight action on augites, and in the case of the aluminiferous augites the action is inappreciable. E. Lord observed no separation when titaniferous augite is digested with hydrochloric acid. G. Becker investigated the action of hydrochloric acid. H. Lotz, and W. B. Schmidt studied the action of sulphurous acid on augite and observed but a slight action after 12

months' exposure. E. C. Sullivan found a basic exchange occurs when augite is treated with a soln. of cupric sulphate. V. P. Smirnoff studied the action of humic and crenic acids on augite. The natural transformation products of augite in nature are numerous.²⁷ Picrophyll, pitkarantite, pyralolite, traversellite, pyroschlerite, grengesite, and strakonitzite have been previously indicated. Cingolite, steatite, mica, epidote, and green-earth or glauconite, have also been reported. J. Roth has discussed the various changes; and other reports have been made by J. Lemberg, T. S. Hunt, A. Streng, G. Tschermak, and G. A. Kenngott. A. Erdmann found a yellow, slightly altered pyroxene at Bergen, Norway, and he called it *monradite*—after M. J. Monrad. S. H. Cox reported a greenish pyroxenic mineral from the serpentine rocks of the Dun Mts., New Zealand. He called it *hectorite*—after J. Hector. G. Friedel and F. Grandjean discussed the transformation of augite into chlorite; C. F. Rammelsberg, the alteration to opal; and M. F. Heddle, and N. Kispatic, the serpentinization of augite.

The mineral **hornblende** or *Hornstein* probably received its name from the old miners in allusion to its toughness. C. A. S. Hofmann²⁸ indicated that the term may be of Swedish origin. J. G. Wallerius designated it *corneus fissilis*, *corneus solidus*, *corneus crystallosus*, and *skiorl*. A. Cronstedt called it *skörl*, etc. J. B. L. Romé de l'Isle classed it as a *schorl*. A. G. Werner, L. A. Emmerling and A. Estner used the term *hornblende* for the mineral.

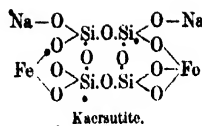

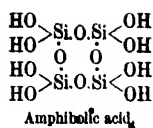

The term *pargasite* was applied by G. von Steinheil to green, bluish-green, or greyish-black crystals of hornblende from Pargas, Finland. A. Breithaupt called the black hornblende from Nordmark, Wernland, *diastatite*—from *διαστατός*, standing apart—and later *wallerius*. He called the black hornblende from Vesuvius, *syndugmatite*—from *σύνδυγμα*, arranged; and the colourless or grey hornblende from Edenville, New York, *edenite*. The light-coloured hornblende with but little iron is often called *edenite*, and the darker varieties *pargasite*. N. Nordenskjöld called a variety from Lake Baikal, Siberia, *kokscharoffite*—after N. von Kokscharoff—and J. D. Dana, one from Nora, Westmanland, *noradite*. A. Breithaupt obtained a green mineral from Gamsgrad, Serbia, which he called *gamsgradite*, and which A. Lacroix showed to be a hornblende. P. Lucchetti obtained needle-like crystals of a hornblende from Monte Altino, Bergamo, Italy, which he called *bergamaskite*. J. Lorenzen obtained crystals of a hornblende at Kaersut, North Greenland, and he called the mineral *kaersutite*. Its composition was examined by B. Gossner. T. Thomson, A. des Cloizeaux, and T. S. Hunt described *raphallite*—from *ραψάς*, a needle—found by the first-named at Perth, Lanarkshire. It is a variety of hornblende. F. D. Adams and B. J. Harrington reported a hornblende in the nepheline-syenite of Dunganion, Hastings, Ontario, and they called it *hastingsite*. T. L. Walker gave for the indices of refraction, $\alpha=1.695-1.697$; $\beta=\gamma=1.710-1.711$; and pleochroism with a pale yellow, and β and γ , a deep greenish-blue. G. Platania referred to a variety occurring in minute crystals in the hematite of Acicatena, Sicily; it was named *ziphonite*—after Xiphonia, an old town near the locality. R. A. Daly applied the name *philipstadite* to an amphibole from Philipstad, Sweden. W. C. Brögger found an amphibole intermediate in properties to barkevikite and arfvedsonite which he named *cataphorite*. It came from South Norway. Its composition was examined by B. Gossner. A. Lacroix mentioned a similar mineral from Haute-Loire. L. Duparc and F. Poarcé named an amphibole from Koswinsky, Urals, *soresite*—after C. Soré; and another related to riebeckite and arfvedsonite, was called *tachischewite*. J. A. Krenner called an amphibole occurring with the jadeite of Central Asia, *szechenyite*—after Count Szechenyi. L. L. Fernor called a blue amphibole from the manganese mines of Central India, *winchite*—after H. J. Winch. L. C. Beck applied the term *hudsonite* to a mineral from Cornwall in the vicinity of the Hudson River, New York. Hudsonite is black, lamellar, massive, and often has a bronze lustre. It was shown by S. Weidman to be an amphibole, not, as formerly supposed, a pyroxene. A. G. Werner called a dark-coloured hornblende from Sanalpe, Carinthia (Kärnten), *karinthine*. A. Breithaupt regarded it as a special species of amphibole, but J. F. L. Hausmann showed that it is a variety of hornblende. E. Denayer described *lorandrikite* as a magnesian ferric amphibole from Fine, Ouadai.

Among the more or less altered hornblendes which have been reported are T. Thomson's *kirvanite*—after R. Kirwan—which is a green chlorite-like mineral whose nature was established by A. Lacroix. The *loganite* of T. S. Hunt—named after J. R. Logan—occurs at Calumet Falls, Quebec, and it is near penninite in composition. G. A. Bertels described a yellow, fibrous, hornblende-like mineral which he called *phaeactinite*—from *φαῖς*, black; and *ἀκτίς*, a ray. A. Knop, G. A. Kenngott, and C. F. Rammelsberg described a green mineral from Waldheim, Saxony, which was called *waldheimite*, and which was found to be an altered product of hornblende.

R. J. Haiiy³⁰ regarded the *variété verte* of diallage as synonymous with the *smaragdite* of H. B. de Saussure. A. G. Werner regarded smaragdite from Corsica as a granular kind of hornblende (Steahlstein). Observations were made by W. Haidinger, G. Rose, G. Tschermak, R. von Drasche, H. Rosenbusch, and F. Zirkel. Analyses were made by J. V. Lewis, J. B. Trommsdorff, F. A. Genth, etc. C. Boulanger has described a chromiferous smaragdite. Smaragdite has a light grass-green colour, and is a thin foliated variety of amphibole, which closely resembles actinolite in composition, but contains some alumina. Usually, it has probably been derived from pyroxene or diallage, and it retains much of the structure of diallage. Saussurite and smaragdite form the greenish rock called saussuritic gabbro; and the Corsican mineral is from the rock *verde di Corsica duro* used in the arts.

G. Rose³⁰ applied the term *urallite* to a mineral which had the crystalline form of augite and the structure of hornblende; this name was selected because the mineral is widely distributed in the Urals. The mineral is a pyroxene which has been changed to an amphibole. The urallitization of pyroxene is generally attended by an increase in the proportion of magnesium, and a decrease in the proportion of calcium. The change was discussed by G. Rose, W. Haidinger, F. Becke, R. J. Haiiy, H. Rosenbusch, C. A. Müller, and H. Fischer. L. Duparc and T. Hornung say that urallitization is not a case of mol. transformation; nor a case of hydrochemical alteration. They suggest that after the pyroxene had crystallized from the magma, it was acted on by the residual magma and transformation occurred in patches into amphibole. Analyses have been reported by C. F. Rammelsberg, B. J. Harrington, P. Dehms, L. Duparc and T. Hornung, G. vom Rath, and J. Kudernatch. Traversellite—*vide* diopside—has probably been formed by a similar process to urallite.

P. A. von Bonsdorff³¹ made an analysis of hornblende, and since then numerous analyses have been reported. As with the augites, the composition of the hornblendes is very variable. The hornblendes bear the same relation to the amphiboles as the augites bear to the pyroxenes. E. T. Wherry³² applied the at. vol. theory of isomorphism to explain the various replacements in the amphiboles. S. L. Penfield and F. C. Stanley quoted a number of analyses to show that in the hornblendes, magnesium and iron preponderate over calcium, while the reverse condition prevails among the augites. The constitution of hornblende is generally assumed to be analogous to that of augite. C. F. Rammelsberg made attempts to deduce a formula for hornblende. C. G. C. Bischof, T. Scheerer, and J. Roth discussed the nature of the sesquioxides in this mineral; E. T. Allen and J. K. Clement, the nature of the water. G. Tschermak regarded hornblende as an isomorphous association of the silicates $\text{CaMg}_3(\text{SiO}_3)_4$, $\text{CaFe}_3(\text{SiO}_3)_4$, $\text{Na}_2\text{Al}_2(\text{SiO}_3)_4$, $\text{K}_2\text{Al}_2(\text{SiO}_3)_4$, $\text{CaMgAl}_4\text{Si}_2\text{O}_{16}$, and $\text{CaMgFe}_4\text{Si}_2\text{O}_{12}$, which he afterwards reduced to the first three, and $\text{CaMg}_2\text{Al}_3\text{Si}_3\text{O}_{12}$. P. Groth gave for hornblende $(\text{Mg}, \text{Fe})_3\text{Ca}(\text{SiO}_3)_4$, and $(\text{Mg}, \text{Fe})_2\text{Al}_2(\text{SiO}_3)_2(\text{AlO}_3)_2$; and for richterite, $(\text{Mg}, \text{Fe}, \text{Mn})_3\text{Ca}(\text{SiO}_3)_4$, and $\text{Na}_2(\text{Al}, \text{Fe})_2(\text{SiO}_3)_4$. A. Sauer assumed that Al_2SiO_5 is present in hornblende from Darbach. R. Scharitzer regarded hornblende and richterite as mixtures of an actinolite, $\text{CaMg}_3(\text{SiO}_4)_3$, with a silicate of the garnet type, $\text{R}''_3\text{R}'''_2\text{Si}_3\text{O}_{12}$, to which he applied the term *syntagmatite*. F. Berwerth, F. R. van Horn, G. F. Becker, J. Soellner, H. Haeflke, and F. D. Adams and B. J. Harrington also assumed the presence of orthosilicates—first, because the proportion of oxygen is larger than that required for metasilicates, and second, because they alter into mixtures containing orthosilicates. The first argument is not strong because some hornblendes have more oxygen than is required for the orthosilicate ratio, and the excess in both cases can be explained by assuming the existence of basic radicles. S. L. Penfield and F. C. Stanley suggest that hornblendes may be regarded as polymetasilicates with the bivalent radicles $\text{Al}_2\text{OFe}_2''$, $\text{Al}_2\text{O}(\text{OH})_2''$, $\text{R}'\text{Al}_2\text{O}_3''$, $\text{Na}_2\text{R}'\text{Al}_2\text{O}_4''$, and the univalent radicle MgF' ; this explains the presence of water, and fluorine. X. Galkin, and B. Gossner supported this hypothesis. E. T. Allen and J. K. Clement assumed that the water in these minerals is adsorbed, occluded, or in solid soln. In agreement with G. Tschermak, S. L. Penfield and F. C. Stanley assumed that the hornblendes are salts of an *amphibolic acid*, $\text{H}_3\text{Si}_3\text{O}_{12}$; and H. S. Washington suggested a constitutional formula for kaersutite, based on this assumption.

P. Eroulisse argued that the hornblendes (and augites) are solid soln. of derivatives of the aluminosilicic acid, $\text{H}_2\text{Al}_2\text{SiO}_6$, and of metasilicic acid. Hornblende is found in both igneous and metamorphic rocks; it is a common constituent of granite, syenite, diorite, trachyte, diabase, gabbro, norite, gneiss, chlorite schist, mica schist, etc. Edenite occurs in crystalline limestone and seems to have been produced by contact metamorphism; pargasite is found in metamorphic rocks, gneisses, and crystalline limestones. Basaltic hornblende is an early secretion in andesite, dacite, phonolite, basalt, and other eruptive rocks. The reports of T. Schärer, and C. W. C. Fuchs³³ of the occurrence of hornblende in slags were shown by C. C. von Leonhard, and G. Tschermak to be unreliable. H. J. Johnston-Lavis reported finding hornblende on fossil bones in the volcanic tufa of Faiano, Nocera, and he assumes that it was formed under pressure and at a temp. insufficient to carbonize or discolour the organic matter of the bones. K. von Chruschoff synthesized hornblende by heating a mixture of dialyzed silica, alumina, ferric and ferrous hydroxides, magnesium hydroxide, calcium hydroxide, and water in an autoclave for 3 months at 550° . C. Doelter also prepared crystals of hornblende by fusing a mixture of magnesia, iron oxide, alumina, silica, and boric oxide. He also recrystallized amphiboles from fused borax, or a fused mixture of magnesium and calcium chlorides. Olivine, scapolite, magnetite, anorthite, or orthoclase were also produced. K. Bauer obtained hornblende by fusing at 800° a mixture of biotite, boric acid, sodium phosphate, and calcium fluoride. A. Becker showed that when hornblende is fused, a pyroxene, possibly mixed with olivine, is formed; and A. Lacroix found that heat alone, or contact with molten magmas, must have converted hornblende into augite in the volcanic rocks of Auvergne. Indeed, the amphiboles are not stable at elevated temp. Their appearance as pyrogenic minerals is therefore conditioned by the rapid cooling of the mother magma, the presence of water, or some undetermined influence of pressure. An excess of magnesia favours the development of the hornblendes, while an excess of lime favours the formation of the augites—*vide* magnesium metasilicate. E. T. Allen and co-workers found that when magnesium metasilicate is heated above its m.p. and rapidly cooled, amphiboles are produced; and if slowly cooled, pyroxenes are formed. When rhombic amphibole and water are heated at 375° – 475° , the monoclinic form is produced; and the latter is obtained when a soln. of magnesium ammonium chloride or of magnesium chloride and sodium hydrocarbonate is heated along with sodium silicate or amorphous silica in a steel bomb for 6 days at 375° – 475° . Some quartz and forsterite were formed at the same time.

The colours of pargasite and common hornblende vary from light to dark green, bluish-green, and black. G. Murgoci discussed the blue amphiboles. A zonal structure is sometimes developed and the central portion is brown while the outer portion is green, or *vice versa*. Hornblende is often free from inclusions, but it sometimes contains apatite, magnetite, and titanite when of igneous origin, and rutile when formed by metamorphism. Gas, glass, and liquid inclusions are rare. Parallel growths of pyroxene and amphibole are not uncommon. According to A. E. von Nordenskjöld,³⁴ the axial ratios of the monoclinic crystals of hornblende are $a : b : c = 0.54826 : 1 : 0.29377$, and $\beta = 75^\circ 2'$. Observations were made by A. des Cloizeaux, N. von Kokscharoff, W. H. Miller, J. D. Dana, A. Lévy, and C. F. Naumann, M. Vendl, A. Schrauf, P. Groth, G. H. Williams, F. A. Quenstedt, G. vom Rath, C. S. Weiss, G. Tschermak, etc. The crystals often appear as slender prisms, and short thick prisms. The forms common to all monoclinic amphiboles are (110), (010), and less often, (100) and (130); the common terminal planes are (011),

($\bar{1}01$); sometimes ($\bar{1}01$) and (211); and rarely (001). The faces of the crystals of hornblende are usually quite simple, the unit prisms have (110) strongly developed, the second pinacoid (010) is subordinate, and less frequently, the first pinacoid (100) is quite small. The terminal faces are usually (011) and (101). The relations between the crystals of augite and of hornblende were discussed by G. Rose. H. Haga and F. M. Jäger studied the X-radiograms of hornblende. The common case of twinning has the composition plane (100), and in some cases there are several lamellae twinned between larger parts. A second form of twinning, rather rare, is parallel to the basal pinacoid (001), and is usually polysynthetic. As in the case of pyroxene, it is produced by press. Observations on the twinning were made by E. Cohen, K. Oebbecke, F. Becke, C. H. Williams, O. Mügge, E. Dathe, and W. Cross. The cleavage parallel to (110) is highly developed, yielding $55^\circ 30'$, as illustrated diagrammatically in Fig. 184, where the outer dotted line represents the primary

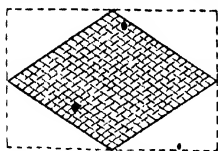

FIG. 184.—Cleavage of Hornblende.

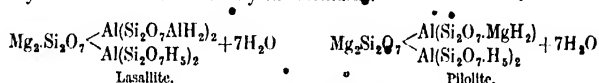

form; the continuous line, a secondary form of that of the cleavage solid. Cleavages parallel to (100) and (010) are sometimes distinct, but rare. Parting parallel to the twinned lamellae is sometimes developed. A. des Cloizeaux gave for the optic axial angle $2H=92^\circ 37'$; G. Tschermak gave $2E=107^\circ 30'$ and $2V=59^\circ$. M. Vendl gave $2V=82^\circ 45'$. Observations were also made by J. D. Dana, H. Rosenbusch, G. Flink, A. Michel-Lévy and A. Lacroix, and K. Zimanyi. A. des Cloizeaux found that for pargasite, $2H=95^\circ 53'$ at 17° , and $100^\circ 38'$ at $170^\circ 8'$. A. Belowsky, and A. Schrauf also studied this subject. G. Tschermak, C. Schneider, A. Belowsky, and F. J. Wiik studied the effect of composition on the axial angles; and F. Rinne, the effect of heat.

The sp. gr. of most of the samples analyzed were determined; the numbers range from 2.9–3.4. M. Vendl gave 3.178 at 20° . The actual number naturally depends on the composition—thus the greater the iron-content, the greater the sp. gr. The hardness ranges from 5–6. F. Pfaff found the coeff. of thermal expansion in the direction of the crystallographic axes b and c to be $b=0.00000843$ and $c=0.00009530$, and for a , at right angles to b and c , 0.000008119 ; and for the coeff. of cubical expansion 0.00002845. H. Fizeau gave for the coeff. of cubical expansion 0.000025971. F. E. Naumann gave for the sp. ht. 0.1958–0.1976; R. Ulrich, 0.1941 between 21° and 98° ; and J. Joly, 0.2113. A. Brun gave 1070° for the m.p. of hornblende; R. Cusack, 1187°–1200°; A. L. Fletcher, 1237°–1250°; C. Doelter, 1150°–1220°; and H. Leitmeier, 1180°–1200° for coarse-grained hornblende, and 1130°–1180° for the fine-grained mineral. The indices of refraction for hornblende given by A. Michel-Lévy and A. Lacroix are $\alpha=1.680$, $\beta=1.725$, and $\gamma=1.752$; for pargasite, K. Zimanyi gave $\alpha=1.616$, $\beta=1.620$, and $\gamma=1.635$; and M. Vendl, $\alpha=1.698$, $\beta=1.6825$, and $\gamma=1.6929$. Other observations were made by H. Rosenbusch, A. Belowsky, G. Tschermak, A. des Cloizeaux, and A. Franzenau. For the birefringence, K. Rosenbusch gave $\gamma-\alpha=0.0264$, $\gamma-\beta=0.0114$, and $\beta-\alpha=0.0148$. The optical character is negative, rarely positive. Attempts to find a relation between the composition and the optical properties have been made by G. Tschermak, F. J. Wiik, W. C. Brögger, G. Murgoci, S. Krentz, A. Laitakari, W. E. Ford, S. L. Penfield and F. C. Stanley, and A. N. Winchell. G. Tschermak, A. Michel-Lévy and A. Lacroix, H. Rosenbusch, M. Vendl, and F. Becke studied the pleochroism of the crystals. W. Vernadsky found the crystals are triboluminescent. O. Mügge studied the pleochroic halos produced by radium radiations. C. Doelter found the non-ferruginous hornblendes are transparent to the X-rays, but not so with the ferruginous hornblendes.

C. Schneider³⁵ studied the action of steam on heated hornblende. According to G. A. Kenngott,³⁶ powdered and moistened tremolite, hornblende, and maragdite, calcined or uncalcined, react alkaline to litmus. R. Müller found that carbonated water has a strong action on hornblende, and about 1.536 per cent. is dissolved.

E. A. Stephenson studied the action of alkaline soln. on hornblende. C. Doelter found that when heated to redness for 3 hrs. in a stream of hydrogen chloride, about 4.15 per cent. of lime and 1.57 per cent. of magnesia was rendered soluble in water. The ferruginous varieties of hornblende are attacked by hydrochloric acid, but the non-ferruginous varieties are not appreciably affected. J. W. Mellor found that an hour's treatment of coarse-grained and fine-grained hornblende with hot conc. sulphuric acid decomposed respectively 1.79 and 15.09 per cent. W. B. Schmidt, and H. Lotz investigated the action of sulphurous acid and found about 6.7 per cent. was dissolved. A. Becker, and C. Doelter studied the corrosive action of molten silicate magmas on hornblende. E. C. Sullivan studied the action of soln. of cupric sulphate on amphibole. G. Tammann and C. F. Grevenmeyer found that magnesia does not act on hornblende at 1000°; lime acts slowly at 500°; and baryta acts quickly at 275°–300°. For the transformation of hornblende into pyroxene, *vide supra*. The transformation of hornblende in nature has been discussed by C. F. Rammelsberg, J. Lemberg, M. F. Heddle, K. Vrba, C. R. van Hise, J. D. Dana, C. A. Joy, F. Becke, and B. Kolenko. The mineral alters into pyroxene as indicated above, and also into biotite, calcite, chlorite, epidote, quartz, siderite, etc.

T. von Saftschienkoff³⁶ found and analyzed a soft, tough, white, fibrous mineral in the Paligoris mine of the Permian mining district, Ural; it was regarded as an altered asbestos, and called **paligorscite**. Analyses were also made by A. Fersmann, and G. Friedel. The composition approximates $H_4Mg_2Al_2Si_{11}O_{38} \cdot 3H_2O$; and A. Fersmann called it *α-paligorscite*, to distinguish it from a similar mineral with the composition $H_{10}Mg_2Al_2Si_7O_{34} \cdot 4H_2O$, and called *β-paligorscite*. The latter was also analyzed by A. Kasakoff, G. S. Whitby, M. F. Heddle, G. Tschurowsky, and A. Rzehak. A variety high in lime was called *calcio-paligorscite*. The sp. gr. of paligorscite is 2.217; it is not acted on by acids. According to P. A. Schemjatschensky, it is an altered asbestos. M. F. Heddle³⁷ applied the term **pilolite**—from *πίλος*, felt—to a fibrous, more or less flexible, and tough mineral resembling the so-called *mountain-cork*, or *mountain-leather*, the colour white, buff, or grey. Analyses were also made by A. E. Delesse, Z. Rozen, A. F. Collins, T. Thomson, and A. Fersmann. The last-named called samples approximating $H_4Mg_4Al_2Si_{10}O_{34} \cdot 6H_2O$, *α-pilolite*, and those approximating $H_{18}Mg_6Al_2Si_{13}O_{44} \cdot 8H_2O$, *β-pilolite*. G. Friedel described snow-white masses of a fibrous mineral from the antimony mine of Miramont, France, etc., and named it **lasallite**—after M. Lasalle. He considers it to be a variety of pilolite. F. W. Clarke represented the analyses of the two minerals by the formulae:

E. F. Glocker³⁸ applied the term **xylotile**—from *ξύλον*, wood—to a kind of asbestos which is green or brown in colour, and very delicately fibrous. Analyses were made by A. Erdmann, A. Fersmann, M. C. J. Thauloff, C. von Hauer, and W. Lipdgren and W. F. Hillebrand. The composition approximates to that of paligorscite. R. Hermann's *xylite* is a kind of hydrated asbestos. G. A. Kennigott regarded xylotile as an altered chrysotile. The sp. gr. is 2.40–2.56. A. Fersmann concluded that all these minerals, paligorscite, pilolite, lasallite, mountain-cork, mountain-leather, and the like, should be grouped together as *paligorscites*. The composition of the group is explained by assuming that they are various mixtures of two components—the one, called **parasepiolite**, has the composition $H_3Mg_2Si_3O_{12}$; and the other, called **paramontmorillonite**, has the composition $H_2Al_2Si_4O_{12} \cdot 5H_2O$.

P. Pusirewsky³⁹ found a massive white or rose-red mineral resembling lithomarge near Nertschinsk. He called it **nefedieffite** or **nefedjewite**, and represented its analysis by the formula $H_4MgAl_2Si_5O_{16}$, or $MgAl_2Si_5O_{14} \cdot 2H_2O$. When confined over

sulphuric acid, about 11.3 per cent. of water is given off in 22 days, and this water is restored on exposure to a moist atm.; at 250°, the mineral loses 19.23 per cent. of water, and 4.73 per cent. more when heated to the m.p. A. Fersmann and L. Zitladeffa represented it by the formula $(\text{Mg}, \text{Ca})\text{Al}_2\text{Si}_5\text{O}_{14} \cdot 7\text{H}_2\text{O}$, or **magnesium aluminium mesopentasilicate**, $\text{MgAl}_2\text{Si}_5\text{O}_{14} \cdot 7\text{H}_2\text{O}$. The sp. gr. is 2.25, and the hardness 1½. Water dissolves 6.2 per cent. of this mineral and acquires an alkaline reaction.

T. S. Hunt⁴⁰ described a green clay-like mineral which he found at Springfield, Penn., and which he called *venerite*—after Venus, the alchemist's symbol of copper. It contains 18.55 per cent. of magnesia; 17.58, cupric oxide; 5.35, ferric oxide; 14.67, alumina; 30.73, silica; and 12.83, water.

G. Steiger⁴¹ obtained a number of thalliferous silicates by the action of thallous nitrate on the zeolites, in a sealed tube at 250°–290°—e.g. *thallo-analcite*; *thallo-leucite*; *thallo-chabazites*; *thallo-stilbite*; *thallo-natrolite*, and *thallo-mesolite*. A. Lamy, and G. Müller⁴² made observations on *thallium glasses* (q.v.) with thallium oxide as one of the bases. H. Flemming dissolved silica in a boiling aq. soln. of thallous hydroxide, and on cooling obtained a white crystalline mass which, when dried over sulphuric acid, lost 5.38 per cent. of water, and no more when heated to 150°. The composition approximates $3\text{Tl}_2\text{O} \cdot 10\text{SiO}_2$. The soln. deposits silica when treated with carbon dioxide, and the hot soln. of thallous carbonate redissolves silica. The soln. becomes turbid on cooling, and clarifies when heated. G. Wyrouboff obtained yellow needles of **thallous silicate**, $\text{Tl}_6\text{Si}_2\text{O}_7 \cdot \text{H}_2\text{O}$, which belong to the tetragonal system, and have the axial ratio $a : c = 1 : 0.3946$. The crystals are not altered by heating to 130°, but at 150° they become opaque, and at a higher temp. lose weight by the expulsion of water. L. Bourgeois⁴² failed to make **silicates of cerium, lanthanum, and didymium** by heating mixtures of the oxides of these elements and silica.

§ 47. The Silicates of the Phosphorus Family

W. Skey¹ melted quartz and other silicates with a mixture of alkali carbonate and phosphate, treated the product with hydrochloric acid, and washed the insoluble matter until the wash-water was free from phosphoric acid. Aq. ammonia dissolves both silica and phosphoric acid from the residue, which is considered to be a mixture of silicic and phosphoric acids or a *silicophosphoric acid*, *silicon phosphate*, or *phosphorus silicate*. For P. Hautefeuille and P. Margottet's *silicyl metaphosphate*, $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$, or $\text{SiO}(\text{PO}_3)_2$, and $\text{SiO}_2 \cdot 2\text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, *vide* silicon phosphates. H. N. Stokes reported $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ to be formed when $\text{SiP}_2\text{O}_6\text{Cl}_2$ is heated until no more phosphoryl chloride is evolved. The **calcium phosphosilicates**—*carnotite*, *staudite*, and *ciplyte*—and the **calcium ferrous phosphosilicate**—*thomsonite*—were discussed, 3, 24, 25, and 30. G. Saring also reported a series, $\text{Ca}_3(\text{PO}_4)_2 \cdot (\text{CaO})_2(\text{K}_2\text{O})\text{SiO}_2$, with the silica replaceable by analogous oxides from the same family group of elements. For the **sodium cerium phosphosilicate**, *erikite*; and the **calcium cerium phosphosilicate**, *britholite*—*vide* the rare earths. O. Meister referred to the uses of **tin phosphosilicate** for weighting silk. S. J. Thugutt obtained *arsenito-sodalite*, $6(\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2) \cdot \text{Na}_4\text{As}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$, or **sodium aluminium arsenito-silicate**, by heating in an autoclave a mixture of kaolinite, arsenic trioxide, sodium hydroxide, and water for 54 hrs. at $207^\circ\text{--}208^\circ$. By using arsenic pentoxide, he obtained acicular crystals of *arsenatosodalite*, $6(\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2) \cdot \text{Na}_3\text{AsO}_4 \cdot n\text{H}_2\text{O}$, or **sodium aluminium arsenitosilicate**, when $n=7$ and 14. G. Flink described a **manganese arsenitometasilicate**, $(\text{HOMn})_2\text{Mn}_2\text{SiO}_3(\text{AsO}_3)_2$, whose X-radiogram corresponded with the hexagonal or rhombohedral symmetry. The mineral was called *dixenite*; the sp. gr. was 4.20; the hardness, 3-4; and the mean index of refraction, 1.96. It was uniaxial and positive. R. B. Gage and co-workers

described a hydrated **manganese arsenatometasilicate** which occurs in veinlets in the normal zinc ore at Franklin, New Jersey, and which they called *schallerite*—after W. T. Schaller. Its companion is $12\text{MnO} \cdot 9\text{SiO}_2 \cdot \text{As}_2\text{O}_5 \cdot 7\text{H}_2\text{O}$, or $9\text{MnSiO}_3 \cdot \text{Mn}_3\text{As}_2\text{O}_8 \cdot 7\text{H}_2\text{O}$, and recalls that of *Friedelite*, $9\text{MnSi}_3 \cdot \text{MnCl}_2 \cdot 7\text{H}_2\text{O}$. It occurs massive, light brown in colour, with a conchoidal fracture, and a vitreous or waxy lustre; its sp. gr. is 3.368, and its hardness 4.5 to 5.0. It fuses with difficulty, gives off water at a low red-heat, and arsenic is evolved at a higher temp. The mineral is uniaxial, and has a perfect basal cleavage. The indices of refraction are $\omega=1.704$, and $\epsilon=1.679$; the optical character is negative. A. Raimondi mentioned a mineral from the vicinity of Tibaya, Arequipa, Peru, which he called *arequipite*, and which he stated to be a **lead antimonatosilicate**. T. L. Walker reported a yellowish-green, pulverulent mineral from Ontario with a composition corresponding with **ferrous antimonatosilicate**, $5\text{FeO} \cdot \text{Sb}_2\text{O}_5 \cdot 5\text{SiO}_2 \cdot 2\text{H}_2\text{O}$. He called it *chapmanite*. It has a sp. gr. 3.58; indices of refraction $\alpha=1.85$, $\gamma=1.96$, and is doubly refracting. It is dissolved by hydrofluoric acid, but not by other acids. G. Flink reported iron-black hexagonal crystals of a **manganese ferrous antimonatosilicate**, $37\text{Mn}_2\text{SiO}_7 \cdot 10\text{Fe}_3(\text{SbO}_4)_2$, from Klingban, Wernland, Sweden. It was named *långbanite*, or *longbanite*. The axial ratio $a:c=1:1.6437$. The sp. gr. is 4.918, and the hardness 6.5.

C. M. Kersten² found a reddish-brown mineral, sometimes yellow or black, at Schneeberg, Saxony, and he called it *eulytine*—from *ελυτος*, easily dissolved or fusible. Analyses were made by C. M. Kersten, and G. vom Rath. The composition represents **bismuth orthosilicate**, $\text{Bi}_4(\text{SiO}_4)_3$. The crystals belong to the cubic system. A. Frenzel found monoclinic crystals of a mineral with the same composition at Johannegeorgenstadt, Saxony. He called it *agricolite*—after G. Agricola. Bismuth orthosilicate thus appears to be dimorphous. According to A. Frenzel, *agricolite* is the arsenical bismuth of A. Breithaupt, and A. G. Werner. The sp. gr. of *eulytine* is 6.106, and the hardness $5\frac{1}{2}$ –6. It is decomposed by hydrochloric acid with the separation of gelatinous silica. A. Frenzel also found a ferruginous bismuth silicate in the same locality, which he called *bismutiferite*; its composition approximated $\text{Bi}_2\text{O}_3 \cdot 2\text{Fe}_2\text{O}_3 \cdot 4\text{SiO}_2$, and its sp. gr. was 4.47.

According to J. J. Berzelius,³ when a vanadyl salt is added to a soln. of an alkali silicate, a pale grey precipitate of **vanadyl silicate** is formed. On exposure to air, this silicate turns brown, and finally green, and at the same time becomes insoluble in water. A. von Lasaulx⁴ noticed a mineral at Salm Chateau, Ardennes, which he called *Mangandisthene* on account of its supposed resemblance to cyanite; and later **ardennite**. F. Pisani called it *dewalquite*—after G. Dewalque. Analyses were made by A. Lasaulx and A. Bettendorff, and F. Pisani; and the results agree roughly with the formula $\text{H}_{10}\text{Mn}_{10}\text{Al}_{10}\text{Si}_{10}\text{V}_2\text{O}_{55}$ or $\text{H}_5\text{Mn}_4\text{Al}_4\text{Si}_4\text{VO}_{23}$, or $8\text{MnO} \cdot 4\text{Al}_2\text{O}_3 \cdot \text{V}_2\text{O}_5 \cdot 8\text{SiO}_2 \cdot 5\text{H}_2\text{O}$, **manganese aluminovanadatosilicate**. Some arsenic may replace vanadium, ferric iron the aluminum, and magnesium and calcium the manganese. The prismatic crystals of *ardennite* are yellow or yellowish-brown in colour. According to G. vom Rath, the rhombic crystals have the axial ratios $a:b:c=0.4663:1:0.3135$. The cleavage 010 is perfect, and the 110-cleavage is distinct. There are partings parallel to *c* with horizontal striations like cyanite. The sp. gr. is 3.577–3.620; and the hardness 6–7. The mineral is pleochroic. A. Michel-Lévy and A. Lacroix made some observations on the optical properties of the mineral. J. Blake⁵ found a *vanadium-mica* at Granite Creek, El Dorado, Cal., and named it *roscoelite*—after H. E. Roscoe. Other finds were reported and analyses made by F. A. Genth, W. F. Hillebrand and co-workers, E. S. Simpson, and H. E. Roscoe. Attempts to derive a formula have not been very successful. H. E. Roscoe concluded that the mineral has the composition $4\text{AlVO}_4 \cdot \text{K}_4 \cdot \text{Si}_2\text{O}_7 \cdot \text{H}_2\text{O}$; F. A. Genth gave $\text{K}_4(\text{Mg},\text{Fe})_2(\text{Al},\text{V})_8\text{Si}_{24}\text{O}_{64} \cdot 8\text{H}_2\text{O}$, or $\text{H}_4\text{K}(\text{Mg},\text{Fe})(\text{Al},\text{V})_4(\text{SiO}_3)_{12}$. F. W. Clarke, and P. Groth assumed that the mineral is compounded of three different silicates; and the former considers that the idealized mineral has the composition **potassium divanadium dihydroalumino-**

triorthosilicate, $\text{KH}_2\text{V}_2\text{Al}(\text{SiO}_4)_3$, or $(\text{V}=\text{SiO}_4)_2=\text{Al}-\text{SiO}_4=\text{KH}_2$, analogous to phlogopite, $\text{KH}_2\text{Mg}_3\text{Al}(\text{SiO}_4)_3$. Roscoelite occurs in minute scales often in stellate or fan-shaped groups coloured dark brown, greenish-brown, or brownish-green. F. E. Wright observed that the corrosion figures agree better with the monoclinic than with the triclinic system. According to F. A. Genth, the sp. gr. is 2.92-2.94; H. E. Roscoe, 2.902; and F. E. Wright, 2.5-3.0. H. E. Roscoe said that the hardness is 1. F. E. Wright found that the cleavage parallel to (001) is perfect and good when parallel to (010); the optic axial angles $2E=42^\circ-69^\circ$ for Na-light, and $34^\circ-60^\circ$ for Li-light; the indices of refraction are $\alpha=1.610$, $\beta=1.685$, and $\gamma=1.704$. The optical character is negative. The mineral is pleochroic. A. des Cloizeaux made some observations on the optical properties. The mineral is but slightly attacked by boiling conc. sulphuric acid; but it is rapidly decomposed by dil. sulphuric acid in a sealed tube at 180° .

According to C. Friedheim and C. Castendyck,⁶ when ammonium vanadate and ammonium silicomolybdate are mixed into a paste with water, interaction occurs, and a clear red soln. is obtained. The intensity of the colour is greatest when the mol. ratio $(\text{NH}_4)_2\text{O} \cdot \text{V}_2\text{O}_5 : 2(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 8\text{H}_2\text{O}$ is 2 : 1, and the soln. deposits large, lustrous red crystals of **ammonium silicovanadatomolybdate**, $3(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 27\text{H}_2\text{O}$ —often 2 cms. in length: These crystals are easily soluble in water, and during their formation become contaminated by sparingly soluble ammonium vanadiomolybdates of varying composition, the latter being separated mechanically. The composition of these ammonium vanadiomolybdates, according to the order of their separation, is as follows: (1) $2(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 5\text{MoO}_3 \cdot 8\text{H}_2\text{O}$, yellow; (2) $(\text{NH}_4)_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot 2\text{MoO}_3 \cdot 4\text{H}_2\text{O}$, yellowish-green; (3) $2(\text{NH}_4)_2\text{O} \cdot 3\text{V}_2\text{O}_5 \cdot 4\text{MoO}_3 \cdot 11\text{H}_2\text{O}$, bright brown; (4) $(\text{NH}_4)_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 2\text{MoO}_3 \cdot 8\text{H}_2\text{O}$, reddish-brown; (5) $4(\text{NH}_4)_2\text{O} \cdot 12\text{V}_2\text{O}_5 \cdot 5\text{MoO}_3 \cdot 24\text{H}_2\text{O}$, brownish-red. The first three of these are microcrystalline whilst the two last form felted needles. On recrystallizing the foregoing ammonium silicovanadatomolybdate from water, either hot or cold, decomposition occurs, and a series of compounds, (1) $3(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 9\text{MoO}_3 \cdot 20\text{H}_2\text{O}$; (2) $3(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 10\text{MoO}_3 \cdot 21\text{H}_2\text{O}$; (3) $3(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 24\text{H}_2\text{O}$, is obtained: these differ little from the parent substance and from one another in colour and crystalline form, but are differentiated by the behaviour of their sat. soln. with silver, lead, and mercurous nitrates. The following table gives their principal physical properties:

Ammonium silicovanadatomolybdate.	Sp. gr. of solid at 18° .	Sp. gr. of saturated soln. at 18° .	Solubility in grams per c.c.
3 : 1 : 1 : 9 + $20\text{H}_2\text{O}$	2.8020	1.21322	0.32016
3 : 1 : 1 : 10 + $21\text{H}_2\text{O}$	2.8044	1.25275	0.35026
3 : 1 : 1 : 11 + $27\text{H}_2\text{O}$	2.8074	1.29266	0.38086
3 : 1 : 1 : 15 + $24\text{H}_2\text{O}$	2.8162	1.43761	0.48097

It is noteworthy that the addition of each mol. of molybdenum trioxide causes a regular increase of approximately 0.00237 unit in the sp. gr. of the solid salt; 0.037 unit for the sat. soln.; and 0.030 unit for the solubility. The salts containing 9MoO_3 and 15MoO_3 can be recrystallized unchanged from water, but that containing 10MoO_3 yields a mixture of the other three salts. Their formulation is illustrated by:

When potassium chloride is added to cold sat. soln. of these salts, crystalline **potassium ammonium silicovanadatomolybdates** are formed in which $2(\text{NH}_4)_2\text{O}$ of the parent substance is replaced by $2\text{K}_2\text{O}$. The physical properties of these complexes are as follows:

Composition.	Sp. gr. of solid.	Sp. gr. of sat. soln. at 18° .	Solubility in grams per c.c.
$(\text{NH}_4)_2\text{O} \cdot 2\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 9\text{MoO}_3 \cdot 20\text{H}_2\text{O}$	2.8648	1.17031	0.24021
$(\text{NH}_4)_2\text{O} \cdot 2\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 10\text{MoO}_3 \cdot 21\text{H}_2\text{O}$	2.8682	1.19184	0.25914
$(\text{NH}_4)_2\text{O} \cdot 2\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 11\text{MoO}_3 \cdot 12\text{H}_2\text{O}$	2.8704	1.21378	0.27914
$(\text{NH}_4)_2\text{O} \cdot 2\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot \text{V}_2\text{O}_5 \cdot 15\text{MoO}_3 \cdot 14\text{H}_2\text{O}$	2.8803	—	—

Similar laws to those obtaining in the case of the original ammonium compounds regulate the change of sp. gr. and solubility of these salts; moreover, the replacement of 4K for 4NH₄ in the original salts increases the sp. gr. in each case by a constant amount equal to 0.0634 unit. On the other hand, the difference between the sp. gr. of sat. soln. of the corresponding ammonium and potassium salts increases by approximately 0.02 unit for each addition of 1MnO₃, whilst a similar increase of 0.01 unit is observed in the solubility.

According to C. Friedheim and W. H. Henderson, silicovanadatotungstates can be obtained by the action of hydrofluosilicic acid on a mixture of tungstate and vanadate. From the product of reaction between ammonium vanadate and ammonium silicotungstate a hydrated **ammonium silicovanadatodecatungstate** of the formula (NH₄)₈SiV₂W₁₀O₄₀.21H₂O has been obtained. It forms reddish-brown, octahedral crystals of sp. gr. 3.428 at 20°. One c.c. of its sat. soln. at 17° contains 0.6652 gm. of the hydrated salt. If the product be not evaporated to dryness, but subjected to fractional crystallization, a salt of the formula (NH₄)₆SiV₂W₉O₃₇.24H₂O is obtained having a sp. gr. 3.396. Two series of salts have been produced, a deca-series with the ratio of SiO₂ to WO₃ 1 : 10, and a series with the ratio 1 : 9. The deca-salts which have been prepared are: hydrated **sodium silicovanadatodecatungstate**, Na₆SiV₂W₁₀O₄₀.29H₂O, in reddish-brown crystals of sp. gr. 3.344° at 20°; the potassium salt, K₆SiV₂W₁₀O₄₀.22H₂O, in the form of reddish crystals with a sp. gr. 3.664 at 20°, the barium silicovanadatodecatungstate, Ba₃SiV₂W₁₀O₄₀.28H₂O, with a sp. gr. 3.66 at 20°. One c.c. of the sat. soln. of the barium salt contains 0.0384 gm. of salt. A **potassium ammonium silicovanadatodecatungstate**, NH₄K₅SiV₂W₁₀O₄₀.23H₂O, soluble to such an extent that 1 c.c. of its sat. soln. contains 0.5072 gm., and an **ammonium potassium barium silicovanadatodecatungstate**, (NH₄)₂K₂BaSiV₂W₁₀O₄₀.25H₂O, which crystallizes in holohedral forms of the regular system, have also been obtained. **Potassium and barium silicovanadatoenneatungstates** are obtained at the same time as the deca-salts. By the action of potassium silicotungstate on potassium vanadate, a salt of the formula K₁₄Si₂V₆W₁₈O₈₀.42H₂O is produced, and it gives the salt K₁₂Si₂V₆W₁₈O₇₉.31H₂O on crystallizing from water; both these are red solids which form crystals belonging to the monoclinic system. The **barium silicovanadatoenneatungstates** are: BaSi₂V₄W₁₈O₈₀.83H₂O and Ba₆Si₂V₄W₁₈O₇₉.50H₂O; they are both red and form rhombic crystals. These salts are all decomposed by conc. acids or alkalis; they give characteristically coloured precipitates with lead, silver, and mercurous salts. Their formulation is illustrated by:

G. Flink⁷ found small octahedral cubic crystals, sometimes hollow and otherwise irregular, associated with *ægirite* at Narsarsuk, Greenland. The mineral was named *chalcolamprite*—from *χαλκός*, copper; and *λαμπρός*, lustre—in allusion to the copper-red metallic iridescence. The composition approximates **calcium fluocolumbatosilicate**, CaSiO₃.CaCb₂O₆F₂, and there are small proportions of the cerium earths, alkalis, manganese oxide, and tantalum oxide also present. The colour is dark greyish-brown inclining to red. No cleavage was observed. The sp. gr. is 3.77, and the hardness 5.5. O. B. Böggild described a mineral from the nephelite-syenite region of Julianehaab, and Kangerdluarsuk, Greenland. It was named *epistolite*—from *ἐπιστολή*, a letter—in allusion to the flat rectangular form and white colour. The composition approximated to that of a **sodium fluocolumbatotitanosilicate**, 10Na₂O.4NaF.(Ca,Mg,Mn,Fe)O.4TiO₂.19SiO₂.5C₂O₆.21H₂O. F. Zambonini discussed the chemical composition; and showed that the water is not constitutional. At 22°, over sulphuric acid of sp. gr. 1.835, the mineral lost 0.66 per cent. of water in 1 hr. and 1.63 per cent. in 143 hrs.; and when heated, the percentage losses were:

	65°	120°	170°	195°	240°	310°	345°	390°	400°
Loss	1.13	2.90	6.35	7.16	7.92	8.86	9.10	9.40	9.47

The total loss was 10.52 per cent. According to O. B. Böggild, the rectangular tabular crystals belong to the monoclinic system, and have the axial ratios $a : b : c = 0.803 : 1 : 1.206$, and $\beta = 74^\circ 42'$. The 001-cleavage is very perfect yielding thin plates, and the 110-cleavage is distinct. The sp. gr. is 2.885; the hardness 1-1.5; the optic axial angle, $2W = 80^\circ$; and the refractive index, 1.67. The optical character is negative. G. Flink⁸ found a chocolate-brown mineral at Narsarsuk, Greenland, which he named *endeolite*—from *ένδεα*, want; and *λίθος*, stone—in allusion to the fact that the analysis showed a considerable loss. The composition approximates **calcium hydroxycolumbatosilicate**, $\text{CaC}_2\text{O}_6(\text{OH})_2 \cdot \text{CaSiO}_3$. The minute octahedral crystals belong to the cubic system. The sp. gr. is 3.44; and the hardness 4. The mineral was also examined by O. B. Böggild and C. Winther.

The minerals epistolite, dysanallyte, pyrochlore, æschynite, euxenite, blomstrandite, priorite, marignacite, and boranskite are either complex columbatotitanates or complex tantalatotitanosilicates, and they have been discussed in connection with the rare earths, and scandium.

§ 48. The Silicates of the Titanium-Lead Family

R. Rieke¹ found that mixtures of silica and titanic oxide give a V-eutectic at about 1530° with 40 per cent. of titanic oxide; and there is here inconclusive evidence of a maximum corresponding with the formation of a **titanium silicate**, $\text{TiO}_2 \cdot \text{SiO}_2$. Observations with titanic oxide and slag or clay (q.v.) were made by H. A. Seger and E. Cramer, H. Ries, C. Bryce, R. Rieke, and G. F. Comstock. The softening temp. of binary mixtures of titanic oxide and clay, by R. Rieke, were:

TiO ₂	0	10	20	30	40	50	60	80	100 per cent.
Temp.	1770°	1740°	1660°	1580°	1530°	1610°	1670°	1660°	1610°

For colloidal titanium silicates, *vide supra*, water-glass. L. Bourgeois obtained crystals containing the dioxides by fusing the dioxides of tin, silicon, or titanium with calcium fluoride.

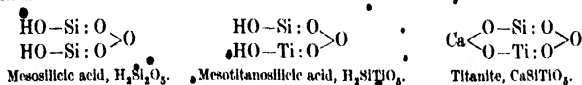

In 1787, M. A. Pictet² described *une nouvelle substance minérale* from Chamouni, which J. C. Delamétherie called *picrite*. M. H. Klaproth analyzed the mineral from Passau, and he named it **titanite**. L. J. M. Daubenton designated the mineral *titane siliceo-calcaire*. A. G. Werner called it *Braunmenakerz*—after Menaccan, Cornwall. H. B. de Saussure referred to it as *schorl rayonnante en goditière*; and R. J. Haüy called a related mineral *sphene*—from σφην, a wedge. The chemical identity of titanite and sphene was established by the analyses of P. L. A. Cordier, M. H. Klaproth, and G. Rose.

An apple-green variety of sphene from Liguria, Apennines, was called by D. Viviani³ *ligurite*; a brown variety from Lewis Co., New York, was called *lederite* by C. U. Shepard; and a red variety from Modmont was called *greenovite*—after G. B. Greenough—by P. A. Dufrenoy. It was also described by A. Breithaupt, J. C. G. de Marignac, A. Delesse, and A. des Cloizeaux, and is coloured by manganese. The Norwegian mineral, the *eucolite-titanite* of T. Scheerer, resembles eucolite or eudialyte, and, according to W. C. Brögger, it contains 2-3 per cent. cerium oxide, and 35 per cent. titanic oxide—*vide rare earths*. A greenish variety from Maronne, Dauphiné, was called by F. de Belleue *semeline* from its resemblance to flax-seed—*semen lini*, and by R. J. Haüy, *spinthere*—from σπυθρη, spark—in allusion to its lustre. A dark brown titanite from Plauen Grund, Dresden, was investigated by P. Groth, and called by J. D. Dana, *grothite*. The sp. gr. is 3.5, and the hardness 6. It contains from 2-5 per cent. of yttria and 31 per cent. titanic oxide. C. W. Blomstrand described a greyish or brown mineral from Alsheda, Småland, Sweden, with a sp. gr. 5, and hardness 3; he called it *alshedite*—*vide rare earths*. P. C. Weibye called a yellowish-green variety occurring in lanceolate crystals at Arendal, Norway, *aspidolite*. A. von Lasaulx applied the term *titanomorphite* to a white altered variety from Lampersdorf, Silesia, which was considered by A. Bettendorff to be calcium titanite but A. Cathrein showed its relationship to titanite. W. von Gumbel applied the term *leucocene* to a greyish-white opaque alteration product of titaniferous iron. A. Cathrein, H. Rosenbusch, and F. Zirkel showed it to be a variety of titanite. C. U. Shepard applied the term *xanthitane* to a yellow alteration product of titanite from Green River, Henderson Co., North Carolina. L. G. Fekins regarded it as a clay with titanic oxide in place of silica. C. U. Shepard called a reddish-brown or black mineral from McDowell Co., North Carolina, *pyromelane*; it is a variety of titanite. A. Breithaupt found yellow monoclinic crystals of a mineral which he called *castellite*, at Hohenkluk Mt., near Probscht. A. Erdmann applied the term *keilhautite*—after B. M. Keilhau—to a dirty brown or black titanosilicate of calcium, aluminium, ferric iron, and the yttrium elements approximating $15\text{CaTiSiO}_5 \cdot (\text{Al, Fe, Y})_2(\text{SiTi})\text{O}_3$, and containing about 26-36 per cent. of titanic oxide, 12 per cent. of ceria earths, and 6-9 per cent. of yttria earths. T. Scheerer called it *yltrotitanite*—*vide titanosilicates*. The monoclinic crystals are isomorphous with those of titanite. The sp. gr. varies from 3.52 to 3.77, and the hardness is 6.5. F. S. Beudant referred to what he called a *minéral de Coromandel*, and this has been identified with the black mineral *tscheffkinite* found by G. Rose in the Ural Mts., Ural. Analyses were made by H. Rose, etc.—*vide rare earths*. C. F. Rammelsberg, and A. des Cloizeaux gave formulae for the mineral. R. C. Price's analysis corresponds with $(\text{Ca, Fe})_2(\text{Di, Ce, La, Fe})_2(\text{Si, Ti})_2\text{O}_{15}$. R. Hermann found thorium present in the Russian mineral, but A. Damour found no thorium in the Indian mineral. The mineral analyzed seems to be an alteration product, and is possibly related to keilhautite.

Analyses were made by M. H. Klaproth,⁴ G. Rose, P. L. A. Cordier, K. Rose, C. Busz, H. Rosales,⁵ F. A. Genth, F. W. Clarke, M. Schmöger, A. Cathrein, J. N. von Fuchs, A. Delesse, W. C. Brögger, J. C. G. de Marignac, J. Lemberg, M. F. Heddle, A. Erdmann, D. Forbes, C. F. Rammelsberg, G. Lindström, C. W. Blomstrand, E. B. Knerr and E. F. Smith, A. E. Arppe, J. Harrington, R. Soltmann, T. S. Hunt, J. Bruckmoser, P. Groth, C. Hintze, H. Lenk, F. Zambonini, etc.

H. Rose⁵ represented titanite by a formula in which the titanic oxide was considered to be basic, but J. J. Berzelius showed that titanic oxide is more probably acidic, and he regarded titanite as a compound of calcium silicate and calcium titanate. C. W. Blomstrand favoured H. Rose's hypothesis and represented the mineral by the formula $\text{Ca} : \text{O}_2 : \text{Si} : \text{O}_2 : \text{TiO}$. F. W. Clarke, F. Zambonini, and O. Hauser, like C. W. Blomstrand, regard titanite as a basic salt, **calcium titanyl orthosilicate**, $\text{Ca}(\text{TiO})\text{SiO}_4$. P. Groth regarded titanite as the calcium salt of

mesosilicic acid, **calcium mesotitanosilicate**, in which part of the silicon is replaced by titanium :

The varieties of titanite which contain sesquioxides are supposed by P. Groth to be mixtures of CaTiSiO_5 and $(\text{Al}, \text{Y})_2\text{SiO}_5$; while C. W. Blomstrand supposed that the complexes Al_2O_3 , Fe_2O_3 , etc., can replace the titanyl group, while bivalent iron and manganese can replace calcium. According to F. W. Clarke, xanthitane approximates to $\text{Al} \equiv \text{Ti}_3\text{O}_7 \equiv \text{H}_3$; tscheffkinite to $(\text{Fe}, \text{Ca})_3\text{Ce}_6\text{Ti}_6\text{Si}_6\text{O}_{32}$; and keilhauite resembles titanite with Ca or TiO replaced by $\text{R}'''(\text{OH})$ or $\text{R}'''(\text{OH})_2$.

Titanite is a pyrogenic mineral and is found as secretions in the oldest siliceous rocks—granites, diorites, syenites, and trachytes. It occurs as a secondary mineral derived from rutile or ilmenite. Titanite does not seem to be easily synthesized. S. Smolensky measured the f.p. of mixtures of calcium metasilicate and metatitanate, and found two breaks in the cooling curve. The upper ones correspond with the crystallization of the mixture to form homogeneous solid soln., and the lower one as produced by the resolution of the solid soln. into the component metasilicates. The f.p. curve has a minimum at 1420° and 33.4 molar per cent. of calcium metatitanate; and the decomposition curve has a maximum at about 1350° . J. J. Ebelmen⁶ observed greenish-yellow crystals of titanite were formed in fused mixtures of titanic oxide, silica, and an alkali or alkaline earth carbonate. F. Fouqué and A. Michel-Lévy made a similar observation. P. Hautefeuille melted a mixture of silica and titanic oxide or rutile with an excess of calcium chloride; if some manganese oxide is also present the resulting crystals of titanite are rose-red. L. Bourgeois, and S. Smolensky also observed the separation of crystals of titanite from various magmas containing silica and titanic oxide. S. Smolensky found the blue artificial crystals enclose small crystals of perovskite. L. Michel found titanite crystals were formed by heating mixtures of titaniferous iron, calcium sulphide, silica, and carbon. P. Sustschinsky, and E. van der Bellen observed titanite crystals were formed after heating to 1400° a mixture of lime, quartz, and rutile.

The color of titanite may be brown, grey, yellow, green, rose-red, and black; and it may be transparent or opaque. The monoclinic crystals vary in habit; they are wedge-shaped and flattened, or prismatic. The mineral is sometimes massive and compact—rarely lamellar. The crystals have been studied by A. des Cloizeaux,⁷ C. Busz, W. H. Miller, V. Goldschmidt, F. Hessenberg, V. von Zepharovich, A. C. Lane, J. C. G. de Marignac, A. Lévy, G. vom Rath, H. B. Patton, A. Streng, H. Credner, P. Groth, H. Traube, R. Helmhaecker, F. Becke, O. Mügge, J. F. Kemp, F. Kretschmer, A. von Lasaulx, A. Schmidt, C. Palache, W. J. Lewis, I. Bachinger, L. J. Igelström, F. J. Wiik, G. Flink, A. von Elterlein, D. F. Wiser, E. Artini, A. Arzruni, J. D. Dana, W. C. Brögger, J. F. Williams, P. von Jeremejeff, etc. The axial ratios, according to A. des Cloizeaux, are $a : b : c = 0.75467 : 1 : 0.85429$, and $\beta = 60^\circ 17'$. Both contact and cruciform penetration twins are common, the former yielding forms apparently hemimorphic. The twinning plane (100) is common, and (001) rare. Polysynthetic twinning lamellae occur sometimes giving rise to easy parting. Parting produced by twinning has been studied by P. von Jeremejeff, G. H. Williams, and O. Mügge. The faces 100 and (112) are often striated. The

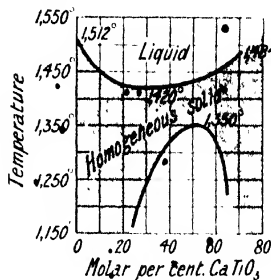

Fig. 185.—Freezing-point curves of Mixtures of Calcium Metasilicate and Metatitanate.

cleavage (110) is distinct; and (100) and $\bar{1}12$ imperfect; in greenovite, the (111) cleavage is easy, and $\bar{1}11$ is less so. According to C. Busz, the **optic axial angle** $2E=57^{\circ} 20'$ with Li-light, $52^{\circ} 29'$ with Na-light, and $47^{\circ} 54'$ with Ti-light; and $2V=29^{\circ} 30'$ with Li-light, $27^{\circ} 0'$ with Na-light, and $24^{\circ} 27'$ with Ti-light. The optic axial angles vary widely, but the effect of composition is not clear. C. Busz observed no marked change in the optic axial angles when the temp. was raised to 200° ; and A. des Cloizeaux found that at 26.5° , $2E=53^{\circ} 34'$; at 171° , $2E=55^{\circ} 48'$.

The **specific gravity** of titanite ranges from 3.4–3.8; that of yttrötitanite is 3.8. The **hardness** is nearly 5; that of yttrötitanite is nearly 6. I. I. Saslavsky studied the **molecular volume** and the **compressibility**. According to R. Cusack, the **melting point** of titanite is 1127° – 1142° ; A. Brun gave 1210° ; S. Smolensky, 1221° ; and C. Doelter, 1230° . A. L. Fletcher found that various titanites begin to show signs of melting at about 1250° and 1350° ; keilhaute melted at 1110° . According to L. Bourgeois, titanite when melted is unstable, and it furnishes perovskite, and calcium metasilicate. G. A. Kenngott said that the coloured varieties become paler when heated, but become darker just before fusion. C. Busz found for the **indices of refraction** of titanite, $\beta=1.8839$ and $\gamma=1.9987$ for Li-light; $\beta=1.8940$ and $\gamma=2.0093$ for Na-light; and $\beta=1.9041$ and $\gamma=2.0239$ for Ti-light. H. Rosenbusch found the **pleochroism** gave a almost colourless; b, yellow with a greenish tinge; and c, reddish-yellow to brownish-red. C. Pulfrich, W. C. Brögger, and T. Liebisch made observations on this subject. The **optical character** is positive. G. W. Hankel studied the **pyroelectric** properties of titanite.

G. A. Kenngott found that the moistened powdered mineral—calcined or uncalcined—reacts alkaline to litmus. The mineral is but partially dissolved by hot hydrochloric acid; it is completely decomposed by sulphuric acid; but best broken down by conc. hydrofluoric acid. According to J. Bruckmoser, hydrochloric acid acts slowly at ordinary temp., and only a part of the titanic acid goes into soln.; at higher temp. the decomposition is faster and almost all the titanic acid goes into soln. The residual silica has the properties of mesosilicic acid, $H_2Si_2O_5$. J. Lemberg found that when titanite is treated with a soln. of magnesium chloride part of the calcium is replaced by magnesium; but no interchange of bases occurs with soln. of sodium carbonate or silicate. A. Johnsen found that the ferrous oxide in sphene could be oxidized by heating in oxygen, or reduced by heating in hydrogen. L. G. Eakins noted the transformation of sphene into xanthitane; P. Mann reported the alteration of titanite into rutile; B. Doss observed pseudomorphs of anatase after titanite; and K. Schneider showed that titanite can be altered into perovskite.

G. Flink⁸ found minute acicular crystals, colourless or tinged violet or brown, in the pegmatite of Narsarsuk, Greenland, and he called the mineral **lorenzenite**—after J. Lorenzen. The analysis by R. Mauzelius corresponds with **sodium titanyl orthosilicate**, $Na_2(TiO)_2Si_2O_7$, in which part of the titanium is replaced by zirconium. P. Groth regarded it as a salt of a polysilicic acid, $Na_2(Ti, Zr)_2Si_4O_9$, with Ti : Zr = 9 : 2. F. W. Clarke gives $4Na_2(TiO)_2Si_2O_7 \cdot Na_2(ZrO)_2Si_2O_7$. F. Zambonini also regarded it as a double salt. The crystals belong to the rhombic system and have the axial ratios $a : b : c = 0.6042 : 1 : 0.3592$. The (120) cleavage is distinct; the sp. gr. 3.42; the hardness 6–6½; the optic axial angle $2E=72^{\circ}$; and the indices of refraction, $\alpha=1.7320$ and $\gamma=1.7786$ for red light; and $\alpha=1.7785$ and $\gamma=1.7876$ for yellow light. The optical character is positive. E. E. Kostyleva described a mineral with the same composition as lorenzenite which was collected by A. E. Firsman in the pegmatite veins of Khibinskii and Lovozerskii tundras. It was named **ramsayite**, after W. Ramsay, the Finnish geologist. The mineral occurs in black or dark brown aggregates; and possesses a metallic lustre. The rhombic crystals have the axial ratios $a : b : c = 1.2116 : 1 : 1.6520$. The (100)-cleavage is perfect; the (110)-cleavage is less good. The sp. gr. is 3.43, and the hardness 6. The mineral readily fuses to a black bead. The mean index of

refraction is 1.9; and the birefringence $\gamma - \alpha = 0.09$; the dispersion is strong; and the pleochroism marked.

G. Flink⁹ found a mineral which he named **narsarsukite** in several localities near Narsarsuk, Greenland. According to F. W. Clarke, C. Christensen's analysis corresponds with **sodium titanium dimesotrisilicate**, $\text{Ti}(\text{Si}_3\text{O}_8\text{Na}_2)_2$, in which about one-sixth of the sodium is replaced by the univalent radicle FeO . F. Zambonini represents it by the formula $6\text{Na}_2\text{Si}_3\text{O}(\text{FeO})_2\text{Ti}_4\text{O}_9$, which is regarded as a salt of tetrakisilicic acid, $\text{H}_2\text{Si}_4\text{O}_9$, where the silicon is in part replaced by titanium and, may be, zirconium. The colour is yellow or reddish-brown. The tabular or cubic crystals belong to the tetragonal system, and have the axial ratio $a : c = 1 : 0.5235$. The cleavage (110) is distinct. The sp. gr. is 2.751, and the hardness 7-7½. The indices of refraction are $\omega = 1.5532$, and $\epsilon = 1.5842$ for Na-light. The optical character is positive. The mineral is not attacked by ordinary acids.

H. A. Brouwer¹⁰ described a mineral from Rustenberg, Transvaal, which he called **molengraaffite** after G. A. F. Molengraaff. The analysis corresponds closely with that of yttritanite; and F. W. Clarke represents its composition as a hydrated **sodium calcium titanosilicate**, $\text{HNa}_3(\text{Ca}_4\text{Ti}_3\text{Si}_4\text{O}_{20})$. The yellowish-brown imperfect crystals are probably monoclinic, possibly rhombic. Polysynthetic twinning is common; the (100) cleavage is perfect; the pleochroism is feeble; the refractive indices are $\alpha = 1.735$, $\beta = 1.770$; the optic axial angle $2E = 50^\circ$; and the optical character is positive.

G. D. Louderback mentioned a titanosilicate of calcium and iron from Joaquin, California. H. Leitmeier called it *joaquinite*. It has not been examined carefully.

G. Flink¹¹ obtained a mineral near Igalliko, Greenland, which he called **neptunite**. A sample from San Benito, California, was named *carlosite* by G. D. Louderback. Analyses by G. Flink, W. M. Bradley, and O. A. Sjöström correspond with $\text{R}'_2\text{R}''\text{TiSi}_4\text{O}_{12}$. The mineral is thus closely related to titanite. F. W. Clarke regarded neptunite as **sodium ferrous titanium trimetasilicate**, with part of the sodium replaced by potassium; and part of the bivalent iron by manganese:

The colour of the mineral is black, but in thin splinters, blood-red. The crystals were described by Ö. B. Böggild, A. Wallenström, G. Nordenskjöld, W. E. Ford, etc. According to G. Flink, the prismatic crystals are monoclinic, with the axial ratios $a : b : c = 1.3164 : 1 : 0.8076$, and $\beta = 64^\circ 22'$. Twinning occurs about the plane (001); the (110) cleavage is distinct. The optic axial angle $2V = 48^\circ$. The optical character is positive. The mineral is pleochroic. The sp. gr. is 3.234, and the hardness 5-6.

P. C. Weibye, and T. Scheerer¹² found a mineral on the islands of the Langesund fiord, Norway, and named it **astrophyllite**—from *ἀστρον*, star; and *φύλλον*, leaf—in allusion to the stellate aggregation and foliated micaceous structure. J. Lorenzen found it at Kangerdluarsuk, Greenland; G. Gürich, on the Los Island, Africa; and G. A. König, at Pike's Peak, Colorado. A yellowish-brown related mineral from Kola, Lapland, was called by W. Ramsay and V. Hackman, *lamprophyllite*. Analyses have been reported by T. Scheerer, F. Pisani, C. F. Rammelsberg, H. Bäckström, G. A. König, and L. G. Eakins. W. C. Brögger writes the formula $\text{R}'_4\text{R}''_4\text{Ti}(\text{SiO}_4)_4$; and P. Groth gave $(\text{K}, \text{Na}, \text{H})_4(\text{Fe}, \text{Mn})_4\text{TiSi}_4\text{O}_{16}$. The composition varies, but the dominant molecule seems to be **sodium potassium ferrous titanium orthosilicate**,

with some ferrous iron replaced by manganese and ferric iron as FeOH'' . F. W. Clarke regarded the Colorado mineral as a mixture of 3 molar proportions of the above with one of $\text{TiOH}(\text{SiO}_4 \equiv \text{FeH})_3$. The colour of astrophyllite is bronze-

yellow or gold-yellow. The crystals are often elongated into thin strips or blades, sometimes arranged in stellate groups. The faces are often striated. A. Norden-skjöld, and A. des Cloizeaux made the crystals rhombic; H. Bücking, monoclinic; and W. C. Brögger, triclinic. The last-named later showed that the variation in the angle and optical character earlier noted is probably without significance, being due to deformation produced by press. The axial ratios of the rhombic crystals are $a : b : c = 1.0098 : 1 : 1.47556$. The (100) cleavage is perfect, and (001) very imperfect. The percussion figure on a cleavage surface has two rays crossing at $81^\circ-65^\circ$. A. des Cloizeaux gave for the optic axial angle $2H_0 = 118^\circ-124^\circ 11'$ with the red ray, and $2V = 103^\circ 25'$; H. Bücking gave $2H_0 = 122^\circ 18'$ for the Li-ray and $124^\circ 52'$ for the Na-ray; and W. C. Brögger, $2H_0 = 114^\circ 37\frac{1}{2}'-123^\circ 28'$, and $2E = 160^\circ$ for white light. A. des Cloizeaux found that raising the temp. to 146.5° produced no perceptible change in the optic axial angles. The sp. gr. of astrophyllite is 3.324-3.375; and the hardness is 3. A. Michel-Lévy and A. Lacroix gave for the indices of refraction $\alpha = 1.678$, $\beta = 1.703$, and $\gamma = 1.733$ for yellow light. The crystals are pleochroic, a = deep orange-red, b = citron-yellow, and c = orange-yellow. The optical character is positive. The mineral is decomposed by hydrochloric acid with the separation of flocculent silicic acid.

According to F. W. Clarke, the minerals *johnstrupite* and *rinkite*—vide titanium silicates—can be regarded as fluoriferous astrophyllites. In the former, a little zirconia, thorium, and cerium may replace some titania. Johnstrupite is essentially a hydrated sodium calcium titanium orthosilicate, with some cerous fluoride in place of sodium:

and *rinkite* is supposed to be a mixture of 3 mols of $\text{Ti}(\text{SiO}_4) \equiv (\text{CaNa})$ and 2 mols of $\text{TiF} \equiv \text{SiO}_4 - \text{Ti}[\text{SiO}_4 \equiv \text{Ca}(\text{CeF}_2)]_2$. He also represents *mosandrite*—rare earths—by $4\text{Rf}(\text{SiO}_4 \equiv \text{CaH})_2 \cdot \text{R}(\text{OH})(\text{SiO}_4 \equiv \text{HNa}[\text{Ce}(\text{OH})_2]_2)$, where R is used in place of Ce'' : $\text{Zr} : \text{Ti} = 1 : 2 : 2$.

S. Smolensky¹³ found that barium metasilicate and metatitanate give a complicated system, but determined only the m.p. of binary mixtures with the following molar percentage proportions of BaTiO_3 :

	0	10.8	21.4	31.9	42.1	52.2	62.1	71.8
m.p.	1470°	1461°	1450°	1420°	1405°	1376°	1384°	1409°

G. D. Louderback found crystals of a mineral which he called *benitoite* associated with the neptunite and natrolite near the head waters of the San Benito River, California. The composition approximates **barium titanotrisilicate**, $\text{BaTiSi}_3\text{O}_9$; this would make benitoite the barium salt of teterosilicic acid, $\text{H}_2\text{Si}_4\text{O}_9$, with an atom of silicon replaced by one of titanium. E. H. Kraus considers the mineral as a metasilicate isomorphous with beryl, $\text{Ba}_2\text{Ti}_2(\text{SiO}_3)_6$, but W. C. Blasdale has shown that the titanium is not likely to be basic. F. W. Clarke regards benitoite as a *barium titanyl mesotrisilicate*, $\text{TiO} \equiv \text{Si}_3\text{O}_8 \equiv \text{Ba}$. The ditrigonal crystals were found by G. D. Louderback to have the axial ratio $a : c = 1 : 0.17326$; C. Palache gave $1 : 0.7319$; and B. Jezek, $1 : 0.7353$. F. Rinne found that the X-radiograms of benitoite correspond with the ditrigonal bipyramidal class. The colour is usually sapphire blue to light blue; colourless or green crystals are rare. The mineral is used as a gem-stone. G. D. Louderback, and B. Jezek gave $3.64-3.67$ for the sp. gr., and $6\frac{1}{4}-6\frac{1}{2}$ for the hardness. C. Hlawatsch found the indices of refraction for the D -line to be $\omega = 1.756$, and $\epsilon = 1.802$; C. Palache gave $\omega = 1.77$, and $\epsilon = 1.80$. The mineral is strongly dichroic, ϵ being deep blue, and ω , colourless. Benitoite is insoluble in hydrochloric, but is decomposed by hydrofluoric acid.

G. Flink¹⁴ found a white or greyish-blue mineral which he called **leucosphenite**—from *λευκός*, white; and *σφην*, a wedge—occurring sparsely in the pegmatite at Narsarsuk, Greenland. The composition approaches that of petalite or eudidymite; and R. Mauzelius' analysis corresponds with $\text{Na}_2\text{Ba}(\text{TiO})_2(\text{Si}_2\text{O}_5)_5$, which makes leucosphenite **sodium barium titanyl mesodisilicate**. P. Groth writes the formula $\text{BaNa}_4\text{Ti}_2\text{Si}_{10}\text{O}_{27}$, where the titanium is anionic. F. W. Clarke writes

the formula $\text{Na}_3\text{Ba}_2\text{Ti}_4(\text{Si}_3\text{O}_8)_7$. F. Zamboni makes leucosphenite a double salt, $\text{BaSi}_4\text{O}_9 \cdot 2\text{Na}_2\text{TiSi}_3\text{O}_9$. G. Flink found that the monoclinic crystals have the axial ratios $a:b:c=0.5813:1:0.8501$, and $\beta=93^\circ 23'$. The crystals are wedge-shaped. Twinning is common; the twinning plane is (001); the cleavage (010) is distinct. The sp. gr. is 3.05; and the hardness 6.5. The indices of refraction for the red ray are $\alpha=1.6401$, $\beta=1.6572$, and $\gamma=1.6829$; and for the yellow ray, $\alpha=1.6445$, $\beta=1.6609$, and $\gamma=1.6878$. The optic axial angle $2V=79^\circ 26'$ for the red ray, and $77^\circ 4'$ for the yellow ray. The optical character is negative. Leucosphenite is decomposed by hydrofluoric acid. A titanium ultramarine of a green colour has been reported by F. Singer¹⁵ to be formed when the zeolitic substance, with a composition approximating $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{TiO}_2 \cdot 4\text{H}_2\text{O}$, is treated with sodium sulphide.

S. Smolensky¹⁶ measured the f.p. of binary mixtures of manganese metasilicate and metatitanate, and obtained the curves shown in Fig. 186. There is a eutectiferous series with a eutectic at 1120° and 22.3 molar per cent. of MnTiO_3 . Solid soln. are formed with from 38.3 to 100 molar per cent. of manganese metatitanate but not at the other end of the series. A decomposition of the solid soln. occurs at about 1050° .

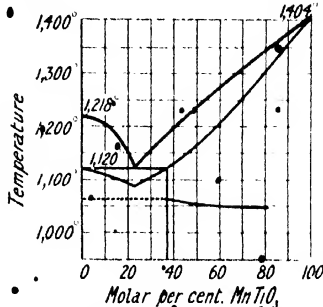

FIG. 186.—Freezing-point Curves of Mixtures of Manganese Metasilicate and Metatitanate.

A. Breithaupt¹⁷ found black prismatic crystals of a mineral associated with the arvedsonite of Greenland. He called it *kölbingtonite* after F. Kölbinger—and another similar mineral was called *enigmatite*—from *αἰνύμα*, an enigma—and regarded as a pseudomorph after kölbingtonite. *Enigmatite* had a sp. gr. 3.833–3.863, and kölbingtonite a sp. gr. 3.60–3.61. J. Lorenzen showed that the crystals of *enigmatite* cannot be pseudomorphs; and W. C. Brögger showed that kölbingtonite is probably a parallel intergrowth of arvedsonite and *enigmatite*. Analyses of *enigmatite* were reported by W. C. Brögger, and H. Förstner. The mineral is essentially **sodium ferrous titanometasilicate**, with part of the silicon replaced by titanium, and a small admixture of a basic salt, $\text{RFe}''_2\text{SiO}_6$. J. Söllner represented it as a mixture of $\text{Fe}''_2\text{Fe}''_4(\text{Si}_2\text{O}_7)_{12}$ and $(\text{Na}_2\text{K}_2\text{Fe})_4(\text{Si,Ti})_4\text{O}_{12}$. The crystals approximate closely to those of the monoclinic amphiboles in habit, angle, and form. The prismatic crystals of *enigmatite*, however, are triclinic. J. D. Dana recalculated H. Förstner's values for the axial ratios, and obtained $a:b:c=0.6778:1:0.3506$, and $\alpha=90^\circ$, $\beta=76^\circ 19'$, and $\gamma=90^\circ$. Contact twinning on the (010) plane is common, and there are twinning lamellae giving striations on the terminal planes and on the (100) face. The prismatic cleavage is distinct. The sp. gr. is indicated above. The optic axial angle $2E=60^\circ$, according to W. C. Brögger. The optical character is positive. The pleochroism is well-marked. The radioactive haloes were studied by O. Mügge.

J. Söllner obtained triclinic crystals of a black or brownish-black mineral isomorphous with *enigmatite* but containing less ferrous oxide and alkalis, and approximating $(\text{Ca},\text{Na},\text{K})_4\text{Mg}_4\text{Fe}_2\text{Fe}''_4(\text{Si,Ti})_4\text{O}_{12}$. The mineral was first found in the Rhön district, and called *rhönite*. The crystals are short prisms or tabular; the twinning plane is (010); the cleavages parallel to (110) and to (110) are good. The sp. gr. is 3.587. H. Förstner found minute black crystals in the liparite lavas of the Island of Pantelleria whose ancient name was *Cossyra*; and he called the mineral *cossyrite*. Analyses were made by J. Söllner, and H. Förstner. The composition and crystal form were shown by W. C. Brögger, J. Söllner, B. Gossner, and H. Förstner to be like those of *enigmatite*. The sp. gr. is 3.802; the hardness is 5½; the index of refraction is near that of hornblende, and the double refraction is feeble. The mineral is but little affected by the ordinary acids, but is completely decomposed by hydrofluoric acid.

For the so-called *titanolivine*, $(\text{Mg,Fe})_2(\text{Si,Ti})\text{O}_4$, *vide* olivine. There are numerous titaniferous pyroxenes and amphiboles—e.g. the triclinic *ænigmatite* (*q.v.*). A number of garnets carrying titanium have been reported by A. Damour,¹⁸ A. Knop, A. Stromeyer, W. Petersson, A. Claus, G. A. König, F. A. Genth, and A. Sauer. The proportions here run up to 10.84 per cent. TiO_2 . The *ferrotitanite* of J. D. Whitney had 22.10 per cent. TiO_2 . C. U. Shepard called this mineral *schorlomite*, owing to its resemblance to schorl. The analyses approximate $\text{Ca}_3(\text{Fe,Ti})_2(\text{Si,Ti})\text{O}_{10}$, or *calcium diferric tetrorthotitanatosilicate*. The sp. gr. is 3.81–3.88; and the hardness 7–7½. It furnishes trapezohedral and dodecahedral crystals belonging to the cubic system. C. U. Shepard regarded the mineral as hydrated silicate of ferric oxide, yttria, and possibly thorium; but C. F. Rammelsberg, and G. A. König showed that the mineral is really a garnet. N. Nordenskjöld obtained a mineral from Ivaara, Finland, which he called *ivaarite*. It closely resembles schorlomite. H. S. Washington gave for the refractive index 1.94; for *ivaarite*, 2.01; and for melanite, 1.86–1.88.

R. Riecke¹⁹ made some observations on the fusibility of mixtures of zirconia and clay. The history of **zircon** is discussed in connection with the history of zirconium (*q.v.*). Although zircon is not itself readily altered, it is gradually hydrated and transformed by weathering, forming a whole series of products containing 3–70 per cent. of zirconia; at the same time other bases like alkalis, alkaline earths, and the rare earths have been taken up, producing minerals of great complexity. Most of them have been reported from Norway, Sweden, Greenland, and Russia. Some of the altered forms have received special names; very few of them are of general interest. T. Scheerer²⁰ described a brown mineral from Hitterö, Norway, which he called **malacone**—from *μαλακός*, soft—in allusion to its being softer than ordinary zircon. A. des Cloizeaux found malacone at Chanteloube, Haute Vienne, occurring in thin plates 3–4 mm. thick; and occasionally with crystals on their surface; and he regarded it as hydrated zircon. C. F. Rammelsberg said that without doubt malacone is *eine Pseudomorphose des Hydrate nach der wasserfreien Verbindung*. Analyses were made by T. Scheerer, A. Hermann, E. S. Kitchin and W. G. Winterson, A. C. Cumming, R. Hermann, and A. E. Nordenskjöld. Malacone contains from 47–67 per cent. of zirconia, about 32 per cent. of silica, 3–4 per cent. of water, and traces of yttria, magnesia, iron oxide, and manganese oxide. V. M. Goldschmidt and L. Thomassen found that malacone from Hitterö, Norway, contained hafnium. Idealized malacone approximates to **zirconium dihydroxytriorthosilicate**, $\text{Zr}_3(\text{SiO}_4)_3 \cdot \text{H}_2\text{O}$ —*vide infra*. E. S. Kitchin and W. G. Winterson stated that it is one of the few minerals known to contain argon. From the radioactivity of the mineral, R. J. Strutt suggested some uranium is present, and E. S. Kitchin and W. G. Winterson found 0.33 per cent. U_3O_8 , but A. C. Cumming found none. A brownish-yellow powder from Rosendal, Finland, was shown by A. E. Nordenskjöld to resemble malacone very closely. The crystal. of malacone were described by T. Scheerer, E. Zschlau, and W. C. Brögger. The sp. gr. is 3.9–4.05, and the hardness 6.5.

W. J. Knowlton²¹ found a mineral in the granite at Rockport, Mass., and he named it **cyrtolite**—from *κυρτός*, bent—in allusion to the curvature of the pyramidal faces of the tetragonal crystals which appear like rhombic dodecahedra. Analyses were made by C. W. Blomstrand, J. P. Cooke, F. A. Genth and S. L. Penfield, and A. E. Nordenskjöld. The mineral appears to be a brownish-red variety of malacone with zirconia from 60–67; of silica, 26–28; ceria, 1.4–2.1; iron oxide, 2.5; water, 2.2–4.7 per cent. Although under ordinary conditions the dominant constituents of minerals are alone determined in analyses, the composition appears exceedingly complex when the constituents present in smaller proportions are determined. For example, the following is compiled from three analyses of cyrtolite from Devil's Head Mountain, Colorado, by W. F. Hillebrand:

SiO_2	Ta_2O_5	SnO_2	ZrO_2	ThO_2	Ce_2O_3	$(\text{La,Di})_2\text{O}_3$	Er_2O_3	Y_2O_3
19.90	0.71	0.03	47.81	1.16	0.06	0.19	4.69	2.63
Fe_2O_3	MnO	CaO	MgO	K_2O	Na_2O	H_2O	P_2O_5	F
5.45	0.46	2.02	0.12	0.19	0.46	12.61	1.44	0.36

G. Hevesy and V. T. Jantzen found 9 per cent. of hafnia in cyrtolite from the United States. This was previously included in analyses with the zirconia. F. W. Clarke represented the mineral as **zirconium octahydroxylorthosilicate**, $\text{Zr}(\text{SiO}_4)_2(\text{OH})_2[\text{H}(\text{ZrO}_2\text{H}_2)]_2$ - *vide infra*. The sp. gr. is 3.29-4.04; and the hardness 5.5-5.5—after ignition, the hardness is 7-7.5. C. W. Blomstrand found a cyrtolitic mineral near Ytterby to which H. Backström applied the term *anderbergite*. The mineral is honey-yellow to coal-black in colour and is microscopically amorphous, but with a pseudomorphous tetragonal form. It was analyzed by A. E. Nordenskjöld, and G. K. Almström; it approximates $2\text{CaO} \cdot \text{R}_2\text{O}_3 \cdot 6\text{ZrO}_2 \cdot 8\text{SiO}_2 \cdot 12\text{H}_2\text{O}$. F. W. Clarke's view of the constitution is indicated below. The sp. gr. is 3.28-3.33; and the hardness 5.5-6. D. Forbes and T. Dahll found at Alve and Narestö, Norway, crystals of a reddish-brown mineral which they called **alvite**. It also occurs at Ytterby, Sweden. • It is a zirconosilicate of the rare earth metals, calcium, magnesium, beryllium, copper, aluminium, and zinc, and a small proportion of water. V. M. Goldschmidt and L. Thomassen found that alvite from Hitterö, Norway, contained some rare earths, tungsten, yttrium, thorium, manganese, and hafnium; and they represented its composition by the formula $(\text{Zr}, \text{Hf}, \text{Th})\text{O}_2 \cdot \text{SiO}_2$. († Hevesy and V. T. Jantzen found 16 per cent. of hafnia in alvite from Kragerö and this was formerly regarded as zirconia. The analysis of the Ytterby mineral was reported by A. E. Nordenskjöld, and it appears different from that of D. Forbes and T. Dahll—but the analyses by the latter is not satisfactory. B. Szilard, W. C. Brögger and co-workers, and R. J. Strutt have made some observations on this subject. The rare earths amount to 3.48 per cent.; the yttria earths, 22 per cent.; and zirconia, 30.5-61.4 per cent. F. W. Clarke's view of the composition is indicated below. The crystals are tetragonal, optically isotropic, forming pseudomorphs after zircon. The sp. gr. is 3.3-4.3; and the hardness 5-6. P. C. Weibye²² found dark reddish-brown crystals in gneiss near Kragerö, Norway, to which he applied the term **tachyphalite**—from *ταχύς*, quick; and *ἀέρος*, flying ~~to~~ pieces—in allusion to the ready separation of the mineral from the gangue when struck. N. J. Berlin's analysis gave: zirconia, 38.96 per cent.; silica, 34.58; thoria, 12.8; iron oxide, 3.7; and water, 8.5 per cent. Its sp. gr. is 3.6; hardness, 5.5. G. Forchhammer applied the term **oerstedite**—after H. C. Ørsted—to a reddish-brown mineral from Arendal, Norway. It has 68.9 per cent. of zirconia; 19.7, silica; 2.05, magnesia; 2.61, lime; and 5.5 of water. • Its sp. gr. is 3.629, and hardness, 5.5. P. C. Weibye found that the mineral always crystallized in the form of zircon. R. Hermann applied the term **auerbachite**, to a brownish-coloured crystalline mineral found by J. Auerbach in Mariupol, Russia. It has 55.18 per cent. zirconia; 42.9, silica; 0.93, iron oxide; and 0.95, water. The sp. gr. is 4.06; and the hardness, 6.5. The mineral was also studied by N. von Kokscharoff, P. von Jeremejeff, and J. D. Dana.

Analyses of zircon have been reported by M. H. Klaproth,²³ L. N. Vauquelin, M. H. Cochran, C. W. Nylander, A. Corsi, A. Liversidge, F. A. Genth, G. A. König, K. von Chrustschoff, A. Osann, J. J. Berzelius, T. S. Hunt, C. F. Rammelsberg, G. Grattarola, G. Woitschach, G. P. Tschernik, P. J. Holmquist, A. Schmidt, A. Knop, C. M. Wetherill, W. Gibbs, J. F. John, W. Henneberg, C. F. Chandler, J. P. Cooke, W. J. Knowlton, A. Damour, R. Hermann, N. J. Berlin, etc. G. von Hevesy and V. T. Jantzen reported 1.3-6 per cent. of hafnium (or cerium) dioxide in samples of zircon from various localities. • The composition of the purer varieties of zircon approximates to that of **zirconium orthosilicate**, ZrSiO_4 , or $\text{ZrO}_2 \cdot \text{SiO}_2$, with up to about 3 per cent. of thoria, yttria, and other oxides. Zircon is either an isomorphous mixture of the two oxides or a zirconium silicate. Since the ratio $\text{ZrO}_2 : \text{SiO}_2$ in the various analyses varies between 39:44 and 30:65, and since the mixture 1:2 behaves very like zircon, C. Doelter and E. Dittler²⁴ incline to believe that zircon is an isomorphous mixture of the two oxides. W. C. Brögger regards zircon as zirconyl metasilicate, $\text{ZrO} \cdot \text{SiO}_3$, and, in agreement with P. J. Holmquist, writes this graphically $\text{O}=\text{Zr}=\text{O}_2=\text{Si}=\text{O}$. This view is based on the close morphological relations between zircon, rutile, and cassiterite. The minerals cassiterite, SnSnO_4 ; rutile, TiTiO_4 ; zircon, ZrSiO_4 ; thorite, ThSiO_4 ; polianite, MnMnO_4 ; plattnerite, PbPbO_4 ; and xenotime, YPO_4 , are analogous in form and composition even if they are not strictly isomorphous. The absence of any information as to the mol. wt. of a mineral is tacitly considered to be a license to adopt any desired mol. wt. F. W. Clarke assumes the tetradic association $\text{Zr}_4(\text{SiO}_4)_4$, in order to harmonize the constitution of zircon with those of some related minerals.

The space lattice of the zircon family, as revealed by the X-radiograms of L. Vegard, and C. M. Willboms, shows that the silicon and zirconium atoms are arranged as atomic centres in tetragonal lattices of the diamond type, and the tetragonal arrangement is not produced by the atomic centres but by the tetragonal arrangement of the oxygen atoms. Consequently, the lattice has a kind of mol. structure with units of the type MO_2 , where M represents an atom of silicon, zirconium, titanium, or tin; the three atoms form one mol. and are situated on a straight line with M in the central position. The straight line or mol. axis is always perpendicular to the tetragonal axis. The distance apart of the atoms, and the geometrical relations of the lattice vary with the nature of the central atom M. This supports the view that the groups MO_2 form chemically bound molecules. The space lattice of xenotime does not belong to the zircon type, for there is a different arrangement of the oxygen atoms. In xenotime, the oxygen atoms are arranged in groups of four around each atom of phosphorus so that the space lattice gives the constitutional formulae YPO_4 and $\text{ZrO}_2 \cdot \text{SiO}_2$ respectively for xenotime and zircon. The specimens of the mineral, thorite examined by L. Vegard preserved the outer form isomeric with zircon, but internally, the crystals had become isotropic. The space lattice was completely broken down, and no X-radiogram could be obtained. The absolute dimensions of the space lattices of the zircon group are indicated in Table XXXI. M. L. Huggins found the structure of zircon resembles that of

TABLE XXXI.—DIMENSIONS OF THE SPACE LATTICES OF THE ZIRCON FAMILY.

	Crystal axes in cm.			Volume in c.c. atom.	Distance from the O to the M atom in cm.
	a	c	a : c		
Zircon, $\text{ZrO}_2 \cdot \text{SiO}_2$	9.20×10^{-8}	5.87×10^{-8}	1 : 0.639	4.97×10^{-22}	$\frac{\text{Zr}}{\text{Si}} \ 2.71 \times 10^{-8}$

rutile; and A. Johnsen discussed the structure and symmetry of this family of minerals.

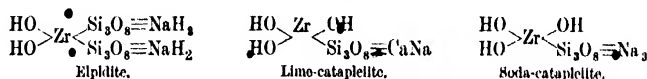

Considerable amounts of ferric oxide are present in some zircons: thus, G. A. König found 9.2 per cent. in a zircon from Pike's Peak, Colorado, and this gave for the formula $\text{Zr}_{10}\text{Fe}_2\text{Si}_{10}\text{O}_{43}$. Ferric oxide is present in all natural zircons—may be in solid soln. or as an iron zirconate. Similarly the cerium and yttrium, often present, may be there as a solid soln. of silicate or zirconate of these elements. Anderbergite may be regarded as having a composition:

Alvite may be regarded as a mixture of two compounds, $\text{Zr}(\text{SiO}_4)_4(\text{ZrOH})_4$ plus $\text{Zr}(\text{SiO}_4)_4(\text{BeOH})_{12}$. According to this hypothesis, these minerals are salts of a dodecabasic *zirconatosilicic acid*, $\text{H}_{12}\text{ZrSi}_4\text{O}_{12}$. The water present in many zircons may represent zircon altered by hydration. The dehydration experiments of F. Zambonini fit very well with the assumption that hydrated zircon is simply zircon with variable amounts of dissolved water. F. W. Clarke, on the other hand, assumes that the water is intrinsically associated with the molecule. Thus, he regards malacone as the first hydration derivative; and the analyses of some cyrtolites correspond with a still further stage, namely, $(\text{HO})_2\text{Zr} \cdot \text{H}(\text{ZrO}_2\text{H}_2)_{1/2}$, in which part of the ZrO_2H_2 may be replaced by other bases. Thus, anderbergite has a composition corresponding with:

The minerals elpidite, lime-catapleite, and soda-catapleite represent more advanced stages in the hydration and replacement of zircon; thus:

On the other hand, F. Zambonini regards the water in these minerals as extrinsic and not intrinsic or constitutional; and he regards elpidite as a metasilicate, $\text{Na}_2\text{ZrSi}_3\text{O}_{15} \cdot 3\text{H}_2\text{O}$, and catapleite, $\text{Na}_2\text{ZrSi}_3\text{O}_{15} \cdot 2\text{H}_2\text{O}$, that is, $\text{O} = \text{Zr} \text{---} \text{Si}_3\text{O}_8 \text{---} \text{Na}_2 + 2\text{H}_2\text{O}$.

Zircon is common in nearly all kinds of igneous rocks, particularly the more siliceous ones like granite, syenite, diorite, etc. H. Thürauf,²⁵ W. C. Brögger, T. L. Watson and F. L. Hess, etc., have discussed this subject. It seems to be one of the earliest minerals to crystallize from cooling rock magmas. Instead of zircon, complex silicates like the zircon pyroxenes may be formed. Zircon has been repeatedly obtained synthetically. A. Daubrée, H. St. C. Deville, and H. Caron made it by heating zirconia in a current of silicon tetrachloride. H. St. C. Deville also made it by heating a mixture of zirconia and quartz in the same gas. The first stage of reaction is supposed to involve the formation of zirconium fluoride, which reacts with quartz regenerating silicon tetrafluoride. A small quantity of this gas produces an indefinitely large amount of zircon. P. Hautefeuille and A. Perrey obtained zircon by heating a mixture of silica, zirconia, and lithium molybdate to 800°; and S. Stevanovic employed a similar process. W. E. Gürtler used sodium metaborate as *agent minéralisateur*. K. von Chrustschoff heated a mixture of gelatinous silica and gelatinous zirconia in a steel bomb at a temp. approaching redness. C. Friedel and E. Sarasin used a somewhat similar process.

Small crystals of zircon are not uncommon in granites, basalts, syenites, diorites, and many crystalline or igneous siliceous rocks. It is rarely found in basic igneous rocks like the gabbros and peridotites. Well-shaped crystals are also found among the heavier grains of sands, etc., derived from the disintegration of these rocks. Crystals of zircon are common in auriferous and gem-sands, particularly those of Southern India, Ceylon, and Brazil. Zircon is mined in North Carolina, where in the Henderson county it is extracted from a decomposed granite.

The colour of zircon has attracted some attention. The crystals may be transparent or opaque, and colourless or coloured pale yellow, pale grey, orange-yellow, yellowish-green, brownish-yellow, reddish-brown, or red. Some thin sections are violet-blue. The colours are sometimes distributed zonally. F. Sandberger²⁶ attributed the red colour of hyacinths to the presence of a small quantity of cuprous oxide. This is improbable. W. Hermann showed that oxide of iron is the probable colouring agent of zircon; and that in green zircons he found chromium and manganese oxides are present. T. Wolff, F. Sandberger, and G. vom Rath observed that rose and flesh-coloured crystals become paler when exposed to light; and G. F. Richter, and L. Michel noted that the hyacinth-red variety becomes brownish-red when exposed to light—rapidly in sunlight, slowly in diffuse daylight; when kept in darkness, the original colour is partially restored. C. Doelter observed but little change in the colour when exposed to the arc-light, but in ultra-violet light, the colour becomes paler. T. Wolff, K. Simon, F. Sandberger, and G. vom Rath found that, when heated, the colour is weakened. B. R. Geijer also observed that the colour is destroyed by heat. C. A. S. Hofmann obtained similar results, and W. Henneberg showed that thermoluminescence accompanies the decolorization by heat, and the effect is not dependent on the colour. G. A. Kenngott found that by heat

reddish-brown crystals became brownish-yellow and remained transparent. H. Traube found that yellow and red crystals were decolorized by heat, and the colour was not restored on cooling. C. Doelter found that the temp. at which decolorization occurs in air is about 700° . E. Newbery and H. Lupton found that some Tasmanian hyacinths became nearly colourless when heated in a hard glass tube, and quite colourless in the Bunsen flame; some French specimens remained yellow after 5 mins' heating in the blowpipe flame. The colour was restored quickly with the Tasmanian specimens, and slowly with the French specimens, on exposure to radium rays. All the crystals which had been recoloured by radium lost their colour at a temp. lower than was originally required to decolorize the natural crystals. G. Spezia concluded that the coloration is not produced by organic matter, and that the colour changes are not simply produced by raising the temp., but that the colour of zircon is produced by the state of oxidation of the iron—varying when heated in oxidizing or in reducing atm. K. von Kraatz-Koschlaue and L. Wöhler said that when iron is present, it is not uniformly distributed and cannot therefore be the cause of the uniform coloration of these minerals; and they showed that the loss in weight which occurs on heating corresponds with the loss of organic matter. G. Spezia emphasized the fact that heating the decolorized mineral in an oxidizing atm. restores the colour; and when this is again heated in a non-reducing atm. it is not decolorized. Again, some crystals are not decolorized if heated in a non-reducing medium. He thinks that when organic matter is present, it affects the coloration by iron as a reducing agent, but does not colour the mineral *per se*. S. Stevanovic confirmed G. Spezia's observations, and concluded that there are two tinctorial agents in the hyacinth—one is a volatile organic substance which exerts a reducing action so that crystals containing only this agent remain after its removal. The other agent is non-volatile, can be reduced and oxidized, and is possibly a compound of iron. From his experiments on the action of radium rays, C. Doelter concluded that it is unlikely that an organic substance is the cause of the coloration; rather is it more probably a colloidal substance which is not stable when heated.

The euhedral crystals of zircon are commonly short prisms, Fig. 187, but frequently long prisms are found. Large crystals weighing nearly 6 kgrms. have been found at Renfrew, Ontario. Anhedral crystals are not common in igneous rocks, showing that the zircon must have been one of the earliest crystals to separate in the magma; it is also common as inclusions in other minerals. The larger crystals sometimes

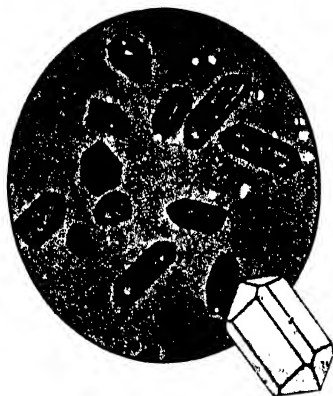

FIG. 187.—Crystals of Zircon.

contain inclusions of other minerals—possibly apatite and glass. F. Rutley²⁷ explained the raising of the sp. gr. by calcination as an effect of the expulsion of the liquid (water) and gas inclusions. The crystal belongs to the ditetragonal dipyramidal class of the tetragonal system, and, according to A. T. Kupffer, have the axial ratio $a : c :: 1 : 0.640373$. The crystals were examined by J. B. L. Romé de l'Isle, R. J. Haüy, and F. Mohs, etc. Numerous other observations have been made on the form of the crystals. The angle $(111) : (110)$ with zircon, ZrSiO_4 , is $47^{\circ} 50'$; with rutile, TiTiO_4 , $47^{\circ} 40'$; and with cassiterite, SnSnO_4 , $46^{\circ} 27'$. This resemblance is taken to indicate that if these minerals are not strictly isomorphous, they are at least analogous in form and composition. **Twinning** is rare. The composition plane is (101) . The geniculated twins resemble those of rutile and cassiterite. They are not found with crystals in igneous rocks. Large twinned crystals come from

St. Jerome, Quebec. The cleavage parallel to 110 is imperfect and that parallel to (111) is less distinct. H. Traube studied the corrosion figures with molten potassium hydrofluoride; and C. Doelter and E. Hussak, etching with fused basalt. G. Grattarola found the optic axial angles $2E=19^{\circ} 44' 10''$, and $2V=10^{\circ} 1' 28''$. The X-radiogram of zircon has been discussed in connection with the space-lattice—*vide supra*.

The specific gravity of zircon has attracted some attention. C. A. S. Hofmann²⁸ made a collection of the determinations which had been made. W. Henneberg, and L. F. Svanberg noted that the sp. gr. was augmented by calcination. A. Damour emphasized the fact that the sp. gr. of different zircons ranges from 4.04 to 4.674; and he noted that the sp. gr. is increased by calcination without change in the chemical composition. He concluded that the zircon exists in different allotropic states. A. H. Church made a similar observation. H. de Sénarmont, and A. des Cloizeaux then showed that the refractive indices of light and heavy zircons are different. R. Köchlin tried to establish a relation between the sp. gr. and colour.

R. Köchlin found green zircons have a sp. gr. between 4.04 and 4.29; pale green, 4.00 and 4.16; yellowish-green, 4.21 and 4.39; dark yellow-green, 4.22 and 4.23; dark green, 4.08; brownish-green, 4.20 and 4.27; greenish-yellow, 4.27; greenish-brown, 4.50 and 4.70; yellow, 4.38 and 4.61; yellowish-orange, 4.60; orange, 4.40; reddish-yellow, 4.53; brownish-yellow, 4.59; reddish-yellow, 4.68; red, 4.57-4.64; dark red, 4.70; brownish red, 4.61; yellowish-brown, 4.46 and 4.70; reddish-brown, 4.60 and 4.69; bluish, 4.44 and 5.6; pale violet, 4.68; brownish-violet, 4.66; and colourless, 4.74.

R. Köchlin assumed that zircon exists in two forms, and that intermediate forms with a sp. gr. 4.35-4.55 are isomorphous mixtures of the heavy and light varieties. As L. J. Spencer has emphasized, a low sp. gr. is not alone sufficient to establish the existence of a special modification. S. Stevanovic inferred that there are three related forms of zircon, with properties indicated in Table XXXII. This hypothesis cannot be regarded as established until the equilibrium conditions of the alleged allotropes have been elucidated. On calcination, β -zircon passes into α -zircon; but γ -zircon does not change on calcination, and hence S. Stevanovic assumed that an unknown element closely related to zirconium is present. This has not been confirmed by the fractionation of zirconium.

TABLE XXXII.—PROPERTIES OF THE DIFFERENT FORMS OF ZIRCON.

	Sp. gr.	Index of refraction Na-light.	Birefringence.	Axial angles.	Hardness.
α -zircon	4.7	$n=1.98$; $n_o=1.93$	Strong	Uniaxial	7-8
β -zircon	4.3	Not exactly known	Strong	Biaxial	
γ -zircon	4.0	1.81	Feeble	Uniaxial	Below 7

R. Köchlin showed that the hardness of zircon varies with the sp. gr. The samples with a sp. gr. below 4.3 are softer than quartz, while those with a higher sp. gr. are harder. Normal zircon, for instance, with a sp. gr. 4.7, has a hardness between 7 and 8. E. Modélung and R. Fuchs gave 3.01×10^{-12} dynes per sq. cm. for the coeff. of compressibility. F. Pfaff²⁹ gave for the coeff. of thermal expansion, 0.06264 in the direction of the c -axis, and 0.04116540 in the direction of the a -axis; and H. Fizeau gave 0.0443 parallel to the c -axis and 0.0233 in a direction perpendicular to the c -axis. H. V. Regnault gave 0.14558 for the specific heat of zircon between 24° and 99° ; and H. Kopp, 0.132 between 16° and 47° . Zircon cannot be fused before the blowpipe, and R. Curzack did not succeed in fusing the mineral. E. D. Clarke, and A. Damour melted zircon to a white enamel in the oxyhydrogen blowpipe flame, and by heating it in a flame fed with warm oxygen, G. Spezia fused zircon to a white enamel. A. Brun gave about 1900° for

the melting point of zircon, and A. L. Fletcher found cyrtolite does not flow freely at 1560°. C. Matignon observed that natural crystalline zircon did not

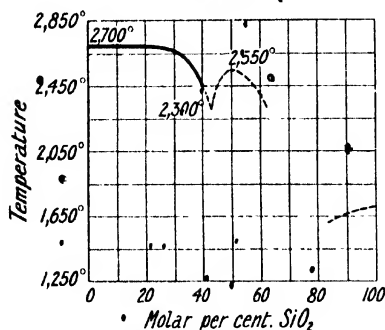

FIG. 188.—Melting Points of Binary Mixtures of Zirconia and Silica.

melt at 2126°, but at 1800°, dissociation could be observed, and at 1900°, dense white fumes of silica appeared; the residue melted at 2600°; zirkite did not melt at 1950°. E. W. Washburn and E. E. Libman found the m.p. of natural zircon to be near 2550°, and a mixture of Zirconia and silica in equi-molar proportions melts at the same temp. The portion of the m.p. curve so far determined is indicated in Fig. 188. There is a eutectic between zirconium dioxide and zircon melting in the neighbourhood of 2300°. The observed data are:

ZrO ₂ : SiO ₂	1 : 0	3 : 1	2 : 1	3 : 2	1 : 1	2 : 3	1 : 2	1 : 3
Melts at.	2720°	2685°	2650°	2460°	2550°	2420°	2420°	2420°

The indices of refraction of zircon of sp. gr. 4.654 are given by S. Stevanovic³⁰ $\omega=1.91778$, and $\epsilon=1.97298$ for wave-length 6563; $\omega=1.93015$, and $\epsilon=1.98320$ for wave-length 5166; and $\omega=1.94279$, and $\epsilon=1.99612$ for wave-length 4862. D. Brewster gave for normal Singalese zircon, $\omega=1.961$, and $\epsilon=2.015$; A. des Cloizeaux gave $\omega=1.85$, $\epsilon=1.86$; H. de Sénarmont, for one of sp. gr. 4.636, $\omega=1.92$ and $\epsilon=1.97$ for red light; M. Sanger, $\omega=1.9239$ and $\epsilon=1.9682$, and for a sample from Miask, $\omega=1.9313$, and $\epsilon=1.9931$ for Na-light. For doubly refracting olive-green beccarite, sp. gr. 4.654, G. Kalb gave for the blue zircon of Siam, $\omega=1.9180$, $\epsilon=1.9769$, and $\epsilon-\omega=0.0589$ for Li-light; $\omega=1.9255$, $\epsilon=1.9847$, and $\epsilon-\omega=0.0592$ for Na-light; and $\omega=1.9326$, $\epsilon=1.9920$, and $\epsilon-\omega=0.0594$ for Ti-light. G. Grattarola gave $\alpha=1.9272$, $\beta=1.9277$, and $\gamma=1.9820$. A. Damour proved that the index of refraction decreases with the sp. gr. of zircon. S. Stevanovic found that with Na- and Li-rays respectively, the index of refraction of natural zircon was 1.8163 and 1.8259; after a mild calcination, 1.8067 and 1.8125; and after a strong calcination, 1.7872 and 1.7914. The birefringence of zircon is strong, $\epsilon-\omega=0.062$. R. Köchlin found that a zircon of sp. gr. 4.44 with a zonal structure had different double refractions in different parts ranging from 0.022-0.038. J. Babinet, A. Breithaupt, and A. Madelung showed that zircon crystals may be optically anomalous in that a basal section rarely gives a normal uniaxial figure, for the black cross is usually broken into a number of lemniscate or hyperbolic brushes. P. A. von Sachsen-Coburg assumed that the effect is due to polysynthetic twinning. H. Rosenbusch said that the microscopic zircons do not show the effect. E. Mallard accordingly argued that the crystals are really mimetic twins of monoclinic individuals, but R. Brauns said that the effect is due to mechanical strains. W. Klein produced the effect by irregular heating. A. des Cloizeaux found that the effect of raising the temp. from 14°-186° was not appreciable. A. Madelung found that beccarite is made biaxial by heat.

H. Becquerel³¹ measured the absorption spectrum of uraniferous zircon, and obtained the results illustrated by Fig. 189. According to A. H. Church and C. A. MacMunn, the absorption spectrum of Singalese zircon has dark bands with the strongest absorptions where $\lambda=639.5$, 683.5, 661, 653, 622.5, 616, 589, 562, 538, 515, and 484. V. von Agafanoff found that plates of zircon are transparent or ultra-violet light as far as the cadmium lines 7, 8, and 9. Wa W. Coblenz showed that with ultra-red light there are absorption bands at 2.1 μ , 3.1 μ , 3.6 μ , and complete opacity beyond 5 μ . T. Liebisch and H. Rubers studied the reflecting power

of zircon for the long infra-red rays. According to W. Haidinger, the **pleochroism** of zircon is usually feeble. Brown Singalese crystals had a reddish-brown, and a, green. Observations were also made by E. Hussak, and G. H. F. Ulrich.

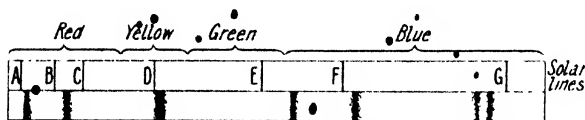

FIG. 189.—The Absorption Spectrum of Zircon.

R. J. Strutt³² studied the **radioactivity** of the zircon minerals and found malacone, alvite, and cyrtolite exhibited the strongest radioactivity, and these minerals contain thorium. He found Raade-Moss alvite with 1.95 per cent. thorium possessed had a radioactivity 1.81 in millionths per cent. of that of radium bromide; Carolinian zircon, 0.307 per cent. thorium, 0.30; Virginian zircon, 0.217 per cent. thorium, 0.52; Llano cyrtolite, 5.05 per cent. thorium, 8.98; and Hittero malacone, 1.15 per cent. thorium, 1.40. He also found the radioactivity of Ural zircon to be 865×10^{-12} grm. radium; Carolina zircon, 658×10^{-12} ; Brevig zircon, 139×10^{-12} ; and Kimberley zircon, 74.8×10^{-12} . Observations were made by C. Gockel, and C. Doelter and co-workers. A. C. Cumming found that when radioactive malacone is digested with hydrochloric acid, the radioactive substance passes into solution and the residue is no longer radioactive. He found no uranium present. E. S. Kitchin and W. C. Winterson also made some observations on this subject. A. Piutti examined the relation between the radioactivity, helium content, and sp. gr. of a number of zircons. R. J. Strutt found 12 c.c. of helium occluded per 100 grms. of Hittero malacone. The small circular coloured spots known as pleochroic haloes were studied by J. Joly and co-workers, and O. Mügge.

The bleaching action of light and heat on coloured zircons has been previously discussed. K. Simon³³ found that the temp. needed for decolorization depends to some extent on the size of the fragments. The presence of oxygen retards the decolorization; the colour is more or less restored by exposure to sunlight or to **radium radiations**. According to C. Doelter, dark brown and red zircons do not change when exposed to radium radiations; but the paler zircons have their colour intensified. Zircons decolorized by heat have their original colour restored by exposure to radium radiations, although, as W. Hermann showed, the intensity of the colour may not be so great. Observations were also made by K. Simon, S. Lind and D. C. Bardwell, and R. Brauns. The latter showed that a colourless zircon was coloured by a conc. preparation of radium, but not by a dil. one. M. Weber discussed the **pleochroic halo** developed in a zircon crystal in contact with a cordierite crystal. E. Newbery and H. Lupton showed that all specimens of zircon, heated or unheated, showed a greenish luminescence when exposed to radium. The colour of the unheated ones was not changed, but the heated ones all regained their colour to a greater or less extent; they also found that **cathode rays** restored the colour of a decolorized crystal, and the mineral glowed with a blue light; R. Brauns, and C. Doelter showed that **ultra-violet light** weakened the colour of decolorized zircon whose colour had been restored by exposure to radium rays; but the colour of natural crystals was weakened in ultra-violet light. E. Newbery and H. Lupton found that the colour of a crystal which has been obtained by exposing decolorized crystals to radium rays, is discharged by heat at a lower temp. than was needed for the original crystal. W. Henneberg observed the **thermoluminescence** of zircon during decolorization; the non-luminescent varieties are not decolorized by heat; and G. Spezia believed that there is some connection between the thermoluminescence and the colour. A. H. Church said that the glow with a green zircon was orange; and D. Hahn, green. The subject was studied by F. P. Venable. K. Keilhack observed that zircon phosphoresced when exposed to the **X-rays**. E. Newbery

and H. Lupton observed blue and violet phosphorescence with radium radiations and with cathode rays. Et Bichat examined the action of the so-called **N-rays**.

Zircon has a poor **electrical conductivity**. W. Schmidt³⁴ found that the **dielectric constant** of a crystal from Ceylon was 12.6 parallel to the principal axis, and 12.8 perpendicular thereto. E. T. Wherry found zircon showed no evidence of the rectification required by a radio-detector. L. Grätz studied the dielectric capacity, and B. Bavink, the **magnetic properties** of zircon.

Zircon is not attacked by acids; but when very finely powdered, it is attacked a little by sulphuric acid. For the action of chlorine, and of carbonyl chloride—*vide* zirconium tetrachloride. It is broken down by fusion with alkali hydroxides, and, according to J. C. G. de Marignac,³⁵ by alkali carbonates, and hydrosulphates. R. Hornberger, and H. Traube found zircon is attacked by fusion with potassium fluoride, or hydrofluoride; and C. Baskerville decomposed it by heating it to 450° in a stream of carbonyl chloride. For the hydration of zircon by weathering, etc., *vide supra*.

T. H. Lee³⁶ described a zirconium silicate from the Caldas region, Minas Geraes, Brazil, which he named *orvillite*—after Orville A. Derby—it had a composition $8\text{ZrO}_3 \cdot 6\text{SiO}_2 \cdot 5\text{H}_2\text{O}$, and is soluble in a mixture of hydrofluoric and hydrochloric acids. It is possibly more or less altered zircon.

R. Schwarz and A. Haacke³⁷ found that the m.p. of pure lithium orthosilicate, 1249°, is lowered by the addition of zirconium orthosilicate in proportion to the conc. of the latter, up to 30 mol. per cent. ZrSiO_4 , at which composition a pure eutectic is formed, m.p. 1021°. As the proportion of zirconium orthosilicate is still further increased, the m.p. again rises to a maximum at 1152°, the m.p. of

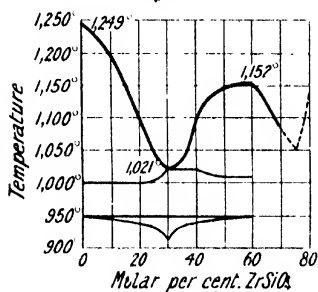

FIG. 190. — Freezing-point Curves of Zirconium and Lithium Orthosilicates.

octolithium trizirconium pentorthosilicate, $3\text{ZrSiO}_4 \cdot 2\text{Li}_4\text{SiO}_4$. Further increasing the proportion of zirconium orthosilicate, the m.p. falls as far as 70 mol. per cent. ZrSiO_4 , to rise again subsequently, but experiments could not be continued beyond this point, as the mixtures could not be fused in the furnace used. The two silicates do not form mixed crystals. The mixtures containing 50 mol. per cent. or more of lithium orthosilicate are readily attacked by cold water, the others by boiling water. Those containing a high proportion of zirconium orthosilicate resemble extremely hard porcelain. The sp. gr. increases from 2.28 (Li_4SiO_4) to a maximum 4.024 for the binary compound, falls slightly, and again rises to 4.51 (ZrSiO_4). The mol. wt. of zirconium silicate, calculated from the depression of the f.p. of lithium silicate, corresponds with the simple mol. ZrSiO_4 .

M. E. Chevreul³⁸ and P. Berthier fused mixtures of zircon and potassium hydroxide, and after washing the cold mass, obtained white residues which, according to A. Knop, are *Kieseläurefreie*; but D. E. Melliss fused a mixture of zircon and four times its weight of potassium carbonate for 2 hrs. in a platinum crucible; extracted the mass with water; and obtained a microcrystalline powder with a composition $\text{K}_2\text{O} \cdot \text{ZrO}_2 \cdot 2\text{SiO}_2$, **potassium disilicazirconate**, $\text{K}_2\text{ZrSi}_2\text{O}_7$, with a sp. gr. 2.79. It was decomposed by hydrochloric acid. L. Ouvrard melted a similar mixture for 15 mins. at a bright red-heat, and obtained rhombic prisms with the composition $\text{K}_2\text{O} \cdot \text{ZrO}_2 \cdot \text{SiO}_2$, or **potassium silicazirconate**, K_2ZrSiO_6 . L. Ouvrard added that when the fusion is continued for $1\frac{1}{2}$ hrs., only crystalline zirconia is obtained. The crystals were examined by G. Flink. They are attacked by hydrofluoric acid, and ammonium hydrofluoride. W. Gibbs fused zircon with sodium carbonate as

indicated above; boiled the cold cake with a conc. soln. of sodium carbonate, washed the residue with luke-warm water, and obtained a white powder corresponding with sodium silicozirconate, $\text{Na}_2\text{O} \cdot \text{ZrO}_2 \cdot \text{SiO}_2$, or $\text{Na}_2\text{ZrSiO}_5$. L. Bourgeois included some silica with the zircon and sodium carbonate, and after 24 hrs. fusion at a red heat, extracted the cold cake with dil. acid, and obtained rhombic prisms with a strong double refraction. They were decomposed by hot water and with hydrochloric acid, there is a separation of gelatinous silica. T. Scheerer said that sodium zirconate (*q.v.*), not silicozirconate, is obtained in this way. D. E. Melliss boiled with water the cold cake, obtained by fusing a mixture of zircon with 4 times its weight of sodium carbonate, until no more soluble matters were removed. The microscopic hexagonal plates had the composition $\text{Na}_2\text{O} \cdot 0.8\text{ZrO}_2 \cdot \text{SiO}_2 \cdot 11\text{H}_2\text{O}$. The sp. gr. was 3.53. The salt lost water at an incipient red heat; and it was decomposed by sulphuric acid.

P. Berthier fused mixtures of zircon, quartz, and marble in various proportions contained in a carbon crucible. When the proportions of zircon : quartz : marble were 1 : 2.34 : 3.33, a transparent glass, surrounded by a stony crust, was produced; with 1 : 1.01 : 3.33, the mass was pulverulent and baked together; 1 : 2.67 : 2.22 was vitrified and porcelanic; 1 : 3.34 : 2.22 was glassy, 1 : 1.67 : 2.22, merely softened; 1 : 1 : 1.11 was semivitreous; 1 : 0.33 : 1.11 was opaque with a shiny fracture; and 1 : 0.16 : 1.11 was white and stony. Mixtures with the lime less than one-third were decomposed by acids. The evidence does not justify the statement that calcium silicozirconates, CaZrSiO_5 , analogous to titanite, CaTiSiO_5 , were formed. A number of minerals are assumed to be closely related with the silicozirconates—*e.g.* zirkelite, $(\text{Ca}, \text{Fe})\text{O} \cdot 2(\text{Zr}, \text{Ti}, \text{Th})\text{O}_2$, vide zirconates; ulhigite, $3\text{Ca}(\text{Zr}, \text{Ti})_2\text{O}_5 \cdot \text{Al}_2\text{TiO}_5$, vide zirconates; rosenbuschite, $6\text{CaSiO}_3 \cdot 2\text{Na}_2\text{ZrO}_2 \cdot \text{TiSiO}_3 \cdot \text{TiO}_3$, vide rare earths; laventite, $\text{R}(\text{Si}, \text{Zr})\text{O}_3 \cdot \text{Zr}(\text{SiO}_3)_2$, $\text{R} \cdot \text{Ta}_2\text{O}_6$; hainite, $\text{R}(\text{Si}, \text{Zr})\text{O}_3 \cdot \text{Zr}(\text{SiO}_3)_2 \cdot \text{RTa}_2\text{O}_6$; wöhlerite, $12\text{R}(\text{Si}, \text{Zr})\text{O}_3 \cdot \text{R}(\text{Cb}_2\text{O}_3 \cdot \text{R}(\text{Cb}_2\text{O}_3))$; kiortdahlite, $4\text{Ca}(\text{Si}, \text{Zr})\text{O}_3 \cdot \text{Na}_2\text{ZrO}_2 \cdot \text{F}_2$; and eudialyte and eucolite, $\text{Na}_{13}(\text{Ca}, \text{Fe})_6\text{Cl}(\text{Si}, \text{Zr})_{20}\text{O}_{52}$.

G. Lindström, and G. Nordenskjöld³⁹ described crystals of a mineral found near Nagssarsuk, Greenland, to which they applied the term **elpidite**—from $\epsilon\lambda\pi\acute{\iota}\varsigma$, hope. Analyses by G. Lindström show that the white or reddish-coloured mineral has 20–21 per cent. of zirconia and corresponds with $\text{Na}_2\text{O} \cdot \text{ZrO}_2 \cdot 6\text{SiO}_2 \cdot 3\text{H}_2\text{O}$. G. Flink regarded elpidite as a transformation product of a mixed mineral, $\text{Na}_2\text{Si}_2\text{O}_5 \cdot \text{Zr}(\text{Si}_2\text{O}_5)_2$. P. Groth represented it by the formula $\text{H}_6\text{Na}_2\text{ZrSi}_6\text{O}_{18}$; and F. W. Clarke, by $\text{Zr}(\text{OH})_2(\text{Si}_3\text{O}_8 \equiv \text{NaH}_2)_2$, **sodium hexahydroxyzirconatodimesotrisilicate**—*vide infra*. From his dehydration curve, F. Zanbonini inferred that neither water of crystallization nor constitutional water is present; but that the water is simply dissolved. He found the percentage loss of water from elpidite at different temp. to be:

	65°	115°	175°	205°	250°	262°
Loss	0.86	4.03	6.60	7.99	8.88	9.17 per cent.

Dehydration is nearly complete at 262°, for the total loss is 9.80°. At 115° in moist air, a part of the expelled water is resorbed; and at 250°, the percentage amount of water resorbed is:

Hours	16	30	135	183	303	375	447	573
Resorption	1.60	1.74	2.38	2.30	2.49	2.60	2.77	2.73

G. Flink found that the rhombic crystals have the axial ratios $a:b:c = 0.5101:1:0.9781$. The (110) cleavage is masked. The sp. gr. of the white mineral is 2.524, that of the red is 2.594; and the hardness is nearly 7. According to G. Flink, the optic axial $2V = 75^\circ 12'$, while O. B. Bögödd gave $2V_a = 89^\circ 40'$. G. Flink gave for the indices of refraction $\alpha = 1.5600$, $\beta = 1.5650$, and $\gamma = 1.5739$, and the birefringence $\gamma - \alpha = 0.0139$ for yellow light.

P. C. Weibye and H. Sjögren described a mineral from the islands of Langesund fiord, Norway, which was named **catapleite**—from $\kappa\alpha\tau\alpha\pi\lambda\epsilon\acute{\iota}\omega\nu$, satiated—in allusion

to its always being accompanied by a number of rare minerals. Analyses were reported by P. C. Weibye and H. Sjögren, M. Weibull, C. F. Rammelsberg, W. C. Brögger, G. Forsberg, P. T. Cleve, and G. Flink. There are two kinds, one kind is calcareous, and the other almost free from lime.

	SiO ₂	ZrO ₂	CaO	Na ₂ O	H ₂ O
Lime-catapleiite .	39.78-46.83	29.33-40.12	3.45-5.82	8.10-10.83	8.86-9.35
Soda-catapleiite .	41.27-44.04	30.80-32.60	0.81-0.93	14.94-15.05	9.24-9.31

G. von Hevesy and V. T. Jantzen found about 0.2 per cent. of hafnium in catapleiite. P. C. Weibye and H. Sjögren represented the mineral by $\text{ZrO}_2 \cdot 2\text{SiO}_2 + \text{Na}_2\text{SiO}_3 + 2\text{H}_2\text{O}$; C. F. Rammelsberg, by $\text{Na}_{10}\text{Ca}_4\text{Zr}_6\text{Si}_{27}\text{O}_{81} \cdot 18\text{H}_2\text{O}$; C. W. Blomstrand, by $\text{R}_4\text{Zr}_4(\text{O}_2\text{SiO})_{12} \cdot 8\text{H}_2\text{O}$; W. C. Brögger, $\text{H}_2\text{SiO}_3 \cdot \text{Na}_2\text{SiO}_3 \cdot (\text{ZrO}_2\text{H}_2)\text{SiO}_3$; G. Flink, by $\text{Na}_2\text{SiO}_3 \cdot \text{H}_4\text{Zr}(\text{SiO}_4)_2$; and P. Groth, by $\text{Na}_2(\text{SiO}_2\text{H}_2)_2\text{Si}_2\text{O}_7$, with some silica replaced by zirconium. F. W. Clarke represented the mineral as **sodium calcium trihydroxyzirconate-metasilicate**, $\text{Zr}(\text{OH})_3\text{NaCaSi}_3\text{O}_8$ —*vide infra*. F. Zambonini regards the water of catapleiite as dissolved, being present neither as water of crystallization nor as constitutional water; corresponding with the tendency of zirconium to form complex salts as indicated by the work of R. Ruer and co-workers, A. Rosenheim and A. Frank, and W. Mandl. F. Zambonini considers soda-catapleiite to be the sodium salt of the acid $\text{H}_2(\text{ZrSi}_3\text{O}_9)$, with approximately 2 mols of dissolved water—*vide infra*. M. Weibull, W. C. Brögger, and F. Zambonini studied the dehydration of catapleiite, and the last-named found the percentage loss in a moist stream of air at different temp. to be:

	110°	175°	218°	270°	290°	325°	375°	420°-425°
Loss .	0.22	0.70	1.80	3.83	6.19	7.17	7.90	8.33 per cent.

when the total loss is 9.73 per cent. It was found that there is a resorption of water at 270° such that

Hours	24	48	144	264	306
Resorption .	1.53	1.60	1.71	1.83	1.77

The colour of catapleiite may be light yellow to yellowish-brown, greyish-blue, and violet. The crystals are usually thin, tabular, hexagonal prisms with replaced edges. According to W. C. Brögger, at ordinary temp. the crystals are pseudo-hexagonal and monoclinic—if hexagonal, H. Dauber gave the axial ratio $a:c = 1:1.3593$, and W. C. Brögger, $1:1.3605$; while the latter gave for the axial ratios of the monoclinic crystals $a:b:c = 1.7329:1:1.3618$, and $\beta = 90^\circ 11\frac{1}{2}'$. Above 140°, the crystals are hexagonal. G. Flink found the thick crystals of one type become uniaxial at 120°, crystals of another above 200°, and crystals of a third type, at 10°-20°. H. Steinmetz found a transition point at 35°, accompanied by a very small change in vol. O. B. Böggild found, that in one type the change begins at 110° and is complete at 130°; in another, it begins at 160° and is complete at 230°; in another, at 30°-40°; in another, at 10°-20°; and in another, the change is partially complete at ordinary temp. Twinning is common—the twinning planes are (10 $\bar{1}$ 1), (30 $\bar{3}$ 2), (33 $\bar{6}$ 2), and 10 $\bar{1}$ 0). The (10 $\bar{1}$ 0) cleavage is perfect, and the (10 $\bar{1}$ 1) and (10 $\bar{1}$ 2) cleavages are imperfect. W. C. Brögger gave for the optic axial angle of soda catapleiite $2E = 60^\circ$; G. Flink, 30° ; and O. B. Böggild, $41^\circ 3'$ with Na-light; W. F. Foshag gave $2V = 0^\circ-25^\circ$. H. Sjögren gave for the sp. gr. of lime-catapleiite 2.79-2.81; and G. Flink, for soda-catapleiite 2.743. The values of 2 types at different temp. was found by O. B. Böggild to be:

17°	30°	40°	50°	60°	70°
2.764	2.763	2.764	2.763	2.762	2.761
2.751	2.745	2.749	2.739	2.739	2.739

The sp. gr. of the first type does not change very much with temp. since only at 160° does the mineral become uniaxial. The hardness is about 6. O. B. Böggild gave for the indices of refraction $\alpha = 1.5905$, $\beta = 1.5921$, and $\gamma = 1.6269$, and for the

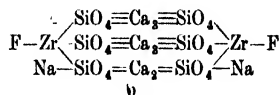

birefringence $\gamma - \alpha = 0.0364$ —with Na-light; W. F. Foshag gave $\alpha = 1.591$ – 1.593 ; $\beta = 1.592$ – 1.593 ; and $\gamma = 1.627$ – 1.628 . The crystals are optically positive. W. C. Brögger found that when soda-catapleite is heated, zircon is formed: $\text{Na}_2\text{ZrSi}_3\text{O}_9 \cdot 2\text{H}_2\text{O} \rightarrow \text{ZrSiO}_4 + \text{Na}_2\text{Si}_2\text{O}_6 + 2\text{H}_2\text{O}$, and he has found pseudomorphs of zircon after catapleite. The mineral decomposes when treated with hydrochloric acid, and gelatinous silica separates.

The gemstone varieties of zircon include *cudalyte* and *cucolite* discussed in connection with the rare earths (q.v.). These two minerals are sometimes regarded as mixtures of metasilicates with the oxychloride, ZrOCl_2 , but F. W. Clarke⁴⁰ considers them to be variable mixtures of zirconium sodium calcium chlorotriorthosilicate, $\text{Zr}(\text{SiO}_4)_3(\text{CaNa})_2\text{Cl}$, and zirconium sodium calcium chlorotrimetrasilicate, $\text{Zr}(\text{Si}_2\text{O}_7)_3(\text{CaNa})_2\text{Cl}$, in which hydroxyl may partly replace the chlorine; and iron and manganese, the calcium. J. E. Teschemacher referred to a mineral which he called *azdrite*, occurring in San Miguel, Azores. It was shown by A. Ben-Saude, J. D. Dana, A. Schrauf, O. Muges, L. L. Hubbard, A. Osann, and P. do Canto e Castro to be a colourless or pale green variety of zircon. The mineral obtained by G. Grattarola and O. Beccari from Point de Galle, Ceylon, and accordingly named *beccarite*, is an olive-green zircon with silica 30.3 per cent.; zirconia, 62.2; alumina, 2.5; and calcium oxide, 3.6. C. U. Shepard found minute brown crystals of a variety of zircon at Haddam, Connecticut, which he called *calypsolite*. T. Wada reported a greenish or brown radioactive zirconium silicate containing 34.89, SiO_2 ; 28.27, UO_2 ; 16.50, ThO_2 ; 7.0, Ta_2O_5 ; 4.10, Cb_2O_5 ; 1.59, CeO_2 ; 1.60, Fe_2O_3 ; 1.71, CaO ; 0.57, MgO ; 3.12, H_2O , from Naegi, Mino, Japan, and he called it *naegite*. The tabular or prismatic crystals belong to the tetragonal system. The sp. gr. is 4.09; the hardness, 7.5. The composition deviates much from the orthosilicate formula. G. Hevesy and V. T. Jantzen found 7 per cent. of hafnia in Japanese naegite. A. Breithaupt applied the term *ostranite* to a mineral from Stokö, Langesund fiord, Norway. It was shown by G. A. Koenig, G. Forchhammer, and W. C. Brögger to be a weathered variety of zircon. N. von Kokscharoff referred to a mineral from Tomsk, Russia, which was called *engelhardtite*, and shown by P. von Jeremejeff to be a variety of zircon.

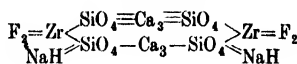

W. C. Brögger⁴¹ called a mineral from the island of Låven in the Langesund fiord, Norway, *låvenite*, although at first it was considered to be mosandrite. It has been also reported from the island Klein-Årø, and Arø; F. Graeff found it in Serra de Tingua and other parts of Brazil; G. Gürich, in Los Islands, West Africa; and A. Osann, in San Miguel, Azores. Analyses were made by P. T. Cleve, and, according to W. C. Brögger, the results correspond with $6\frac{1}{2}(\text{Mn}, \text{Fe})(\text{Ca}, \text{Na}_2)(\text{Si}_2\text{O}_6)_2 \cdot 2\frac{1}{2}\text{ZrSi}_2\text{O}_6 \cdot 2\frac{1}{2}\text{Na}_4\text{Zr}_2\text{F}_4\text{O}_4 \cdot 1\frac{1}{2}(\text{Na}_2\text{H}_2\text{O}_2)(\text{Zr}, \text{Ti})_2\text{O}_6$; P. Groth gave $(\text{Mn}, \text{Ca}, \text{Fe})(\text{SiO}_3)_2(\text{ZrOF})\text{Na}$. The minerals *låvenite*, *guarinite*, *rosenbuschite*, *hiortdahlite*, and *wöhlerite* are sometimes grouped as *zircon-pyroxenes*, and W. C. Brögger considered that just as the pyroxenes are regarded as metasilicates so are the zircon-pyroxenes regarded as metazirconates. The analyses are not clearly interpreted by these formulae which represent the mineral as a **sodium calcium fluozirconatosilicate**. The colour of *låvenite* may be pale yellow, almost colourless, or dark yellow, merging into dark brown. The prismatic or tabular crystals belong to the monoclinic system, and have the axial ratios $a:b:c = 1.0963:1:0.71509$, and $\beta = 69^\circ 42\frac{1}{2}'$. Twins about the (100)-plane are common; and they are also twinned lamellae. The (100) cleavage is nearly perfect. The optic axial angles with Na-light are $2H_a = 90^\circ 16'$; $2H_o = 116^\circ 7'$; $2V = 79^\circ 46'$. The sp. gr. is 3.51–3.55, and the hardness 6. W. C. Brögger gave for the index of refraction $\beta = 1.750$. The birefringence is strong; A. Michel-Lévy and A. Lacroix gave $\gamma - \alpha = 0.03$. The optical character is negative. The crystals are strongly pleochroic. The mineral is incompletely decomposed by the ordinary acids.

G. Guiscardi⁴² described a mineral which was found in cavities in the sanadine bombs of Mont Somma, as a variety of titanite. It was called **guarinite**—after C. G. Guarini. According to F. Zambonini and G. T. Prior, G. Guiscardi must have mistaken titanium for zirconium, since *guarinite* is really the same as that found by W. C. Brögger on one of the Arø Islands, Norway, and called *hiortdahlite*—after T. Hiortdahl. This makes these minerals approximate $(\text{Na}, \text{Ca})(\text{Si}, \text{Zr})\text{O}_2$, **sodium calcium zirconatometasilicate**. W. C. Brögger gave $4\text{Ca}(\text{Si}, \text{Zr})\text{O}_3 \cdot \text{Na}_2\text{ZrO}_2\text{F}_2$. O. Rebuffat found 1.25 per cent. of yttria, and 3.45 per cent. of ceria earths; and,

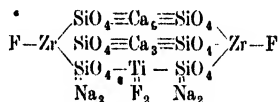

according to F. Zambonini and G. T. Prior, he mistook zirconia for alumina or titania. F. Zambonini and G. T. Prior regard the mineral as a mixed salt of calcium metasilicate and sodium zirconate with some calcium fluoride, $3\text{CaSiO}_3 \cdot \text{Ca}(\text{F}, \text{OF}_2)\text{NaZrO}_3$. F. W. Clarke represents guarinite by the formula :

and hiört Dahlite a 1 : 1 mixture of this with the hydroxyl being

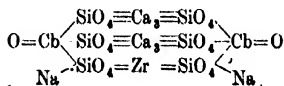

in part replaced by fluorine. The mineral *rosenbuschite*—*viñe* rare earths—**sodium calcium titanium zirconatosilicate**, is assumed to be built on the same plan as guarinite, namely :

The colour is pale yellow to brown. The crystals of hiört Dahlite were stated by W. C. Brögger to be triclinic with axial ratios $a : b : c = 0.99835 : 1 : 0.35123$, and $\alpha = 89^\circ 22' \frac{1}{2}$, $\beta = 90^\circ 36' \frac{1}{2}$, and $\gamma = 90^\circ 5' \frac{1}{2}$. G. Guiscardi, and V. von Lang said that the crystals of guarinite are rhombic, with axial ratios $a : b : c = 0.9892 : 1 : 0.3712$; F. Zambonini gave $0.99268 : 1 : 0.37008$; this would make the zirconatosilicate dimorphous. The optic axial angle $2V = 90'$ nearly. W. C. Brögger gave 3.267 for the sp. gr. of hiört Dahlite; G. Guiscardi gave 3.487 for guarinite, and F. Zambonini, $2.9-3.3$. The hardness of hiört Dahlite is given as $5.5-6$, and that of guarinite as 6 . The index of refraction of guarinite is, according to H. Rosenbusch, $\beta = 1.68-1.71$; F. Zambonini gave for the birefringence $\gamma - \beta = 0.0047$; $\beta - \alpha = 0.0048$; $\gamma - \alpha = 0.0095$. He also found the mineral pleochroic. The optical properties agree closely with those of danburite.

T. Scheerer⁴³ found citron-yellow crystals of a mineral on several islands in the Langesund fiord, Norway. The mineral was named **wöhlerite**—after F. Wöhler. Analyses of the mineral were made by T. Scheerer, R. Hermann, C. F. Rammelsberg, P. T. Cleve, etc. The results correspond with calcium zirconatocolumbatosilicate, $12\text{Ca}(\text{Si}, \text{Zr})\text{O}_3 \cdot \text{CaC}_2\text{O}_6$, with part of the calcium replaced by sodium; some iron and manganese are present; and, according to W. C. Brögger, with the CaZrO_3 replaced in part by $\text{CaZr}(\text{O}_2\text{F}_2)_2$, so that ceria earths may also be present. P. Groth gave $\text{Ca}_{10}\text{Na}_5\text{Si}_{10}\text{Zr}_3\text{C}_2\text{O}_{42}\text{F}_3$. F. W. Clarke represents the composition as a mixed salt having one mol. of the same type as that of rosenbuschite with Zr in place of Ti along with 4 mol. of **sodium calcium zirconium columbatosilicate** ;

G. Hevesy and V. T. Jantzen found 0.7 per cent. of hafnia in wöhlerite from Langesund. The prismatic or tabular crystals were at first thought to be rhombic by P. C. Weibye, A. des Cloizeaux, H. Dauber, J. D. Dana, and G. A. Kenngott. Later, A. des Cloizeaux, W. C. Brögger, C. F. Rammelsberg, showed that the mineral is monoclinic. The axial ratios are $a : b : c = 1.0536 : 1 : 0.70878$, and $\beta = 71^\circ 3'$. The colour is various shades of yellow, brown, and grey. Twins on the 100-plane are often found. The 010-cleavage is distinct. The sp. gr. is $3.41-$

3.44, and the hardness 5.5-6. W. C. Brögger found the optic axial angles $2H_a = 91^\circ 18'$ for Na-light, $2H_0 = 121^\circ 42'$, and $2V = 78^\circ 31'$. Measurements were also made by A. des Cloizeaux, and A. Michel-Lévy and A. Lacroix. Observations with red, blue and green light were also made. The refractive index $\beta = 1.67-1.74$. Raising the temp. to 479° was found by A. des Cloizeaux to make no perceptible change in the optic axial angle. G. P. Tschernik gave $\gamma - \alpha = 0.023$; $\gamma - \beta = 0.014$; and $\beta - \alpha = 0.014$; and the optical character is negative. The crystals are pleochroic. P. Krüss and L. F. Nilson studied the absorption spectra. The mineral dissolves in hot conc. hydrochloric acid with the separation of silica and columbium pentoxide.

J. J. Berzelius⁴⁴ obtained a black mineral from Fredriksvarn, Norway, and he called it **polymignite**—from *μύρον*, a mixture—in allusion to its complex composition. Analyses were reported by W. C. Brögger, J. J. Berzelius, and G. P. Tschernik. Its composition approximates **calcium cerium silicozircatotantalate**, $5R\text{TiO}_3 \cdot 5R\text{ZrO}_3 \cdot R(\text{TaO}_3)_2$, where R denotes iron, calcium, and the cerium metals, and the tantalum, Ta, includes some columbium, Cb. The slender prismatic crystals are often striated. They were examined by G. Rose, M. L. Frankenheim, and W. C. Brögger. They belong to the rhombic system and have the axial ratios $a:b:c = 0.71213:1:0.51207$. The (100) and (010) faces show traces of cleavage. The sp. gr. is 4.77, and the hardness 6.5.

The **thorium silicates** are represented by thorite or oronite, yttrilite, and mackintoshite discussed in connection with the occurrence of thorium, and the complex uranium silicates. The complex **rare earth silicates** are discussed in connection with the occurrence of the rare earths; and for **scandium orthodisilicate**, or thortveitite, *vide* scandium; and **yttrium orthodisilicate**, or thaleitite, *vide* rare earths.

§ 49. The Chromium Silicates

St. M. Godon¹ evaporated an aq. soln. of chromic acid with silicic acid, and obtained a yellow insoluble powder; G. A. Quesneville said that chromic acid dissolves a little hydrated silica, and deposits it again on evaporation, and all the chromic acid can be washed from the residue. F. Angel obtained a chromium silicate as a greyish-green hydrogel by mixing soln. of chromic chloride and sodium silicate. The dehydration curve is a continuous function of the temp. The composition approximates to that of **dichromium hexahydro-triorthosilicate**, $H_{12}Cr_2Si_6O_{24} \cdot H_4SiO_4$, or $2H_6Cr_2(SiO_4)_3 \cdot H_4SiO_4$. H. Kämmerer obtained a green amorphous clay from Okhansk, Siberia, and he called it *wolchonskoite*—after M. Wolchonsky. Analyses were reported by C. M. Kersten, P. Krotoff, F. Angel, and N. von Kokscharoff. It contains from 17.93 to 18.85 per cent. Cr_2O_3 ; 10.43 to 17.85 per cent. Fe_2O_3 ; 3.50 to 6.47 per cent. Al_2O_3 ; 36.84 to 37.01 per cent. SiO_2 ; and 21.84 to 22.46 per cent. H_2O . E. T. Wherry and G. V. Brown gave $Cr_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, or $H_4(Cr_2Si_2O_9)$, **dichromodisilicic acid**, $(HO)_4Al_2(O SiO)_2O$. According to F. Angel, the composition approximates $(H_2Mg, Fe, Ca)_3(Cr, Fe, Al)_2(SiO_4)_3$. About 11.08 per cent. of moisture is lost by wolchonskoite when dried to a constant weight at 100° in the presence of conc. sulphuric acid. There is a terrace in the dehydration curve between 160° and 190°. F. Angel considers the water given off below 160° to be absorbed; that over 190°, to be constitutional. At 190°, the colour of the mineral begins to change, and at 280°–300° it becomes a brownish-black. The sp. gr. is 2.2–2.3. F. Angel gave 2.337. The hardness is 2–2½. E. T. Wherry and G. V. Brown gave 1.585 for the index of refraction, β . The mineral is decomposed by hot hydrochloric acid, with the separation of gelatinous silica; about half the chromium is dissolved.

J. E. Wolff, A. Duflos, and J. Zellner analyzed green clays—*chrome ochres*—from Unst, Shetlands, and Mortenberg, Sweden, etc. These ochres appear to be clays containing chromic and ferric oxides in place of some of the alumina. The *selwynite* of G. H. F. Ulrich—after A. C. Selwyn—from Heathcote, Victoria, contains 4.56 per cent. MgO ; 7.61 per cent. Cr_2O_3 ; 33.23 per cent. Al_2O_3 ; 47.15 per cent. SiO_2 ; and 6.23 per cent. H_2O . A chromiferous allophane was found by S. A. W. von Herder at Rudniak, Serbia, and Volterra, Tuscany. He called it *miloschite*—after Prince Milosch—A. Breithaupt called it *Serbian*. It was analyzed by C. M. Kersten, and E. Dechi. It contains 3.61–8.11 per cent. Cr_2O_3 in place of the alumina of allophane. Its sp. gr. is 2.131, and its hardness 1½–2. E. T. Wherry and G. V. Brown represented its formula $(Al, Cr)_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, and gave for the indices of refraction $\alpha = 1.552$, $\beta = 1.552$, and $\gamma = 1.559$. It is presumed to be monoclinic. S. M. Losanitch described a green mineral from Rudniak, Serbia, which he called *alexandrolite*; its composition approximated $(Al, Cr)_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, its sp. gr. was 2.131, and hardness 1½–2. He also obtained a siliceous chromiferous clay from Avala, Serbia, which he called *avalite*—but it is probably a mixture. H. Laspeyres applied the term *cosmochlore* to a chromiferous mineral in the Toluca meteoritic iron; P. Groth called it *cosmochromite*. The emerald-green crystals are probably monoclinic. The birefringence

is high, the extinction oblique, and there are distinct cleavages parallel to (100) and (010), and less distinct prismatic cleavages. The analysis approximates to $(\text{Ca}, \text{Mg}, \text{Fe})_2 \text{Al}_2 \text{Cr}_2 \text{Si}_4 \text{O}_{14}$ or $(\text{R}''\text{O})_2 \text{R}'_{11} (\text{SiO}_4)_8$. The hardness is 5-6.

A chromium epidote from Tawmaw, Upper Burma, called **tawmawite**, carrying 11.16 per cent. of chromic oxide, was described by A. W. G. Bleek.² The **calcium aluminium ferric chromium silicate** is deep green in colour and strongly pleochroic. H. Hess³ found a chromiferous garnet lining cavities in the chrome iron ore of the Ural, and it has been reported from other localities. He named it *ouvarovite*, *ouwarovite*, or *ouvaroffite*—after Count Ouvarov, Owarow, or Ouvaroff. An impure variety occurring with the chromite of Monterey Co., Cal., was called *trautwivite* by E. Goldsmith. Analyses of ouvaroffite were made by A. Komonen, H. Erdmann, A. Damour, T. S. Hunt, L. Aars-Anderson, A. Borgström, and L. Colomba. The results computed by C. F. Rammelsberg agree with the formula **calcium dichromic triorthosilicate**, $\text{Ca}_3 \text{Cr}_2 (\text{SiO}_4)_3$, plus isomorphous $\text{Ca}_3 \text{Al}_2 (\text{SiO}_4)_3$ and $\text{Ca}_3 \text{Fe}_2 (\text{SiO}_4)_3$. The general properties agree with those of the other garnets—*vide grossular*. The sp. gr. is 3.4184 and the hardness 5-7. W. E. Ford gave for the index of refraction 1.870—*vide* Table XXIX. Z. Weyberg⁴ fused a mixture of silica, chromic oxide, sodium carbonate, and a large excess of sodium chloride, and after washing, he obtained a crystalline powder of the composition $2\text{Na}_2\text{O} \cdot 3\text{Cr}_2\text{O}_3 \cdot 6\text{SiO}_2$. The dark green crystals are rhombic and pleochroic. By using a mixture of sodium metasilicate, chromic hydroxide, and an excess of sodium chloride, rhombic crystals of the composition $5\text{Na}_2\text{O} \cdot 2\text{Cr}_2\text{O}_3 \cdot 11\text{SiO}_2$ were obtained; and with a mixture of ammonium dichromate, sodium metasilicate and sodium chloride, tridymite-like crystals of the composition $3\text{Na}_2\text{O} \cdot 2\text{Cr}_2\text{O}_3 \cdot 9.5\text{SiO}_2$. The products with chromic oxide are thus quite different from those with alumina, or ferric oxide. S. J. Thugutt reported that a kind of *chromatosodalite*, $4(\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2) \cdot \text{Na}_2\text{CrO}_4 \cdot 5\text{H}_2\text{O}$, or **sodium aluminium chromatosilicate**, is formed as a pale yellow amorphous powder when kaolinite, sodium hydroxide and chromate, and water are heated in an autoclave at 176°-206°.

§ 50. Molybdenum, Tungsten, and Uranium Silicates—Heteropolyacids

In 1826, J. J. Berzelius¹ showed that molybdic and phosphoric acids unite and together act the part of a mixed acid in ammonium phosphomolybdate. The observations of J. C. G. de Marignac, reported in his memoir *Recherches sur les*

tungstates, les fluotungstates et les silicotungstates (1862), established the character of these complex acids. This memoir can be regarded as the starting-point of the chemistry of these compounds. Other *complex inorganic acids*, as W. Gibbs called them, were afterwards discussed by A. Laurent, L. Svanberg and H. Struve, F. Margueritte, E. Zettnoff, A. Nutzingen, V. Eggertz, C. Scheibler, A. Lipowitz, H. Debray, F. L. Sonnenschein, M. Sprenger, G. A. Barbieri, D. Klein, F. Mauro, H. Copaux, F. Parmentier, W. Knop, E. H. Jenkins, R. W. Atkinson, R. Finkener, M. Seligsohn, J. Lefort, R. Kehrman and co-workers, M. Fremery, C. Friedheim, A. Miolati, P. Pfeiffer, etc. A. Rosenheim called the complex acids containing more than one mol. of acid anhydride, **polyacids**—e.g. the pyrosulphuric acid, $\text{H}_2\text{S}_2\text{O}_7$, or $\text{H}_2[\text{O}(\text{SO}_3)_2]$; pyrophosphoric acid, $\text{H}_4\text{P}_2\text{O}_7$, or $\text{H}_4[\text{O}(\text{PO}_3)_2]$; tetrachromic acid, $\text{H}_2\text{Cr}_4\text{O}_{13}$, or $\text{H}_2[\text{O}(\text{CrO}_3)_4]$; metatungstic acid, $\text{H}_2\text{W}_4\text{O}_{13}$, or $\text{H}_2[\text{O}(\text{WO}_3)_4]$; etc. In these, the acid radicles are of the same kind, and they are called **iso-polyacids** in contradistinction to the **heteropolyacids** in which the radicles are different—e.g. phosphotungstic acid, $\text{H}_7[\text{P}(\text{W}_2\text{O}_7)_6]$; silicotungstic acid, $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_6]$; silicomolybdic acid, $\text{H}_8[\text{Si}(\text{Mo}_2\text{O}_7)_6]$; etc. There are two classes of heteropolyacids and salts. In the so-called (i) *wirkliche Heteropolystäuren*, the anion contains only anionogenic constituents, while in the so-called (ii) *Metallkomplexsäuren*, the anion contains amphoteric oxides like chromic oxide, ferric oxide, and alumina.

The formation of the polyacidic anions depends on the electroaffinity of the complex, and R. Abegg and G. Bodländer showed that the tendency to form complexes generally increases with decreasing electroaffinity. Consequently, the oxygenous anions and amphoteric oxides with a feeble electroaffinity form heteropolyanions. A. Rosenheim has shown that the oxides of the elements I.—H, Cu, Au; II.—Be; III.—B, Al; IV.—C, Si, Ti, Zr, Ce, Th, Sn; V.—N; V, Sb, Ta, P, As, Sb; VI.—Cr, Mo, W, U, S, Se, Te; VII.—Mn, I; and VIII.—Fe, Co, Ni, Rh, Os, Ir, Pt, exhibit a tendency to form heteropolyacids. Hydrogen forms with its amphoteric oxide, water, hydrogen dioxide and the per-salts and per-acids. Many electronegative anions—perchlorate, chlorate, bromate, etc.—have a tendency to form polyanions. The anions PO_4''' , PO_3'' , HPO_3'' , $\text{H}_2\text{PO}_2'$, AsO_4''' , and AsO_3'' form polyanions. SO_3 and SeO_3 occur frequently in heteropolyanions, while SO_4 and SeO_4 rarely if ever form such anions. Silicic acid exhibits a marked tendency to form heteropolyacids, and a great number of native silicates—particularly the complex aluminum silicates, are possibly heteropolysilicic acids. There is also a series of silicomolybdates, and a series of silicotungstates.

M. Delafontaine² did not succeed in making a silicomolybdate by boiling sodium molybdate with water and silicic acid; but, by other processes, F. Parmentier, W. Asch, and H. Copaux obtained several silicododecamolybdates, and two hydrosilicododecamolybdic acids. W. Asch unsuccessfully tried to make silicomolybdic acids with a smaller proportion of molybdic oxide than is represented by the ratio $\text{MoO}_3 : \text{SiO}_2 = 12 : 1$, by treating a soln. of sodium metasilicate with smaller proportions of molybdic acid. The product was a mixture of tetrasodium silicododecamolybdate, $2\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 4\text{H}_2\text{O}$, and other molybdates.

F. Parmentier obtained **hydrosilicododecamolybdic acid**, $(\text{SiO}_2 \cdot 4\text{H}_2\text{O}) 12\text{MoO}_3 \cdot 22\text{H}_2\text{O}$, by the action of dil. hydrochloric acid on **octomercurous silicododecamolybdate**, $4\text{Hg}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3$, or $\text{Hg}_8[\text{Si}(\text{Mo}_2\text{O}_7)_6]$. The mercury salt was made by pouring a soln. of ammonium silicomolybdate into one of mercurous nitrate or adding mercuric molybdate to a soln. of a silicate in nitric acid. The precipitate was washed many times with dil. mercurous nitrate, and dried on a porous tile; it should not be dried by pressure between filter paper owing to the ready reduction of the salt by organic matters. The mercurous salt forms small yellow crystals, which act on polarized light. The salt is decomposed by water, blackened by alkalis, and decomposed by ammonium hydrosulphide precipitating silica and mercuric sulphide. E. Drechsel obtained the acid by extracting the alkali salt with ether. Hydrosilicododecamolybdic acid forms yellow octahedral crystals belonging to the cubic system. According to E. Bräuer, the composition of the

acid obtained by crystallization from aq. soln. is $\text{H}_8\text{Si}(\text{Mo}_2\text{O}_7)_6 \cdot 28\text{H}_2\text{O}$. A soln. of the acid in hot conc. nitric acid furnishes on cooling small yellow plates of $\text{H}_8\text{Si}(\text{Mo}_2\text{O}_7)_6 \cdot 14\text{H}_2\text{O}$.¹ A. Mielati represented the octobasic acid by the formula $\text{H}_8[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$; and A. Rosenheim showed that the composition of the silver and mercury salts agrees with the octobasicity of the acid. The crystals melt between 45° and 55° in their water of crystallization, and decompose at 100° . The complex acid is sparingly soluble in water and dil. acids. An excess of alkali carbonate and ammonia decomposes the complex acid with the separation of silica. When treated with bases, crystalline salts are formed. Unlike phosphomolybdic acid, potassium hydroxide does not produce an insoluble salt, but with caesium and rubidium salts, sparingly soluble salts are formed. W. Asch made **octosilver silicododecamolybdate**, $4\text{Ag}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 15\text{H}_2\text{O}$, or $\text{Ag}_8[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 15\text{H}_2\text{O}$, by pouring a conc. soln. of silver nitrate into one of sodium silicomolybdate. The yellow amorphous precipitate soon becomes crystalline. A. Rosenheim and J. Pinsker prepared the guanidine salt. E. Brauer found the hydrogen ion conc. of a $0.015N$ -soln. to be $[\text{H}^+] = 4.3 \times 10^{-3}$. Two hydrated **hydrosilicododecamolybdic acids** have been reported, but E. Brauer considers that both acids are really the octobasic acid just described. W. Asch obtained crystals of $(2\text{H}_2\text{O} \cdot \text{SiO}_2) \cdot 12\text{MoO}_3 \cdot 30\text{H}_2\text{O}$ by adding tetrasodium silicododecamolybdate, $2\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 21\text{H}_2\text{O}$, in the cold to a large excess of dil. sulphuric acid (1:5), shaking the soln. in a separating funnel with an excess of ether. Three layers are formed; the bottom layer is a soln. of the free acid in ether; the top layer is aq. ether; and the intermediate layer is a soln. of sodium sulphate in ether and water. The bottom layer is run off, and mixed with much water; the ether is evaporated and the aq. soln. conc. at about 45° . Large crystals of the acid are formed. W. Asch found the sp. gr. of aq. soln. of the free acid of normality N , at 10° and 40° , to be

N	. . .	0.4	0.2	0.1	0.05	0.025	0.0125	0.00625	0.003125
10°	. . .	1.1447	1.0736	1.0384	1.0205	1.0116	1.0069	1.0049	1.0035
40°	. . .	1.1341	1.0647	1.0303	1.0125	1.0038	0.9992	0.9963	0.9960

and the mol. conductivities of soln. with a gram-eq. of the acid in v litres of water,

v	. . .	2.5	5	20	80	160	320	640	1280
10°	. . .	215.9	230.7	257.6	272.75	282.05	286.40	290.90	295.22
40°	. . .	327.6	360.1	402.0	426.00	439.75	453.62	461.98	482.60

The acid is decomposed by alkalis; but with chlorides or sulphates in theoretical proportions two series of salts are produced, $2\text{R}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot \text{Aq.}$, and $1.5\text{R}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot \text{Aq.}$. Aniline, pyridine, and other organic bases give a yellow crystalline precipitate.

H. Copaux obtained crystals of $(2\text{H}_2\text{O} \cdot \text{SiO}_2) \cdot 12\text{MoO}_3 \cdot 31\text{H}_2\text{O}$ by mixing a dil. soln. of sodium silicomolybdate with five times the amount of sulphuric acid, and adding ether. The yellow oil, which collects at the bottom of the flask is treated with an excess of water and evaporated at 20° – 30° for crystals. The same acid was made by mixing hot soln. of ammonium molybdate and sodium silicate in proportions required for $\text{SiO}_2 : 12\text{MoO}_3$, and adding five times the quantity of sulphuric acid. The mixture was treated with ether, etc., as in the previous case. The two acids are probably the same. The yellow octahedral crystals are often opaque and have superficial efflorescence. They belong to the tetragonal system and have the axial ratio $a : c = 1 : 1.007$. They are isomorphous with the corresponding silicotungstic acid. When treated with nitric acid at 35° , a triclinc hydrate with 15 mols. of water is formed.

According to W. Knop, by saturating potassium silicate with nitric acid, and adding ammonium molybdate, a yellow colour is produced, and in the presence of much ammonium chloride, an orange precipitate is formed. E. Richters found that the precipitation is accelerated by warming the soln. to 60° . The precipitate dissolves in aq. ammonia and flocculent silicic acid is slowly formed; but in the presence of much ammonium chloride, the separation of silica is incomplete.

F. Parmentier prepared **tetrammonium silicododecamolybdate**, $2(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot n\text{H}_2\text{O}$, or $(\text{NH}_4)_4\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$, by mixing nitric acid soln. of ammonium molybdate and alkali silicate. The yellow liquid furnishes a crystalline precipitate. The octahedral crystals can be purified by dissolving them in water, and precipitating by the addition of an ammonium salt. W. Gibbs reported the formation of yellow crystals of $(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 5\text{H}_2\text{O}$ by mixing soln. of ammonium molybdate and hydrofluosilicic acid. A. Rosenheim and J. Pinsker prepared the guanidine salt.

H. Copaux made **tetralithium silicododecamolybdate**, $2\text{Li}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 29\text{H}_2\text{O}$, or $\text{Li}_4\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 2\text{H}_2\text{O}$, by evaporating a mixed soln. of the acid and a lithium salt in the cold. The octahedral crystals are singly refracting and belong to the cubic system; they are sparingly soluble in cold water. Five mols. of water are retained at 105° , and 6 mols. when dried in the cold over baryta. F. Parmentier made a **tetrasodium silicododecamolybdate**, $2\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot n\text{H}_2\text{O}$, or $\text{Na}_4\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$, by the same method as that employed for the ammonium salt. H. Copaux obtained a salt with $n=14$ by heating under press. for 7-8 hrs. at 150° , a mixture of sodium silicate and molybdic acid, and evaporating the pale yellow liquid at 40° . The yellow triclinic crystals have the axial ratios $a:b:c=1.633:1:0.544$, and $\alpha=90^\circ 37'$, $\beta=94^\circ 21'$, and $\gamma=83^\circ 30'$. They are stable in air. If the evaporation be conducted at ordinary temp., the triclinic crystals have $n=22$. They deliquesce strongly on exposure to air. W. Asch obtained the salt with $n=21$ by gradually saturating a boiling aq. soln. of sodium metasilicate with molybdic acid. The gelatinous silica first formed dissolves when more molybdic acid is added. The soln. evaporated at 45° , furnishes a syrupy liquid which deposits large yellow monoclinic crystals. The loss of water at different temp. is eq. to 17.59 mols at 100° ; 17.85 mols at 140° ; 20.15 mols at 225° - 235° ; 20.97 mols at 230° - 235° ; and 21 mols at 260° - 265° . The mol. wt. of the salt by the lowering of the f.p. by R. Löwenherz's method is 1912, without taking the water into consideration. When treated with chlorides, nitrates, or sulphates, the corresponding silicomolybdates are formed; and with organic bases like aniline, pyridine, or quinoline- yellow powders, sparingly soluble in water, are formed. The salt is decomposed by sodium carbonate, forming silica, carbon dioxide, and sodium molybdate. F. Parmentier prepared **tetrapotassium silicododecamolybdate**, $2\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot n\text{H}_2\text{O}$, or $\text{K}_4\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$, by the process employed for the ammonium salt. W. Asch made yellow hexagonal prisms with $n=16$ by treating the sodium salt with the calculated quantity of potassium chloride. The crystals effloresce in air and lose their lustre. When heated to 100° , 14.58 mols of water are lost; at 160° , 15.32 mols; at 215° - 240° , 15.50 mols; and at 260° - 265° , 16 mols. The sp. gr. of aq. soln. of normality N , at 10° and at 40° , are:

N	0.4	0.2	0.1	0.05	0.025	0.0125	0.00625	0.003125
10°	1.1550	1.0771	1.0423	1.0797	1.008	1.0046	1.00196	1.009
40°	1.1482	1.0724	1.0344	1.0098	0.9993	0.9967	0.9942	0.9920

The mol. conductivities at 10° and 40° for soln. with a gram-eq. of the salt in v litres of water are:

v	2.5	5	10	20	80	160	320	640
10°	61.05	68.65	72.73	78.24	91.50	98.59	104.12	114.20
40°	110.96	124.10	132.55	141.60	168.98	184.15	204.05	238.62

H. Copaux obtained a potassium salt with $n=18$, by evaporating the soln. at 40° . The hexagonal crystals have a strong negative double refraction, and the axial ratio is $a:c=1:0.6809$. They effloresce in air, and slowly decompose. At ordinary temp. over baryta, 16 mols of water are given off; and at 105° , 17 mols of water are given off. H. Copaux also made **rubidium silicododecamolybdate** in a similar manner. He found that the silicomolybdates are usually isomorphous with the corresponding silicotungstates, which they also closely resemble in degree

of hydration and solubility; the mercurous, thallium, rubidium, and ammonium salts of the two series being very sparingly soluble, whilst the alkaloid silicomolybdates are as insoluble as the corresponding silicotungstates. The potassium salts of silicomolybdic and of silicotungstic acids containing $18\text{H}_2\text{O}$ form hexagonal crystals closely resembling those of quartz, and they are dextro-rotatory, whilst their soln. are optically inactive; laevo-rotatory crystals of these salts can also be obtained from soln. containing traces of alkali impurity; dextropotassium silicomolybdate crystals have $[\alpha]_D = +17.0$ – 17.4° and the laevo-crystals $[\alpha]_D = -17.1^\circ$.

W. Asch, and H. Copaux made tribasic salts of the alkali silicomolybdates. Thus, W. Asch made **trisodium pentahydrosilicododecamolybdate**, $\frac{1}{3}\text{Na}_2\text{O} \cdot \frac{1}{3}\text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 16\frac{1}{2}\text{H}_2\text{O}$, or $\text{Na}_3\text{H}_5[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$, by treating a mol of the normal sodium salt with 6 mols of hydrochloric acid; and H. Copaux, by cooling a mixed soln. of normal sodium silicomolybdate and silicomolybdic acid, concentrated at 35° . The monoclinic tabular crystals have the axial ratios $a:b:c = 1.341:1:0.999$, and $\beta = 100^\circ 38'$. The crystals are stable in air. According to W. Asch, the crystals lose 13.15 mols of water at 100° – 110° ; 13.36 mols at 140° – 145° ; 15.5 mols at 225° – 235° ; 16.5 at 230° – 235° ; and 16.99 at 260° – 265° . The corresponding **tripotassium pentahydrosilicododecamolybdate**, $\frac{1}{3}\text{K}_2\text{O} \cdot \frac{1}{3}\text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 13\frac{1}{2}\text{H}_2\text{O}$, $\text{K}_3\text{H}_5[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$, was made by W. Asch by mixing a mol of the normal potassium salt with 6 mols of hydrochloric acid; by evaporating equimolar soln. of the acid and the normal potassium salt at 45° – 50° ; or by treating a mol of the acid with 2 mols of potassium nitrate. H. Copaux also made this salt and found the yellow monoclinic plates have the axial ratios $a:b:c = 1.200:1:0.860$, and $\beta = 102^\circ 21'$. According to W. Asch, the salt loses 12.16 mols of water at 80° – 100° ; 12.5 mols at 160° ; 13.02 mols at 215° ; and 14.02 mols at 260° – 265° . The salt is stable only in the presence of an excess of acid; and in contact with water the crystals become turbid and then dissolve completely.

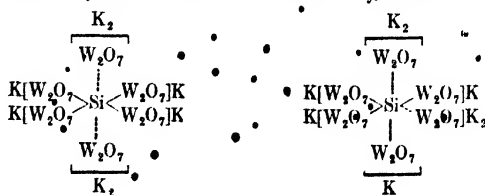

W. Asch made **tetrasilver tetrahydrosilicododecamolybdate**, $2\text{Ag}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 12\text{H}_2\text{O}$, or $\text{Ag}_4\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 12\text{H}_2\text{O}$, by mixing dil. soln. containing 4 mols of silver nitrate and a mol of sodium silicododecamolybdate. The soln. is evaporated at 45° – 50° , and filtered. It furnishes yellow glassy crystals. The salt is decomposed by water with the separation of silica; it is soluble in aq. ammonia; and with hydrochloric acid, it forms silver chloride. F. Parmentier also made tetrasilver silicododecamolybdate. According to W. Asch, if dil. soln. of 3 mols of silver nitrate and a mol of potassium hemihydrosilicododecamolybdate are mixed and concentrated by evaporation, ruby-red crystals of **trisilver pentahydrosilicododecamolybdate**, $\frac{1}{3}\text{Ag}_2\text{O} \cdot \frac{1}{3}\text{SiO}_2 \cdot 2\text{MoO}_3 \cdot 11\text{H}_2\text{O}$, $\text{Ag}_3\text{H}_5[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 9\text{H}_2\text{O}$, are formed. On standing, the crystals become insoluble in water. H. Copaux made **silver potassium silicododecamolybdate**, $\frac{1}{3}\text{Ag}_2\text{O} \cdot \frac{1}{3}\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 7\text{H}_2\text{O}$, $\text{Ag}_3\text{KH}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 5\text{H}_2\text{O}$, by the evaporation and crystallization of a soln. containing potassium silicododecamolybdate, silicomolybdic acid, and silver nitrate. The amount of water of crystallization depends on the temperature at which the soln. is evaporated: at 18° – 20° , red, triclinic crystals containing $7\text{H}_2\text{O}$ are deposited; and at 12° – 14° , yellow, triclinic crystals containing $15\text{H}_2\text{O}$. Yellow, crystalline crusts with $11\text{H}_2\text{O}$ were also formed. The red colour of one of these hydrates is unusual for a silicomolybdate, which are characteristically yellow in colour.

W. Asch treated a soln. of tetrasodium silicododecamolybdate with a calcium salt and obtained **calcium silicododecamolybdate**, $2\text{CaO} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 24\text{H}_2\text{O}$, or $\text{Ca}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 22\text{H}_2\text{O}$, and H. Copaux made crystals of a similar salt with $26\text{H}_2\text{O}$ by evaporating a mixed soln. of a calcium salt and the complex acid at 20° . The uniaxial crystals are positive and feebly doubly refracting. They effloresce superficially on exposure to air. By evaporating the soln. at 10° , a salt with $31\text{H}_2\text{O}$ is formed in regular octahedra. H. Copaux made trigonal crystals of **strontium silicododecamolybdate**, $2\text{SrO} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 26\text{H}_2\text{O}$, or $\text{Sr}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 24\text{H}_2\text{O}$, by the spontaneous evaporation of a mixed soln. of the complex acid and a strontium salt in the cold or at 30° – 35° . The trigonal crystals have the axial

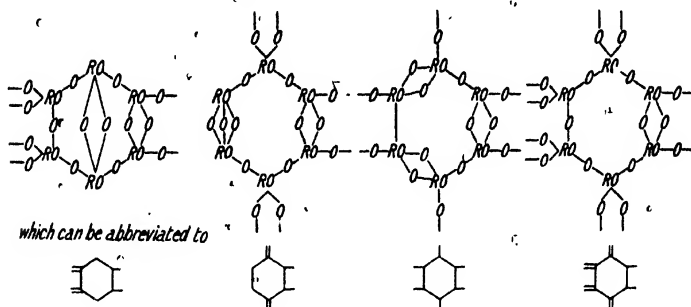

ratio $a : c = 1 : 2.639$, and $\alpha = 56^\circ 44'$. The uniaxial crystals are negative and feebly doubly refracting. They effloresce superficially on exposure to air. H. Copaux made six-sided monoclinic prisms of **barium silicododecamolybdate**, $2\text{BaO} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 16\text{H}_2\text{O}$, or $\text{Ba}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 14\text{H}_2\text{O}$, by evaporating a mixed soln. of the complex acid and a barium salt at 50° . The crystals have the axial ratios $a : b : c = 1.811 : 1 : 1.554$, and $\beta = 104^\circ 15'$. If the soln. be evaporated at $30^\circ 32'$, trigonal crystals, with $22\text{H}_2\text{O}$, and the axial ratio $a : c = 1 : 1.2865$, and $\alpha = 88^\circ 4'$, are formed. The uniaxial crystals are negative and strongly doubly refracting. They effloresce on exposure to air. They dissolve in four times their weight of cold water. By evaporating the soln. at 20° , H. Copaux obtained a salt with $29\text{H}_2\text{O}$ in regular octahedral crystals. W. Asch made yellow crystals of a similar salt with $24\text{H}_2\text{O}$ by double decomposition of a barium salt with the sodium silicododecamolybdate. The salt is soluble in water; and the crystals lose water on exposure to air.

W. Asch made yellow crystals of **magnesium silicododecamolybdate**, $2\text{MgO} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 30\text{H}_2\text{O}$, or $\text{Mg}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 28\text{H}_2\text{O}$, by double decomposition with the sodium complex salt and a magnesium salt. H. Copaux made the magnesium salt with $31\text{H}_2\text{O}$ by evaporating a soln. of the acid with a magnesium salt at $15^\circ 35'$. The yellow octahedral crystals belong to the cubic system. They readily effloresce on exposure, and are sparingly soluble in water. H. Copaux also made yellow cubic octahedral crystals of **zinc silicododecamolybdate**, $2\text{ZnO} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 31\text{H}_2\text{O}$, $\text{Zn}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 29\text{H}_2\text{O}$, by evaporation at $15^\circ 35'$. They effloresce on exposure to air, and are very soluble. Greenish-yellow triclinic crystals of **cadmium silicododecamolybdate**, $2\text{CdO} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 22\text{H}_2\text{O}$, or $\text{Cd}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 20\text{H}_2\text{O}$, were made in a similar way. The axial ratios are $a : b : c = 0.440 : 1 : 0.383$, and $\alpha = 88^\circ 43'$, $\beta = 91^\circ 14'$, and $\gamma = 84^\circ 42'$. They are stable in air, and readily soluble in water. H. Copaux also made yellow, isotropic, octahedral crystals, **aluminium silicododecamolybdate**, $2\text{Al}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{MoO}_3) \cdot 93\text{H}_2\text{O}$, or $\text{Al}_4[\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6]]_3 \cdot 87\text{H}_2\text{O}$, by evaporating in the presence of quicklime, at $15^\circ 35'$, a soln. of 3 mols of silicomolybdic acid and 4 mols of aluminium chloride. S. J. Thugutt made **sodium aluminium silicomolybdate**, $4(\text{Na}_2\text{O} \cdot 2\text{SiO}_2) \cdot \text{Na}_2\text{MoO}_4 \cdot 71\text{H}_2\text{O}$, or **molybdosodalite**, by heating kaolinite, sodium hydroxide, sodium molybdate, and water for 78 hrs. at $195^\circ - 215^\circ$. F. Parmentier made **thallous silicododecamolybdate**, $2\text{Tl}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{MoO}_3 \cdot 10\text{H}_2\text{O}$, or $\text{Tl}_2\text{H}_4[\text{Si}(\text{Mo}_2\text{O}_7)_6] \cdot 8\text{H}_2\text{O}$, as a yellow crystalline powder, by double decomposition of ammonium silicomolybdate or silicomolybdic acid with a soln. of a thallous salt. H. Copaux made **chromium silicododecamolybdate**, $2\text{Cr}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{MoO}_3) \cdot 93\text{H}_2\text{O}$, and **ferric silicododecamolybdate**, $2\text{Fe}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{MoO}_3) \cdot 93\text{H}_2\text{O}$, by a process similar to that employed for the aluminium salt.

A number of complex compounds of silicic and tungstic acids has been studied principally by J. C. G. de Marignac,³ G. Wyrouboff, and H. Copaux. There appear to be three hydrates of **hydrosilicododecatungstic acid**, and an isomeric form. The **octocohydrate**, $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 28\text{H}_2\text{O}$, crystallizes at ordinary temp. below 28.5° from aq. soln.; above 28.5° , rhombic crystals of the **doconhydrate**, $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 22\text{H}_2\text{O}$, appear. Conc. aq. soln. of the acid when treated with fuming hydrochloric acid give thin prisms of the **pentadecahydrate**, $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 15\text{H}_2\text{O}$. An isomeric form, an **icosihydrate**, $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 20\text{H}_2\text{O}$, has also been obtained in triclinic crystals. The isomeric forms are symbolized.

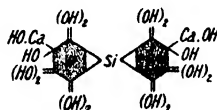

W. and D. Asch's hexite-pentite hypothesis applies better to the deca- and dodeca-tungstic and molybdic acids than to the aluminosilicic acids. In this theory it is assumed that the decamolybdic and dodecatungstic acids and salts are compounded of hexite rings:

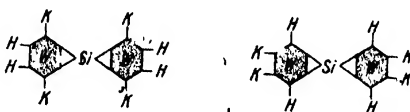

where R represents the sexivalent radicle W or Mo. This makes a series of three possible salts of the type: $4\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 2\text{WO}_3$, and with nuclei:

The calcium salt, $2\text{CaO} \cdot 8\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$, which retains 8 mols of water at 100° , can be represented

Likewise the dimorphous potassium salt, $2\text{K}_2\text{O} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 7\text{H}_2\text{O}$, can be represented

The decatungstic acids and salts are represented in an analogous manner by means of pentite rings. Thus, $4\text{R}_2\text{O} \cdot \text{SiO}_2 \cdot 10\text{WO}_3$ becomes

J. C. G. de Marignac reported **isohydro-silicododecatungstic acid**, $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 24\text{H}_2\text{O}$, or $(\text{SiO}_2 \cdot 4\text{H}_2\text{O}) \cdot 12\text{WO}_3 \cdot 20\text{H}_2\text{O}$, i.e. $\text{H}_8\text{SiW}_{12}\text{O}_{42} \cdot 20\text{H}_2\text{O}$, or $\text{H}_8[\text{Si}(\text{W}_3\text{O}_7)_4] \cdot 20\text{H}_2\text{O}$, to be formed by evaporating an aq. soln. of silicotungstic acid to dryness, digesting the residue with water, and again evaporating the aq. extract to a syrupy liquid which then furnishes fine crystals. H. Copaux represented the composition of the acid by $(\text{SiO}_2 \cdot 2\text{H}_2\text{O}) \cdot 12\text{WO}_3 \cdot 22\text{H}_2\text{O}$.

H. Copaux prepared this acid by dissolving sodium tungstate in 7-8 times its weight of water, and gradually adding 20 per cent. sulphuric acid until the soln. reacts feebly

acid to litmus. An aq. soln. of the calculated quantity of sodium silicate is then added, and the soln. again acidified with sulphuric acid. The mixture is evaporated on the water-bath, until oily drops separate when treated with sulphuric acid and ether. The crystals obtained on cooling are a mixture of the required acid with a higher hydrated acid. The two are separated by converting them into their potassium salts. According to H. Copaux, the former gives $2K_2O \cdot SiO_2 \cdot 12WO_3 \cdot 18H_2O$, the latter $2K_2O \cdot SiO_2 \cdot 12WO_3 \cdot 9H_2O$; the former salt furnishes colourless hexagonal crystals which deliquesce in air; the latter salt furnishes yellow rhombic crystals which do not deliquesce in air. Hence by exposing the mixed salts to air at 40° , the more deliquescent salt is readily removed. The salts are converted to the acids by treatment with a mixture of ether and sulphuric acid.

G. Wyruboff also prepared this acid by a similar process. E. Decheel prepared a silicododecatungstic acid by the action of a soln. of sodium tungstate on gelatinous silicic acid. The proportion of contained water was not determined. The crystals of the hydro-silicododecatungstic acid are triclinic pinacoids, which, according to J. C. G. de Marignac, and P. Groth, have the axial ratios and angles $a:b:c=0.5829:1:0.5534$, and $\alpha=93^\circ 23'$; $\beta=122^\circ 20'$; and $\gamma=84^\circ 1'$. J. D. Klein discussed the isomorphism of silicotungstic and borotungstic acids. The crystals were studied by W. Muthmann, and F. Zambonini. According to H. Copaux, the humidity of the air determines whether the acid is stable or efflorescent. The acid partially melts in its water of crystallization below 100° ; and at 200° , it loses all but two mols of water, forming a fine powder which is readily soluble in water with the development of heat. After heating to 300° , the acid is soluble in water, and on evaporation furnishes the original acid, but if heated to dull redness, the acid is decomposed. The acid is soluble in ether. When the aq. soln. is heated in a sealed tube to 150° , it alters more quickly than does the potassium salt; and the dry crystals also change when kept for some time. F. Bourion stated that at 150° – 280° , chlorine mixed with the vap. of sulphur chloride, SCl_2 , removes all the tungsten from the acid. According to J. C. G. de Marignac, when the acid is melted with sodium carbonate, 17.77 per cent. of carbon dioxide is given off; and the acid also readily unites with 2 and 4 mols of base to form salts. J. D. Klein prepared the two series of salts.

G. Wyruboff, and A. Bertrand prepared complexes of the silicododecatungstic acids with the alkaloids, A. $4A \cdot SiO_2 \cdot 12WO_3 \cdot nH_2O$, by treating a cold conc. soln. of the alkaloid with a 5 per cent. soln. of silicotungstic acid. The use of silicotungstic acid as a test for alkaloids, etc., has been discussed by J. C. G. de Marignac, F. Kehrman, and B. Flürscheim. M. Javillier studied the silicotungstates of cocaine, apatine, and atropine.

J. C. G. de Marignac prepared normal octammonium isosilicododecatungstate, $4(NH_4)_2O \cdot SiO_2 \cdot 12WO_3 \cdot 16H_2O$, or $(NH_4)_4[Si(W_2O_7)_6] \cdot 16H_2O$, by evaporating a soln. of the acid in aq. ammonia; and also by boiling a soln. of normal ammonium decatungstate for a long time, filtering off the precipitated silica, and cooling the soln. The white amorphous mass is readily soluble in hot water. He also made tetrammonium isotetrahydrosilicododecatungstate, $2(NH_4)_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 6H_2O$, i.e. $(NH_4)_4H_4[Si(W_2O_7)_6] \cdot 6H_2O$, by boiling a hydrochloric acid soln. of the preceding salt or of one of the silicododecatungstates, and cooling the soln. It is soluble in hot water and when boiled with an excess of aq. ammonia furnishes ammonium hydrotungstate. G. Wyruboff regards this as the normal salt, and J. C. G. de Marignac's normal salt as a basic salt. J. C. G. de Marignac found that when a soln. of one mol of $SiO_2 \cdot 12WO_3 \cdot 24H_2O$ is treated with 4 mols of sodium carbonate it furnishes a syrupy mass, but if 6 mols of the carbonate are used, trigonal crystals of tetrasodium isotetrahydrosilicododecatungstate, $2Na_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 10H_2O$, or $Na_4H_4[Si(W_2O_7)_6] \cdot 10H_2O$, are formed. The crystals have the axial ratio $a:c=1:1.3277$, and $\alpha=86^\circ 50'$; they are stable in air, lose 8 mols of water at 100° ; and when fused with sodium carbonate, give off 11 mols of carbon dioxide. H. S. van Kleeffer found that fused sodium tungstate and silicate are almost immiscible below 1100° . J. C. G. de Marignac prepared badly-formed, rhombic crystals of normal octopotassium isosilicododecatungstate,

$4\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 20\text{H}_2\text{O}$; they lose 15 mols of water at 100° , and when melted with sodium carbonate give off 9 mols of carbon dioxide.

J. C. G. de Marignac obtained the octocosihydrate, $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_8] \cdot 28\text{H}_2\text{O}$, which he represented **hydrosilicododecatungstic acid**, $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 32\text{H}_2\text{O}$, by treating the mercurous salt with hydrochloric acid, and removing traces of mercury from the filtrate by hydrogen sulphide. The filtrate was conc. by evaporation, and allowed to crystallize. This hydrate crystallizes from aq. soln. at temp. below 28.5° . H. Copaux represented the acid by $(\text{SiO}_2 \cdot 2\text{H}_2\text{O}) \cdot 12\text{WO}_3 \cdot 31\text{H}_2\text{O}$; and made it by the action of a soln. of sodium tungstate on freshly precipitated gelatinous silicic acid; and by the action of hydrated tungstic acid on a soln. of sodium silicate.

H. Copaux prepared the acid as follows: Gelatinous silicic acid is made by adding conc. nitric acid to a dil. soln. of sodium silicate until litmus is reddened. The silicic acid is treated with a soln. of sodium tungstate in five times its weight of water. The mixture is diluted so that the weight of liquid is about eight times that of tungstic oxide employed. The soln. is strongly acidified with acetic acid, and heated to its b.p.; when hydrochloric acid produces no precipitate, the soln. is cooled, and treated with a mixture of ether and 33 per cent. of sulphuric acid until the turbidity persists when stirred. The mixture forms three layers—the lowest layer is a compound of ether with the 24 and 32 hydrated silicotungstic acids. The two acids are separated by fractional crystallization of the potassium salts. The salt of the higher hydrate furnishes the first crop of hexagonal prismatic crystals, the lower hydrate forms rhombic crystals. The potassium salt is converted into the acid by treatment with sulphuric acid and ether as before.

According to J. C. G. de Marignac, the octocosihydrate forms colourless tetragonal crystals, but they sometimes have a yellow tinge. The axial ratios are $a:c = 1:1.0117$. According to G. Wyruboff, the crystals of the acid have an extremely feeble positive double refraction. They effloresce rapidly in air. The crystals begin to melt in their water of crystallization at 36° , and at 53° , fusion is complete; at 100° , 25 mols of water are given off, and no more is lost at 150° ; between 150° and 220° , 6 mols of water are given off; and the remaining water is evolved at 250° . The product so obtained dissolves in water with the evolution of much heat, and when the soln. is evaporated, it gives the original acid; but if heated over 350° , the orange-yellow product is insoluble in water. When melted with sodium carbonate, 16.70 per cent. or 13 mols of carbon dioxide are expelled. At 18° , 100 parts of water dissolve 96 parts of the acid, and the soln. has a sp. gr. 2.843. The acid is readily soluble in absolute alcohol; if an excess of ether be added to the alcoholic soln., two liquids are formed, the lower layer is a syrupy soln. of the acid in ether. Anhydrous ether dissolves the acid and the crystals. E. Brauer found that the acid is not readily hydrolyzed, and the conc. of the hydrogen ion is $[\text{H}^+] = 2.9 \times 10^{-3}$. G. Wyruboff regarded the acid as tetrabasic, $\text{H}_4\text{SiW}_{12}\text{O}_{40} \cdot 31\text{H}_2\text{O}$; J. C. G. de Marignac, A. Rosenheim, and H. Copaux regarded it as octobasic. Silicododecatungstic acid is used on account of the colour reactions it gives with alkaloids, and many organic bases, a subject discussed by E. O. North and G. D. Beal.

J. C. G. de Marignac prepared the docosihydrate, $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 26\text{H}_2\text{O}$, or $(\text{SiO}_2 \cdot 4\text{H}_2\text{O}) \cdot 12\text{WO}_3 \cdot 22\text{H}_2\text{O}$, i.e. $\text{H}_8[\text{Si}(\text{W}_2\text{O}_7)_8] \cdot 22\text{H}_2\text{O}$, by partially melting hydro-silicododecatungstic acid in its water of crystallization and allowing the decanted liquid to crystallize slowly; by crystallizing an aq. soln. of the acid above 28.5° ; by evaporating a soln. of the octocosihydrate acidified with sulphuric or hydrochloric acid. The trigonal crystals have the axial ratios $a:c = 1:1.2360$ and $\alpha = 88^\circ 47'$. G. Wyruboff found the crystals of hexacosihydro-silicododecatungstic acid to be physically and chemically isomorphous with tetracosihydrated silicotungstates of lithium, and the alkaline earths. The crystals of the acid have a strong negative double refraction. The crystals do not effloresce in air, but they lose 18 mols of water at 100° . With fused sodium carbonate, 17.38 per cent. of carbon dioxide is given off. G. Wyruboff regarded the acid as tetrabasic,

$H_4SiW_{12}O_{40} \cdot 24H_2O$; J. C. G. de Marignac, A. Rosenheim, and H. Copaux regarded it as octobasic.

G. Wyruboff, and E. O. North and G. D. Beal prepared non-crystalline **ammonium silicododecatungstate**, $2(NH_4)_2O \cdot SiO_2 \cdot 12WO_3 \cdot 8H_2O$, or $(NH_4)_4H_4[Si(W_2O_7)_6] \cdot 12H_2O$; and also $(NH_4)_4W_{12}SiO_{40} \cdot 4NH_4OH \cdot 14H_2O$, but no acid salt was made. The rhombohedral crystals of **tetralithium silicododecatungstate**, $2Li_2O \cdot SiO_2 \cdot 12WO_3 \cdot 24H_2O$, or $Li_4H_4[Si(W_2O_7)_6] \cdot 12H_2O$, were found by G. Wyruboff to have the axial ratios $a : b : c = 1 : 1.6186$. With soln. at 40° – 45° , triclinic crystals of $2Li_2O \cdot SiO_2 \cdot 12WO_3 \cdot 14H_2O$ having the axial ratios $1.1642 : 1 : 0.9681$ and $\alpha = 90^\circ$, $\beta = 94^\circ 20'$, and $\gamma = 86^\circ 26'$ were formed. The crystals resemble those of $2Na_2O \cdot SiO_2 \cdot 12WO_3 \cdot 13H_2O$. The triclinic crystals are feebly doubly refracting, and rapidly become turbid without loss of weight. The salt loses 8 mols of water at 105° . G. Wyruboff also made trigonal crystals of a higher hydrate, $Li_4H_4[Si(W_2O_7)_6] \cdot 22H_2O$, with the axial ratio $a : b : c = 1 : 1.3096$, and a strong negative double refraction. The crystals were studied by W. Muthmann, and V. Zambonini. The salt loses 1.9 mols of water at 105° . G. Wyruboff also made **dilithium silicododecatungstate**, $Li_2O \cdot SiO_2 \cdot 12WO_3 \cdot 24H_2O$, or $Li_2H_6[Si(W_2O_7)_6] \cdot 21H_2O$, from a mixture of 20 grms. of the previous hydrate, and 10 grms. of silicotungstic acid.

J. C. G. de Marignac prepared normal **octosodium silicododecatungstate**, $4Na_2O \cdot SiO_2 \cdot 12WO_3 \cdot 7H_2O$, or $Na_8[Si(W_2O_7)_6] \cdot 7H_2O$, by boiling acid sodium tungstate with water and gelatinous silica. The liquid, on evaporation, furnishes needle-like crystals; 100 parts of the salt dried at 100° have the composition just indicated, and 100 parts of water at 19° dissolve 476.2 parts of the salt, and the soln. has a sp. gr. 3.05. By treating this salt with hydrochloric acid at different temp., acid salts are produced; with an excess of hydrochloric acid, and at 40° – 50° , triclinic pinacoidal crystals of **henahydrated tetrasodium dihydrosilicododecatungstate**, $2Na_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 11H_2O$, or $Na_4H_4[Si(W_2O_7)_6] \cdot 11H_2O$, are produced. The tabular crystals have the axial ratios $a : b : c = 1.0932 : 1 : 0.9102$, and $\alpha = 88^\circ 52'$, $\beta = 95^\circ 18'$, and $\gamma = 86^\circ 37'$. The crystals are strongly doubly refracting; stable in air; they lose 7 mols of water at 100° ; and expel 11 mols of carbon dioxide from fused carbonate. The hydrochloric acid soln. at 35° , furnishes the **dodecahydrated salt** in triclinic pinacoidal crystals with axial ratios $a : b : c = 1.6083 : 1 : 0.5542$, and $\alpha = 90^\circ 52'$, $\beta = 95^\circ 22'$, and $\gamma = 83^\circ 34'$. The double refraction is negative. The crystals are stable in air. They lose 9 mols of water at 105° . The dehydrated salt dissolves completely in water. At ordinary temp., the hydrochloric acid soln. furnishes the **octodecahydrated salt** which occurs in dimorphous, triclinic, pinacoidal crystals, with a strong double refraction. The α -salt has the axial ratios and angles $a : b : c = 1.0320 : 1 : 0.9092$, and $\alpha = 94^\circ 2'$, $\beta = 93^\circ 32'$, and $\gamma = 88^\circ 21'$, while the β -salt has $a : b : c = 0.8056 : 1 : 1.1221$, and $\alpha = 93^\circ 14'$, $\beta = 103^\circ 39'$, and $\gamma = 88^\circ 3'$. Both forms effloresce rapidly in air. During the evaporation of the aq. soln., crystals of the henahydrate first appear, then crystals of the β -salt, and finally crystals of the α -salt, for the metastable β -salt passes into the α -form. Both varieties of the octodecahydrate rapidly pass into the henahydrate. At 100° , the octodecahydrate loses 14 mols of water, and at a red heat all the water is lost. When fused with sodium carbonate, 11 mols of carbon dioxide are given off. If a soln. of the octodecahydrate be treated with sulphuric acid, or with silicotungstic acid, and evaporated, at 25° – 30° , J. C. G. de Marignac, and C. Wyruboff found that crystals of **disodium hexahydro-silicododecatungstate**, $Na_2O \cdot 3H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 14H_2O$, or $Na_2H_6[Si(W_2O_7)_6] \cdot 14H_2O$, are formed in positive, doubly-refracting, triclinic pinacoids with axial ratios $a : b : c = 1.0748 : 1 : 0.9521$, and $\alpha = 89^\circ 6'$, $\beta = 95^\circ 50'$, and $\gamma = 85^\circ 17'$. When the aq. soln. is evaporated, silicotungstic acid is first formed, and the conc. mother liquid deposits crystals of the original salt. J. C. G. de Marignac, and C. Wyruboff obtained triclinic crystals of **sodium nitratesilicododecatungstate**, $4NaNO_3 \cdot 3(2Na_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 13H_2O)$, with axial ratios $a : b : c = 1.0057 : 1 : 0.8642$, and $\alpha = 89^\circ 35'$, $\beta = 90^\circ 20'$, and

$\gamma=91^{\circ} 6'$. The mixed crystals lose 30 mols of water at 100° , and drive 31 mols of carbon dioxide from fused sodium carbonate.

J. C. G. de Marignac prepared the normal salt **octopotassium silicododecatungstate**, $4K_2O \cdot SiO_2 \cdot 12WO_3 \cdot 14H_2O$, or $K_4H_4[Si(W_2O_7)_6] \cdot 12H_2O$, which F. Kehrman represented by the formula $7K_2O \cdot 2SiO_2 \cdot 26WO_3 \cdot nH_2O$. It was obtained by boiling a soln. of acid potassium tungstate with gelatinous silicic acid, until a few drops of hydrochloric acid produced no turbidity. On cooling, a crust of crystals appeared, and the salt was purified by recrystallization from water. It is also obtained by treating the acid salt with potassium carbonate. The imperfectly formed crystals appear to be cubic, but they are doubly refracting. The salt loses 4 mols of water at 100° ; and drives 9 mols of carbon dioxide from fused sodium carbonate. 100 parts of water at 18° dissolve 10 parts of the salt, and at 100° , 33.3 parts of salt. Three acid salts have been reported. J. C. G. de Marignac made **tripotassium pentahydro-silicododecatungstate**, $3K_2O \cdot 5H_2O \cdot 2(SiO_2 \cdot 12WO_3) \cdot 25H_2O$, say, $K_3H_5[Si(W_2O_7)_6] \cdot 12H_2O$, by concentrating and cooling a soln. of the tetrapotassium salt with an excess of sulphuric acid; the first crop of crystals is an acid silicotungstate, the second crop is mainly hexagonal crystals of the tetrapotassium salt, and the mother liquid furnishes monoclinic prisms of the tripotassium salt. G. Wyrouboff crystallized the salt from the sulphuric acid soln. between 30° and 40° . The axial ratios of the crystals are $a:b:c=1.2148:1:0.8499$, and $\beta=102^{\circ} 16'$. The double refraction is negative. The crystals are stable in air; lose 27 mols of water at 100° ; and give 23 mols of carbon dioxide when fused with sodium carbonate. The salt is decomposed by water so that the concentration of the aq. soln. first gives crystals of the tetrapotassium salt, then crystals of the tripotassium salt, and finally rhombohedral crystals of silicotungstic acid contaminated with potassium. E. O. North and C. D. Beal analyzed potassium silicododecatungstate.

G. Wyrouboff obtained rectangular plates of **tetrapotassium tetrahydro-silicododecatungstate**, $2K_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 13H_2O$, or $K_4H_4[Si(W_2O_7)_6] \cdot 13H_2O$, by evaporation of the soln. acidified with nitric acid at a temp. exceeding 30° , or at ordinary temp. in the presence of conc. nitric acid. The monoclinic prisms have axial ratios $a:b:c=1.4715:1:1.9939$, and $\beta=102^{\circ} 54'$. The double refraction is feebly negative. If the normal octopotassium salt is treated with hydrochloric acid, and the soln. evaporated, J. C. G. de Marignac found that colourless hexagonal crystals of the **octodecahydrate**, $2K_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 16H_2O$, are formed, with the axial ratio $a:c=1:0.8585$. G. Wyrouboff, and C. Soré noted the crystals exhibit circular polarization, 14.4° with the D -line. The crystals effloresce on exposure to air, and lose 17 mols of water at 100° . All the water can be expelled at higher temp., and the dehydrated salt dissolves readily in water. With molten sodium carbonate, 11 mols of carbon dioxide are given off. 100 parts of water at 20° dissolve 33.2 parts of salt. J. C. G. de Marignac also prepared two varieties of the hydrate $2K_2O \cdot 2H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 7H_2O$. It is not clear if the alleged varieties contain the same quantities of water of crystallization. The rhombic bipyramids have axial ratios $a:b:c=0.8243:1:1.3311$. The one form occurs in short thick prisms, the other in six-sided plates. Both varieties lose about 7 mols of water at 100° ; and about 11 mols of carbon dioxide are given off when fused with sodium carbonate. Both forms are very soluble in hot water, and less so in cold water. According to H. Copaux, when heated with water in a sealed tube at 150° , an isomeric derivative of $SiO_2 \cdot 12WO_3 \cdot 32H_2O$ is formed.

R. Godeffroy made normal **octorubidium silicododecatungstate**, $4Rb_2O \cdot SiO_2 \cdot 12WO_3 \cdot nH_2O$, or $Rb_4[Si(W_2O_7)_6] \cdot nH_2O$, as a white precipitate by adding rubidium chloride to a soln. of the acid. Crystals are obtained by evaporating the aq. soln. 100 parts of water at 20° dissolve about 0.67 part of the salt; and at 300° , about 5 parts of the salt; it dissolves sparingly in acidulated water, and readily in ammoniacal water. It is not soluble in alcohol. G. Wyrouboff also made the normal salt and an acid salt— $2RbOH \cdot SiO_2 \cdot 12WO_3 \cdot 5H_2O$, and

$3\text{Rb}_2\text{O} \cdot \text{H}_2\text{O} \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 22\text{H}_2\text{O}$. By mixing a mol of silicododecatungstic acid with 2 mols of rubidium carbonate, he obtained a white gelatinous precipitate which was washed by decantation, and dried in air. The white powder has the composition **tribidium hydrosilicododecatungstate**, $3\text{Rb}_2\text{O} \cdot \text{H}_2\text{O} \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 22\text{H}_2\text{O}$, say, $\text{Rb}_3\text{H}_6[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 9\text{H}_2\text{O}$; it loses 15 mols of water at 105° . When treated with nitric acid, and washed with water, it furnishes **dirubidium silicododecatungstate**, $\text{Rb}_2\text{O} \cdot \text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 5\text{H}_2\text{O}$, or $\text{Rb}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 4\text{H}_2\text{O}$, which loses 5 mols of water at 105° . R. Godefroy also made **octocesium silicododecatungstate**, $4\text{Cs}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$, or $\text{Cs}_4\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot n\text{H}_2\text{O}$, like the corresponding rubidium salt. 100 parts of water at 20° dissolve 0.005 part of the white crystalline powder, and about 0.5 part at 100° . It is not soluble in alcohol or acidulated water, but it dissolves in ammoniacal water.

G. Wyruboff prepared crystals of **cupric silicododecatungstate**, $2\text{CuO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 29\text{H}_2\text{O}$, or $\text{Cu}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 27\text{H}_2\text{O}$, rhombohedral crystals of $2\text{CuO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 27\text{H}_2\text{O}$ with $a:c=1:2.6706$, which are stable below 10° ; between 10° and 40° the pentacosihydrate is formed; and over 40° , the tetradecahydrate. The crystals of the dodecahydrate are isomorphous with the corresponding strontium salt, and have the axial ratios $a:b:c=1.4602:1:1.0283$, and $\gamma=84^\circ 14'$. The crystals were studied by W. Muthmann, and F. Zambonini. J. C. G. de Marignac made **octosilver silicododecatungstate**, $4\text{Ag}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 3\text{H}_2\text{O}$, or $\text{Ag}_8[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 3\text{H}_2\text{O}$, as a pale yellow precipitate, by treating an aq. soln. of the ammonium salt with silver nitrate. It loses its water below a red heat and becomes dark violet. The salt decomposes at a bright red heat. It is not perceptibly soluble in cold water. The wash-water is opalescent, and it clears on boiling. J. C. G. de Marignac prepared **tetrasilver tetrahydrosilicododecatungstate**, $2\text{Ag}_2\text{O} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 7\text{H}_2\text{O}$, or $\text{Ag}_4\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 7\text{H}_2\text{O}$, by evaporating a soln. of silver carbonate in the dil. acid. The salt is sparingly soluble in water, but soluble in dil. nitric acid; hydrochloric acid gives a precipitate of silver chloride. G. Wyruboff found the salt to lose 4 mols of water at 105° .

J. C. G. de Marignac obtained ill-defined crystals of normal calcium silicododecatungstate by dissolving calcium carbonate in the warm acid. Three hydrates of the acid salt of **calcium tetrahydrosilicododecatungstate**, $2\text{CaO} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$, have been obtained by crystallization from a conc. soln. of calcium carbonate in hydrosilicotungstic acid. G. Wyruboff obtained the hexadecahydrate, $2\text{CaO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 18\text{H}_2\text{O}$, or $\text{Ca}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 16\text{H}_2\text{O}$, at 30° from soln. strongly acidified with nitric acid. The six-sided plates are triclinic with axial ratios $a:b:c=1.4228:1:-$, and $\alpha=87^\circ 40'$, $\beta=90^\circ 30'$, and $\gamma=81^\circ 6'$. The crystals were studied by W. Muthmann, and F. Zambonini. The salt loses 10 mols of water at 105° . The docosihydrate was obtained at 45° or at ordinary temp. from soln. acidified with nitric acid. The trigonal crystals have the axial ratio $a:c=1:1.2523$, and $\alpha=89^\circ 8'$. J. C. G. de Marignac said that this salt is isomorphous with rhombohedral silicododecatungstic acid and with the corresponding barium salt; it loses 16 mols of water at 100° ; and drives 11 mols of carbon dioxide from molten sodium carbonate. The salt loses 17 mols of water at 105° . The pentacosihydrate forms trigonal crystals with $a:c=1:2.6419$, and $\alpha=56^\circ 42'$. It loses 19 mols of water at 105° . J. C. G. de Marignac made triclinic crystals of the icosihydrate, $\text{Ca}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 20\text{H}_2\text{O}$, which became moist, but did not deliquesce, in air. The prismatic crystals had the axial ratios $a:b:c=0.4461:1:0.5121$, and $\alpha=86^\circ 52'$, $\beta=119^\circ 38'$, and $\gamma=96^\circ 2'$. The salt is very soluble in water; it loses 13 mols of water at 100° ; and expels 11 mols of carbon dioxide from fused sodium carbonate. Triclinic crystals of another salt, the composition of which is doubtful, but approximates to $5\text{CaO} \cdot 3\text{H}_2\text{O} \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 47\text{H}_2\text{O}$, had axial ratios $a:b:c=0.5917:1:0.8627$, and $\alpha=101^\circ 6'$, $\beta=102^\circ 34'$, and $\gamma=99^\circ 24'$. It lost 30 mols of water at 100° .

G. Wyruboff obtained what are presumably mixed crystals of **calcium nitratossilicododecatungstate**, $\text{Ca}(\text{NO}_3)_2 \cdot 2\text{CaO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 16\text{H}_2\text{O}$, with calcium nitrate by crystallization

at 30° from soln. strongly acidified with nitric acid. The monoclinic prisms have axial ratios $a : b : c = 0.9036 : 1 : 1.1820$, and $\beta = 94^\circ 52'$. The mixed salt loses 8 mols of water at 105°, and all at 250°. He also obtained a triclinic tridecahydrate. Both salts are decomposed by water.

G. Wyrouboff prepared four hydrates of **strontium tetrahydrosilicododecatungstate**, $2\text{SrO} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$, from soln. of strontium carbonate in the silicododecatungstate. The tetradecahydrate separates from aq. soln. over 50°. The monoclinic crystals are isomorphous with those of the barium salt. They lose 9 mols of water at 105°. A nitric acid soln. at 30° deposits first the henicosihydrate and then a pentadecahydrate. The latter forms monoclinic six-sided plates with axial ratios $a : b : c = 1.3001 : 1 : 1.0058$, and $\beta = 96^\circ 46'$. The double refraction is negative. They lose 10 mols of water at 105°. The henicosihydrate forms triclinit six-sided prisms with axial ratios $a : b : c = 1.0212 : 1 : 0.5947$, and $\alpha = 92^\circ 46'$, $\beta = 91^\circ 16'$, and $\gamma = 95^\circ 18'$. The crystals rapidly become turbid on exposure to air, without loss of weight. They lose water at 105°. The henicosihydrate is stable between 30° and 40°; the pentadecahydrate between 40° and 50°; and the tetradecahydrate, over 50°. The pentacosihydrate is formed below 30° in efflorescing trigonal crystals with $a : c = 1 : 2.5933$, and $\alpha = 57^\circ 30'$. The crystals were studied by W. Muthmann, and F. Zambonini. They have a feeble double refraction. The crystals lose 19 mols of water at 105°. G. Wyrouboff also suspected that a docosihydrate can be produced.

J. C. G. de Marignac made **barium silicododecatungstate**, $4\text{BaO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 27\text{H}_2\text{O}$, by adding baryta-water to hydro-silicododecatungstic acid, $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 24\text{H}_2\text{O}$, until more than 2 mols of barium hydroxide have been added. The product forms a sticky mass, almost insoluble in cold water, and sparingly soluble in hot. When the hot soln. is cooled, it redeposits a viscid mass. If kept for many days in contact with cold water, or for a short time in contact with hot water, a white powder is formed which loses 19 mols of water at 100°, and drives 9 mols of carbon dioxide from fused sodium carbonate. According to J. C. G. de Marignac, when an excess of barium chloride is poured into the aq. acid, a sticky mass is precipitated which dries in air to a hard glass of barium silicododecatungstate, $4\text{BaO} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 22\text{H}_2\text{O}$. It loses 15 mols of water at 100°. If barium carbonate be dissolved in an aq. soln. of the acid until a precipitate of normal barium silicododecatungstate begins to appear, on evaporation, and cooling, the filtered soln. furnishes prismatic crystals of dodecahydrated **barium tetrahydrosilicododecatungstate**, $2\text{BaO} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 12\text{H}_2\text{O}$. G. Wyrouboff regards this as the normal salt, and he obtained it by evaporating the soln. above 30°. According to J. C. G. de Marignac, the monoclinic prisms have the axial ratios $a : b : c = 1.7987 : 1 : 1.5440$, and $\beta = 103^\circ 53'$. The crystals were studied by W. Muthmann, and F. Zambonini. The crystals are isomorphous with the strontium salt, and exhibit a strongly negative double refraction. The salt loses 8 mols of water at 100°, and drives 11 mols of carbon dioxide from fused sodium carbonate. If the tetradecahydrate, $2\text{BaO} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 14\text{H}_2\text{O}$, be allowed to stand in contact with its mother liquor, rhombohedral crystals of the docosihydrate appear. The axial ratio $a : c = 1 : 1.3407$, and $\alpha = 86^\circ 26'$. The crystals have a strongly negative double refraction; they gradually effloresce in air; and lose 16 mols of water at 100°. H. Copaux said that 100 parts of cold water dissolve 70 parts of the salt; and G. Wyrouboff that at 15°, 100 parts of water dissolve 25 parts of the salt. He studied the isomorphism of barium silicododecatungstate and silicododecamolybdate.

G. Wyrouboff evaporated a mixed soln. of the barium and potassium salts and obtained monoclinic prisms of what he regarded as **barium potassium silicododecatungstate**, $\text{K}_2\text{O} \cdot \text{BaO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 17\text{H}_2\text{O}$. The axial ratios are $a : b : c = 0.6471 : 1 : 0.8056$, and $\beta = 98^\circ 45'$, and the crystals have a positive double refraction. The crystals are stable in air and lose 14 mols of water at 105°. Rhombic crystals of barium sodium silicododecatungstate, $\text{Na}_2\text{O} \cdot \text{BaO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 28\text{H}_2\text{O}$, were prepared by adding barium chloride to a hot soln. of the acid sodium salt, and cooling. The axial ratios are $a : b : c = 0.7551 : 1 : 0.9833$. If barium nitrate be used in place of the chloride, triclinic crystals

containing barium nitrate are formed, and these decompose when treated with water. Barium sodium silicododecatungstate loses 21 mols of water at 100°, and drives 9 mols of carbon dioxide from fused sodium carbonate. Long washing with water extracts sodium silicododecatungstate and leaves the normal barium salt behind; this, with hydrochloric acid, forms barium tetrahydrosilicododecatungstate.

G. Wyrouboff prepared trigonal crystals of heptacosilyhydrated **beryllium silicododecatungstate**, $2\text{BeO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 29\text{H}_2\text{O}$, or $\text{Be}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 27\text{H}_2\text{O}$, by evaporating a soln. of beryllia in the acid $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 32\text{H}_2\text{O}$ over 45°, or at 30° in the presence of nitric acid. The axial ratio is $a:c=1:2.4282$, and $\alpha=57^\circ 56'$. The crystals lose 10.44 per cent. of water at 105°. Octahedral crystals of the enneacosilyhydrate are deposited if the soln. be evaporated below 45°. The crystals are singly refractive, and they belong to the cubic system. They lose 11.51 per cent. of water at 105°. G. Wyrouboff also reported crystals of $4\text{BeO} \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 45\text{H}_2\text{O}$, by evaporating the nitric acid soln. at 30°. The crystals were studied by W. Muthmann, and F. Zambonini. The doubly refracting crystals do not effloresce in air although they become superficially matt; they lose water at 105°. J. C. G. de Marignac made normal **magnesium silicododecatungstate** in a manner similar to that for the corresponding calcium salt. The crystals were studied by W. Muthmann, and F. Zambonini. J. C. G. de Marignac, and G. Wyrouboff also made acid salts, **magnesium tetrahydrosilicododecatungstate**, $2\text{MgO} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$, with $n=16$ and 25. The hexadecahydrate is obtained by conc. of a soln. of magnesia in the acid. It forms triclinic crystals with axial ratios $a:b:c=0.4062:1:0.3959$, and $\alpha=86^\circ 50'$, $\beta=90^\circ 23'$, and $\gamma=90^\circ 10'$. The double refraction is strongly negative. The crystals do not effloresce in air; they lose 10 mols of water at 100°; and drive 13 mols of carbon dioxide from fused sodium carbonate. The pentacosilyhydrate is formed under 20°; and the trigonal crystals have the axial ratio $a:c=1:2.6600$, and $\alpha=56^\circ 44'$. The crystals have a negative double refraction; they do not effloresce in air.

G. Wyrouboff prepared **zinc silicododecatungstate**, $2\text{ZnO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$, or $\text{Zn}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot (n-2)\text{H}_2\text{O}$, by evaporating a soln. of zinc oxide in silicododecatungstic acid. If crystallization occurs above 25°, the hexadecahydrate appears; if between atm. temp. and 25°, the pentacosilyhydrate; and if about 10°, the heptacosilyhydrate. The hexadecahydrate occurs in triclinic prisms with axial ratios $a:b:c=0.4034:1:0.3911$, and $\alpha=86^\circ 6'$, $\beta=91^\circ 26'$, and $\gamma=91^\circ 5'$. At 105°, 10 mols of water are evolved. The pentacosilyhydrate forms trigonal crystals with the axial ratio $a:c=1:2.6279$ and $\alpha=56^\circ 64'$. The crystals were studied by W. Muthmann, and F. Zambonini. The salt loses 21 mols of water at 105°. The heptacosilyhydrate forms basic rhombohedra, and loses 21 mols of water at 105°. All the hydrates effloresce readily on exposure to air. G. Wyrouboff likewise prepared **cadmium silicododecatungstate**, $2\text{CdO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 23\text{H}_2\text{O}$, or $\text{Cd}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 21\text{H}_2\text{O}$, by evaporating a soln. of cadmium oxide in the hydro-silicododecatungstic acid acidified with nitric acid. The triclinic prisms have the axial ratios and angles $a:b:c=0.3784:1:0.3207$, and $\alpha=88^\circ 7'$, $\beta=96^\circ 9'$, and $\gamma=89^\circ 31'$. The crystals were studied by W. Muthmann, and F. Zambonini. The salt does not effloresce on exposure to air; but it loses 15 mols of water at 100°. The pentacosilyhydrate is obtained by evaporating the soln., free from nitric acid, below 35°. The efflorescent trigonal crystals have the axial ratio $a:c=1:2.6123$, and $\alpha=57^\circ 10'$. They lose 20 mols of water at 105°. If the aq. soln. be evaporated with a large excess of nitric acid at 35°-40°, basic prisms, probably triclinic, of $4\text{CdO} \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 44\text{H}_2\text{O}$, are formed. They lose 22 mols of water at 105°.

J. C. G. de Marignac, and G. Wyrouboff prepared rhomboidal plates of pentahydrated **mercurous silicododecatungstate**, $4\text{Hg}_2\text{O} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 5\text{H}_2\text{O}$, by adding mercurous nitrate to a soln. of the acid $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 33\text{H}_2\text{O}$. The salt becomes anhydrous at 100°. G. Wyrouboff said that if the mercurous salt is precipitated at a very low temp., a higher hydrate is obtained. The pentahydrate is

insoluble in dil. nitric acid, but it dissolves slowly in the conc. acid, forming the acid mercuric salt. The anhydrous salt is insoluble in water, sparingly soluble in dil. nitric acid, and is decomposed by hydrochloric acid, forming mercurous chloride and silicododecatungstic acid. When fused with sodium carbonate, about 13 mols of carbon dioxide are evolved.

G. Wyrouboff made **mercuric silicododecatungstate**, $2\text{HgO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 15\text{H}_2\text{O}$, or $\text{Hg}_2\text{H}_4[\text{Si}(\text{W}_2\text{O}_7)_6] \cdot 13\text{H}_2\text{O}$, by dissolving 2 mols of mercuric oxide in an aq. soln. of hydrosilicotungstic acid, and evaporating at 25° ; also by the action of conc. nitric acid on the mercurous salt, and evaporating at 25° . The crystals forming triclinic prisms have the axial ratios $a:b:c = 0.9848:1:1.0191$, and angles $\alpha = 97^\circ 40'$, $\beta = 94^\circ 22'$, and $\gamma = 90^\circ 40'$. The salt loses 10 mols of water at 105° , and the remainder at 250° ; at a red heat, the mercury is volatilized. The salt is sparingly soluble in water, the aq. soln. decomposes when boiled, and precipitates what G. Wyrouboff regarded as a basic salt, but J. C. G. de Marignac would regard it as the normal salt: $4\text{HgO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot n\text{H}_2\text{O}$.

According to J. C. G. de Marignac, the evaporation of a soln. of gelatinous alumina in hydrosilicododecatungstic acid gives non-deliquescent triclinic crystals of **aluminium silicododecatungstate**, $2(\text{Al}_2\text{O}_3 \cdot 6\text{H}_2\text{O}) \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 75\text{H}_2\text{O}$. The axial ratios are $a:b:c = 1.509:1:1.790$, and $\alpha = 96^\circ 44'$, $\beta = 121^\circ 57'$, and $\gamma = 75^\circ 44'$. The crystals lose 51 mols of water at 100° , and drive 39 mols of carbon dioxide from fused sodium carbonate. G. Wyrouboff prepared triclinic crystals of **aluminium silicododecatungstate**, $2\text{Al}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 60\text{H}_2\text{O}$, by evaporating a nitric acid soln. of gelatinous alumina in hydrosilicododecatungstic acid at 35° . The axial ratios $a:b:c = 0.8563:1:1.0658$, and $\alpha = 87^\circ 44'$, $\beta = 105^\circ 11'$, and $\gamma = 91^\circ 48'$. The crystals are stable in air, and lose 37 mols of water at 105° . If the aq. soln. be evaporated at 35° , or at 18° – 20° in the presence of nitric acid, trigonal crystals of the 81-hydrate are deposited. The axial ratio is $a:c = 1:2.6653$, and $\alpha = 56^\circ 19'$. The crystals were studied by W. Muthmann, and F. Zambonini. They effloresce on exposure to air, and lose 60 mols of water at 105° . According to J. C. G. de Marignac, if the aq. soln. be evaporated at ordinary temp., the 93-hydrate is formed in regular octahedral crystals which effloresce readily on exposure to air. They lose 66 mols of water at 100° , and when fused with sodium carbonate give off 39 mols of carbon dioxide. If a cold soln. of the higher hydrate be rendered turbid by the addition of ammonia, the soln. becomes clear when warmed, and when the excess of ammonia has been expelled, the soln. on cooling deposits octahedral crystals of **ammonium aluminium silicododecatungstate**, $9(\text{NH}_4)_2\text{O} \cdot 2\text{Al}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 75\text{H}_2\text{O}$. They lose 66 mols of water at 100° , and expel 39 mols of carbon dioxide from fused sodium carbonate. G. Wyrouboff prepared **gallium silicododecatungstate**, $2\text{Ga}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3)$ with 60, 87, and 93 H_2O . The 60-hydrate has axial ratios $a:b:c = 0.9057:1:1.1585$ and $\gamma = 74^\circ 20'$, and those of the 87-hydrate $a:c = 1:2.6246$. The crystals were studied by W. Muthmann, and F. Zambonini. G. Wyrouboff made **thallium silicododecatungstate**, $2\text{TlOH} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 9\text{H}_2\text{O}$. He also prepared normal 26-hydrated **cerium**, **lanthanum**, and **praseodymium silicododecatungstates**, with the general formula $2\text{MO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 26\text{H}_2\text{O}$. These salts are isomorphous with the hydrated calcium and strontium silicododecatungstates. The acid salts $3\text{M}(\text{OH})_2 \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 36\text{H}_2\text{O}$ were also prepared. He also made normal 26- and 27-hydrated **neodymium**, **samarium**, and **gadolinium silicododecatungstates** with the general formulae $2\text{MO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 26\text{H}_2\text{O}$, and $2\text{MO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 27\text{H}_2\text{O}$, or $\text{MO}_4(\text{SiW}_{12}\text{O}_{40})_3 \cdot 81\text{H}_2\text{O}$, and in addition 30-hydrated gadolinium salt $2\text{GdO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 30\text{H}_2\text{O}$, as well as the acid salt $3\text{M}(\text{OH})_2 \cdot 2(\text{SiO}_2 \cdot 12\text{H}_2\text{O}) \cdot 36\text{H}_2\text{O}$. The 26-hydrated **yttrium**, **terbium**, and **ytterbium silicododecatungstates** with the general formula $2\text{MO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 26\text{H}_2\text{O}$, and the corresponding acid salts $3\text{M}(\text{OH})_2 \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 49\text{H}_2\text{O}$, and acid **erbium silicododecatungstate**, $3\text{Er}(\text{OH})_2 \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3)$ with 49 and 51 H_2O , were also made. The crystals were studied by W. Muthmann, and F. Zambonini. G. Wyrouboff prepared two **thorium silicododecatungstates**,

$2\text{ThO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3$ with 27 and $30\text{H}_2\text{O}$, and the acid salt $2\text{ThO} \cdot 4\text{H}_2\text{O} \cdot 2(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 45\text{H}_2\text{O}$. The crystals were studied by W. Muthmann, and F. Zambonini.

G. Wyruboff dissolved chromic oxide in a soln. of the acid $\text{SiO}_2 \cdot 12\text{WO}_3 \cdot 33\text{H}_2\text{O}$, and obtained three hydrates of **chromium silicododecatungstate**, $2(\text{Cr}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot n\text{H}_2\text{O})$. If the crystallization occurs at 30° from soln. containing nitric acid, monoclinic prisms of the 60-hydrate are obtained with axial ratios $a:b:c = 0.8658:1:1.0798$, and $\beta = 106^\circ 16'$. The crystals were studied by W. Muthmann, and F. Zambonini. The crystals are stable in air, and lose water at 105° . Trigonal crystals of the 87-hydrate separate at 25° . The axial ratio is $a:c = 1:2.5354$, and $\alpha = 56^\circ 9'$; the crystals have a negative double refraction, and lose 60 mols of water at 105° . If the crystallization occurs below 25° , octahedral, singly refracting crystals of the 93-hydrate are formed; they lose 66 mols of water at 105° . According to G. Wyruboff, if uranyl nitrate be added to a soln. of silicododecatungstic acid, and the soln. be evaporated to drive off the nitric acid, a yellow mass of isotropic octahedral crystals is formed. Quite a number of more or less ill-defined **uranium silicododecatungstates** were reported to be formed by varying the proportions of acid to base. Thus, with the mol. ratio $\text{UO}_3:(\text{SiO}_2 \cdot 12\text{WO}_3):\text{H}_2\text{O}$, G. Wyruboff obtained 6:3:91; 5:3:90; 3:3:88; 2:3:87; 5:9:264; 3:6:177; 4:9:267; as well as a number of others whose composition was not determined. G. Wyruboff prepared crystals of **lead silicododecatungstate**, $2\text{PbO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 21\text{H}_2\text{O}$, with axial ratios $a:b:c = 1.7963:1:1.1203$ and $\gamma = 81^\circ 35'$; as well as crystals of $4\text{PbO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 20\text{H}_2\text{O}$. G. Wyruboff prepared rhombohedral crystals of **manganese silicododecatungstate**, $2\text{MnO} \cdot \text{SiO}_2 \cdot 12\text{WO}_3 \cdot 27\text{H}_2\text{O}$, with axial ratios $a:c = 1:2.6549$, and crystals of the 18-hydrate with axial ratios $a:b:c = 0.4018:1:0.4088$. The crystals were studied by W. Muthmann, and F. Zambonini. Similarly, 18- and 27-hydrated **cobalt silicododecatungstates** with axial ratios respectively $a:b:c = 0.4067:1:0.4055$, and $a:c = 1:2.6760$; and of 18- and 27-hydrated **nickel silicododecatungstates**, with $a:b:c = 0.40451:1:0.4166$, and $a:c = 1:2.6392$, were obtained. The crystals of the cobalt and nickel salts were studied by W. Muthmann, and F. Zambonini. G. Wyruboff made yellow crystals of **ferric silicododecatungstate**, $2\text{Fe}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 93\text{H}_2\text{O}$, and of $2\text{Fe}_2\text{O}_3 \cdot 3(\text{SiO}_2 \cdot 12\text{WO}_3) \cdot 60\text{H}_2\text{O}$, with axial ratios $a:b:c = 0.8465:1:1.0897$, and $\gamma = 73^\circ 20'$.

J. C. G. de Marignac prepared what he regarded as octobasic **heptahydro-silicododecatungstic acid**, $\text{SiO}_2 \cdot 10\text{WO}_3 \cdot 7\text{H}_2\text{O}$, or $(\text{SiO}_2 \cdot 4\text{H}_2\text{O}) \cdot 10\text{WO}_3 \cdot 3\text{H}_2\text{O}$, i.e. $\text{H}_9\text{SiW}_{10}\text{O}_{36} \cdot 3\text{H}_2\text{O}$, by treating the mercurous salt with hydrochloric acid. The aq. soln. should be evaporated in vacuo in the cold. H. Copaux also prepared the acid by treating the ammonium salt with ether and sulphuric acid. The acid obtained by the evaporation of the aq. soln. is a clear glass with a faint yellow tinge. It does not change when heated to 100° , but it cracks and crazes when exposed to air, probably owing to the absorption of moisture. When fused with sodium carbonate, 11 mols of carbon dioxide are given off. The acid is soluble in water, and gelatinous silica sometimes separates from the soln. on evaporation. The aq. soln. is not rendered turbid when salts of barium, calcium, magnesium, aluminium, or lead are added; silver nitrate gives a yellow precipitate insoluble in water, and easily soluble in nitric acid; and mercurous nitrate gives a similar precipitate slightly soluble in nitric acid. Salts other than the ammonium salt have not been obtained of a high degree of purity, but are usually contaminated with salts of the silicododecatungstic acids. J. C. G. de Marignac believed that the acid forms two series of salts—one with two and the other with four mols of base. A. Pinagel could not prepare **silicododecatungstic acid**, $\text{SiO}_2 \cdot 9\text{WO}_3 \cdot n\text{H}_2\text{O}$.

J. C. G. de Marignac prepared normal **octammonium silicododecatungstate**, $4(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 8\text{H}_2\text{O}$, or $(\text{NH}_4)_8\text{SiW}_{10}\text{O}_{36} \cdot 8\text{H}_2\text{O}$, or $(\text{NH}_4)_8[\text{Si}(\text{W}_2\text{O}_7)_5\text{O}]\cdot 8\text{H}_2\text{O}$, by boiling a soln. of ammonium hydrotungstate with gelatinous silica, and evaporating the filtered soln.—the salt crystallizes out on cooling. H. Copaux made it by boiling a soln. of silicododecatungstic acid with an excess of ammonia,

until the silica first precipitated has nearly all dissolved. The strongly ammoniacal liquid is filtered and allowed to cool when rhombic bipyramidal prisms separate. The crystals have axial ratios $a : b : c = 0.5890 : 1 : 0.4774$. At 100° , the crystals lose 2.63 mols of water. According to J. C. G. de Marignac, 100 parts of water at 18° dissolve 22.2 parts of the salt, hot water dissolves much more. The soln. is neutral; loses ammonia when boiled; and deposits silica when boiled for a long time or when treated with an acid. The warm soln. takes up calcium carbonate or gelatinous alumina without depositing silica, but some ammonia is given off, and when the soln. is conc. it forms a sticky mass, which congeals to a clear colourless glass. J. C. G. de Marignac, and A. Pinagel also made **hexammonium silicodecatungstate**, $3(\text{NH}_4)_2\text{O} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 10\text{H}_2\text{O}$ —the former, by boiling a soln. of the normal salt for a long time, and adding water from time to time to replace that lost by evaporation. The monoclinic prisms have axial ratios $a : b : c = 0.688 : 1 : -$ and $\beta = 114^\circ 48'$. At 100° , the salt loses 8 mols of water. A soln. of potassium carbonate in silicodecatungstic acid furnished **potassium silicodecatungstate**, $4\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 17\text{H}_2\text{O}$; or else, according to F. Kehrmann, $\text{K}_7[\text{Si}(\text{W}_2\text{O}_7)_2\text{OH}] \cdot 11\text{H}_2\text{O}$. J. C. G. de Marignac did not succeed in making a definite **sodium silicodecatungstate**; by treating a mol of the acid with 2 or 4 mols of sodium carbonate, the soln. furnished a gum-like mass. A soln. of calcium carbonate in silicodecatungstic acid gives on evaporation a gum-like mass, **calcium silicodecatungstate**. G. Wyrouboff obtained an amorphous precipitate of **barium silicodecatungstate**, $4\text{BaO} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 22\text{H}_2\text{O}$, by adding a barium salt to a soln. of sodium silicodecatungstate. According to J. C. G. de Marignac, when silicodecatungstic acid is mixed with four mols of potassium carbonate, and evaporated at a suitable temp., the first crop consists of the normal silicodecatungstate, then needles of what is regarded as a mixed salt, and finally rhombohedral plates of heptadecahydrated **octopotassium silicodecatungstate**, $4\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 17\text{H}_2\text{O}$. When fused with sodium carbonate, 7 mols of carbon dioxide are evolved. C. Friedheim and W. H. Henderson also made the tetracosihydrate. J. C. G. de Marignac found that if an aq. soln. of the acid be mixed with two mols of potassium carbonate, the first crop of crystals is a mixture of silicodecatungstates, and the final crop is mainly **tetrapotassium tetrahydro-silicodecatungstate**, $2\text{K}_2\text{O} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 10\text{WO}_3 \cdot 8\text{H}_2\text{O}$. The crystals lose 7 mols of water at 100° ; and when fused with sodium carbonate, 9 mols of carbon dioxide are given off.

A series of potassium salts of white **silicohecatungstic acid** intermediate between silicodeca- and silicododecatungstic acid were obtained by J. C. G. de Marignac. For example, tetradecahydrated **octopotassium silicohecatungstate**, $4\text{K}_2\text{O} \cdot \text{SiO}_2 \cdot 11\text{WO}_3 \cdot 14\text{H}_2\text{O}$, crystallizes in rhombic bipyramidal needles with axial ratios $a : b : c = 0.3875 : 1 : 0.4123$. It loses 8 mols of water at 100° , and when fused with sodium carbonate, expels 8 mols of carbon dioxide. A. Pinagel made a 13-hydrate by passing steam into water with potassium paratungstate, $3\text{K}_2\text{O} \cdot 7\text{WO}_3 \cdot 8\text{H}_2\text{O}$, in suspension and gradually adding gelatinous silicic acid. When hydrochloric acid produces no turbidity the filtered soln. is evaporated for crystallization. J. C. G. de Marignac prepared **tetrapotassium tetrahydro-silicohecatungstate**, $2\text{K}_2\text{O} \cdot 2\text{H}_2\text{O} \cdot \text{SiO}_2 \cdot 11\text{WO}_3 \cdot 10\text{H}_2\text{O}$. The yellowish triclinic pinacoidal crystals have axial ratios $a : b : c = 1.810 : 1 : 1.709$, and $\alpha = 96^\circ 31'$, $\beta = 123^\circ 38'$, and $\gamma = 99^\circ 38'$. It loses 8 mols of water at 100° and when fused with sodium carbonate it gives off 10 mols of carbon dioxide.

O. Kallauner and J. Hrudá⁴ studied the fusibility of binary mixtures of uranium oxide and clay. L. Bourgeois failed to make a uranium silicate by heating mixtures of uranium oxide and silica. A. Bornträger mixed a soln. of a uranyl salt (1 : 10) with an equal vol. of a dil. soln. of water-glass of sp. gr. 1.38, and obtained a crystalline precipitate of **uranyl silicate**, $\text{UO}_3 \cdot 7\text{SiO}_2$. A calcium uranium silicate under the name **uranotile** was described by E. Boricky. It occurs at Wölsendorf, Bavaria; Kupferberg, Silesia; and at Neustädte, Saxony, in fibrous masses, or in minute, acicular, lemon-yellow or orange-yellow crystals, which, according to P. Pjatnitsky, belong to the triclinic system and have the axial ratios $a : b : c = 0.6257 : 1 : 0.5943$, and $\alpha = 87^\circ 41'$, $\beta = 85^\circ 18'$, and $\gamma = 96^\circ 31'$. The

crystals were described by V. von Zepharovich and A. Schrauf. A mineral described by M. Websky as *uranophane* is considered to be an impure uranotile. Its crystals are said to be rhombic. Analyses by R. Grunmanh, M. Websky, C. Winkler, F. A. Genth, H. B. von Foullon, and E. Boricky agree with $\text{CaO} \cdot 3\text{UO}_3 \cdot 3\text{SiO}_2 \cdot 9\text{H}_2\text{O}$; or with $\text{CaO} \cdot 2\text{UO}_3 \cdot 2\text{SiO}_2 \cdot 6\text{H}_2\text{O}$; P. Groth represented it by $\text{CaU}_2\text{Si}_2\text{O}_{11} \cdot 5\text{H}_2\text{O}$; and F. W. Clarke regarded it as hexahydrated **calcium uranyl orthodisilicate**, $\text{Ca}(\text{UO}_2)_2\text{Si}_2\text{O}_7 \cdot 6\text{H}_2\text{O}$; and T. L. Watson, $\text{CaO} \cdot 2\text{UO}_3 \cdot 3\text{SiO}_2 \cdot 7\text{H}_2\text{O}$. M. Websky gave for the composition of uranophane, $5(\text{K}_2, \text{Ca}, \text{Mg})\text{O} \cdot 2\text{Al}_2\text{O}_3 \cdot 6\text{UO}_3 \cdot 10\text{SiO}_2 \cdot 28\text{H}_2\text{O}$, **calcium uranyl aluminium silicate**. The sp. gr. of uranotile was given as 3·8–3·9, and that of uranophane as 2·65. The hardness is less than 3. A. Schoep applied the name *sklodowskite*—after Mme. Curie-Sklodowska—to a radioactive mineral with the composition of **magnesium uranyl orthodisilicate**, $\text{Mg}(\text{UO}_2)_2\text{Si}_2\text{O}_7 \cdot 7\text{H}_2\text{O}$. The rhombic prisms are lemon-yellow with the indices of refraction $\alpha=1·613$, $\beta=1·065$, and $\gamma=1·657$. The sp. gr. is 3·52. The pleochroism is yellow, pale yellow, and colourless.

The mineral *mackintoshite*, discussed in connection with the rare earths, may, according to F. W. Clarke, be regarded as a **thorium uranyl silicate**, $\text{UO}_2 \cdot 2\text{ThO}_2 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$; and *thorogummite*, discussed in the same place, as a hydrated derivative.

A. Schoep⁵ described some fine-grained crystal aggregates from Kasolo, Belgian Congo, with the composition $12\text{UO}_2 \cdot 5\text{SiO}_2 \cdot 14\text{H}_2\text{O}$; he called the mineral *soddite*. The crystals are rhombic; the sp. gr. is 4·627 at 17°; and the hardness 3–4. He also described canary-yellow, felted, needle-like crystals occurring on a mass of soddite from Chinkolobwe, Belgian Congo. The crystals have a lower birefringence than soddite, and the optical properties are different. He suggested the name *chinkolobareite*, and regarded it as a dimorphous form of soddite.

A. I. Walcker⁶ stated that a soln. of sodium silicate gives a precipitate with a soln. of stannic chloride, but not with one of stannous chloride; J. M. Ordway obtained similar results, and found that the gelatinous precipitate contained very variable proportions of alkali, stannic oxide, and silica. A. Breithaupt, F. Hessenberg, A. E. Nordenskjöld and A. Gadolin, and G. Bischof applied the term *stannite* to what they regarded as a **stannic silicate**, but A. des Cloizeaux, and G. Tschermak regard it as a mixture of quartz and cassiterite, and F. Geinitz, J. R. Blum, J. H. Collins, R. Pearce, and R. P. Greg and W. G. Lettsom, a pseudomorph of cassiterite after felspar.

A. Hutchinson found that a rare mineral from Roscommon Cliff, St. Just, Cornwall, which he called *stokesite*—after G. Stokes—corresponded with **calcium silicostannate**, $\text{CaO} \cdot \text{SnO}_2 \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, which F. Zambonini would write $\text{O}=\text{Sn}=\text{Si}_3\text{O}_8=\text{Ca}+2\text{H}_2\text{O}$, analogous with his formula for catapleite, $\text{O}=\text{Zr}=\text{Si}_3\text{O}_8=\text{Na}_2+2\text{H}_2\text{O}$. A. Hutchinson considers it to be a salt of tetrasilicic acid, $\text{H}_4\text{Ca}(\text{Si}_3\text{Sn})_4\text{O}_{11}$. On F. W. Clarke's system, the formula would be $(\text{HO})_3\text{Sn}(\text{Si}_3\text{O}_8=\text{HCa})$. The colourless crystals belong to the rhombic system, and A. Hutchinson gave for the axial ratios $a:b:c=0·3462:1:0·8437$. The (110) cleavage is perfect; (010) less so. The sp. gr. is 5·185, and the hardness 6. The optic axial angle $2V=69\frac{1}{2}^\circ$; the index of refraction, $\beta=1·6125$; and the birefringence, $\gamma-\alpha=0·01$ —Na-light. L. Bourgeois found that crystals with the composition $\text{CaO} \cdot \text{SiO}_2 \cdot \text{SnO}_2$ are produced when three parts of silica and four parts of stannic oxide are heated with an excess of calcium chloride to bright redness for about eight hours, and the cooled mass extracted with water. If the time of fusion has been short, the residue is a mixture of tridymite and cassiterite, but if the reaction has proceeded further the residue consists of calcium silicostannate, whilst if the heating has been too far prolonged, the products are calcium disilicate and calcium stannate. The monoclinic prisms, analogous to titanite, have a lower birefringence than titanite. The sp. gr. is 4·34. The crystals are not attacked by acids, alkali-lye, or potassium hydrosulphate. They are less fusible than titanite.

T. W. Hogg⁷ observed that a mixture of lead monoxide and silica at a red heat

unite to form a silicate. The temp. of formation is lower than the fusion temp. of the mixture. Fused lead oxide is a powerful solvent for silica and silicates, and, as shown by E. Biewend; the soln. usually congeals to a glass. These glasses are of industrial importance as the base of many glasses and pottery glazes. Various formulæ are used in the industries, but the formulæ are not intended to represent compounds, but rather the mol. proportions of the components of the glass. The glassy frit sold as "lead bisilicate," for instance, contains lead oxide and silica in the proportions $\text{PbO} : \text{SiO}_2 = 1 : 2$. One of the "heaviest flint glasses", has about 78 per cent. of PbO , and approximates closely to the proportions required for a metasilicate. Such glasses may crystallize when cooled slowly, and often, obtained in this way, was regarded as lead metasilicate, PbSiO_3 , by L. Bourgeois. Crystalline masses have also been found under the fusion hearth of lead roasting furnaces undergoing repair. Analyses of glasses containing such crystals were reported by L. Elsner, E. S. Dana, and S. L. Penfield, H. A. Wheeler, etc. M. Faraday investigated a number of lead glasses, J. J. Berzelius said that lead silicate is formed when lead fluosilicate is heated with ammonia. W. E. B. Blenkinsop and F. M. Lyte heated basic lead sulphate or lead oxychloride and silica. A. C. Becquerel found that a lead silicate is formed on the boundary walls of the collodion membrane separating lead nitrate and potassium silicate soln. B. Huick electrolyzed a 1-2 per cent. soln. of a mixture of 95 per cent. sodium acetate and 5 per cent. of sodium silicate between lead electrodes, and obtained a lead silicate. W. Mostowitsch, and S. Hilpert and co-workers made glasses with $\text{PbO} : \text{SiO}_2 = 6 : 1, 5 : 1, 4 : 1, 3 : 1, 5 : 2, \text{ and } 4 : 3$; but there is nothing to show that the products were chemical individuals—most probably not so.

J. W. Meller and co-workers measured the softening temp. of a series of these glasses and found an abrupt drop from the m.p. of lead oxide, 877° , to 540° with

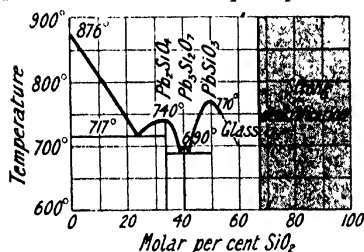

FIG. 191.—Freezing-point Curves, of Binary Mixtures of Lead Oxide and Silica.

mixtures containing one per cent. of silica, and raising the silica up to 12 per cent. lowered the softening temp. 8° more, Fig. 192. Mixtures with these proportions of silica were inclined to devitrify. Mixtures with from 12-30 per cent. of silica softened between 532° and 543° ; and subsequent additions of silica raised the softening temp. rapidly; and, owing to the volatilization of lead oxide, the course of the curve was not followed much further. W. Mostowitsch obtained values for the m.p. nearly

200° higher than these data. S. Hilpert with P. Weiller, and with R. Nachen obtained the results indicated in Fig. 191. There is a maximum at 770° corresponding with the m.p. of the metasilicate, and higher proportions of silica gave mixtures which formed glasses; and silicates with over 32 per cent. of silica by weight melted over 1000° , and formed turbid masses on cooling. There is a maximum at 740° corresponding with lead orthosilicate, Pb_2SiO_4 , and a eutectic between the orthosilicate and lead oxide at 717° ; there are two eutectics close between the ortho- and the meta-silicates, and the intermediate maximum at 690° corresponds with the lead orthodisilicate, $\text{Pb}_3\text{Si}_2\text{O}_7$, or lead pyrosilicate. H. C. Cooper and co-workers also examined the heating curves of the lead silicates and found evidence of the formation of lead orthosilicate, m.p. 746° ; lead metasilicate, m.p. 766° ; and an intermediate eutectic, m.p. 717° . They further obtained evidence of the formation of the pyrosilicate, and showed that the crystals obtained from the lead smelters contain this silicate mixed isomorphously with other silicates. S. Hilpert and R. Nachen measured the velocity of crystallization, and the crystallizing power in terms of the number of nuclei formed in a given time per unit area at different temp. They say that there is inconclusive evidence of the existence of a basic

silicate, $3\text{PbO} \cdot \text{SiO}_2$, or $\text{PbO} \cdot \text{Pb}_2\text{SiO}_4$, *lead orthosilicate*. H. C. Cooper and co-workers showed that when quickly cooled, all fusions containing less than 80 equivalents per cent. of lead oxide give clear, coloured glasses. When slowly cooled, all fusions containing more than 60 eq. per cent. of lead oxide crystallize completely; those which are richer in silica crystallize only in part, but if the resulting solid is finely powdered and heated for several hours to a temp. which is 10° – 100° lower than the m.p., a sintered, crystalline mass is obtained. J. W. Mellor and co-workers found the temp. at which the lead silicate glasses became so soft that the corners of angular fragments were rounded. The results are plotted in Fig. 192.

S. Hilpert and P. Weiller showed that the sp. vol. of the lead silicates were always greater than corresponded with the mixture rule. They found for the sp. gr.

SiO_2 , per cent.	8.6	13.0	17.8	20.28	24.09	27.56	32.54	33.38
Sp. gr.	8.124	7.005	6.45	6.14	5.74	5.28	4.87	4.73

The refractive indices of glasses rich in lead oxide are very high. S. Hilpert and P. Weiller's results are indicated in Table XXXIII. The glasses all showed a complete absorption of the violet and ultra-violet rays. The orthosilicate glass is dark yellow, and the metasilicate light yellow. The colour darkens with rise of

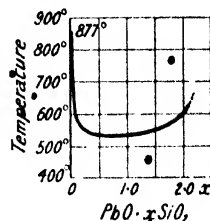

FIG. 192.—Softening Temperatures of Lead Silicate Glasses.

TABLE XXXIII.—INDICES OF REFRACTION OF LEAD SILICATE GLASSES.

Per cent. PbO in glass.	Red H-line.	Orange Hg-line.	Na-line.	Yellow Hg-line.	Green Hg-line.	Blue Hg-line.	Violet Hg-line.
87.00	2.058	—	2.078	2.083	2.095	2.174	—
84.00	—	2.025	2.028	2.038	2.048	2.104	2.112
82.20	—	—	1.979	1.986	—	2.048	—
79.72	—	—	1.960	—	—	—	—
75.91	—	1.922	1.930	—	1.935	1.965	—
72.41	—	—	1.864	1.866	—	1.897	—
29.00	—	—	1.773	1.779	1.785	1.811	1.824

temp. The yellow colour may largely be an effect of traces of silver or iron in the lead oxide. L. Ejsner discussed the colour of the lead silicate glasses. The solubility of lead oxide in fused lead silicate glass increases with the rise of temp., and K. Beck assumes that the yellow colour of the lead silicate glasses rich in bases is really due to a thermolytic dissociation, $\text{PbO} \cdot n\text{SiO}_2 \rightleftharpoons \text{PbO} + n\text{SiO}_2$. From his study of the electrical properties of flint glass, G. L. Addenbrooke inferred that the glass is really a soln. of silica in lead metasilicate, and not a mere mixture of lead and silicon oxides. According to M. Berthelot, the lead silicate glasses are decomposed by exposure to the radiations from a radium salt, and coloured black, or if the lead silicate glass has had its colour bleached by a little manganese oxide, it may be coloured violet. The volatilization of lead oxide from lead silicates was discussed by W. Thomason, S. Hilpert, F. O. Doeltz and J. A. Gräumann, and M. Stoermer. The loss in mgrm. per sq. cm. per hour was found by O. Andersen to be as follows:

PbO	85	78.7	75	70	65	60 per cent.
900°	1	1	—	—	—	—
1000°	8	2	1	1	—	—
1100°	13	4	2	2	1	1
1200°	37	11	8	7	5	4
1300°	100	40	30	23	16	13
1400°	318	131	91	60	46	33

S. Hilpert and P. Weiller found that the highly "lead" glasses are attacked by exposure to air; M. Faraday found the addition of potash rendered the glass stable in air. According to W. Mostowitsch, and S. Hilpert and P. Weiller, the basic glasses up to and including the metasilicate easily dissolve in mineral acids and acetic acid with the separation of silica; the glasses with increasing proportions are less readily attacked, so that the $\text{PbO} \cdot 2\text{SiO}_2$ glass is attacked only by hydrofluoric acid. K. Beck said that lead metasilicate is readily decomposed by a 4 per cent. soln. of acetic acid, or a one per cent. soln. of nitric acid at 25° ; the higher silicates are less readily attacked, and this the more the higher the proportion of silica. W. Balters also tested the solubility of the glasses in acetic acid. According to P. Bartel, the solubility of the lead glasses in 4 per cent. acetic acid decreases with increasing proportions of silica up to $\text{PbO} \cdot 2.5\text{SiO}_2$; increases up to $\text{PbO} \cdot 3.75\text{SiO}_2$; and finally decreases again. The resistance to attack is favoured by additions of calcium, barium, magnesium, zinc, or aluminium oxide. K. Beck and co-workers found that borax and boric acid decrease the resistance to attack, and alumina makes the glass more resistant. Owing to the toxic character of lead compounds used in glazes, and the slight solvent action of the mucous fluids, the Government prescribes certain restrictions in the use of lead compounds in pottery manufacture. A ground frit which does not give up more than 5 per cent. of lead oxide when shaken for an hour with 1000 times its weight of 0.25 per cent. hydrochloric acid is considered innocuous. W. Jackson and E. M. Rich showed that the amount dissolved under these conditions is determpined by the fineness of grinding. The controversy which ensued is an admirable illustration of the influence of desire and temperament on the judgment. K. Beck found that alkali-lye forms alkali silicate and plumbate. The glasses richer in lead than the metasilicate are reduced by hydrogen at 240° ; while the reduction of metasilicate and more siliceous glasses begins only above 300° . W. Mostowitsch observed that the lead silicates are reduced by hydrogen at 290° – 300° , forming a mixture which may contain lead suboxide, Pb_2O ; at 410° , the reduced lead collects in globules. C. Simmonds said that while hydrogen reduces the orthosilicate to silica and metallic lead, the metasilicates and more acid silicates furnish silicites (*q.v.*). Carbon monoxide, and hydrocarbons also reduce lead silicates to the metal. L. Kahlenberg and W. J. Trautman observed no reaction between silicon and lead metasilicate. J. Percy found that lead silicate is partially decomposed by lead sulphide, furnishing metallic lead; and E. Grieshammer noted the solubility of galena in molten glass.

The range of stability of lead orthosilicate, Pb_2SiO_4 , is indicated in Fig. 191; the crystals are readily obtained by annealing the orthosilicate glass. Crystals of lead orthosilicate, were first made by H. C. Cooper and co-workers; and have not been observed in nature. The interference figure of the crystals is negative and biaxial. The index of refraction, and birefringence are high. S. Hilpert and co-workers found 7.005 for the sp. gr. of the glass and for the m.p., 740° ; H. C. Cooper and co-workers gave 746° for the m.p., and 2.07 for the index of refraction of the orthosilicate glass. For the action of acids, etc., *vide supra*.

As indicated above, crystals of lead metasilicate, PbSiO_3 , were prepared in the laboratory by E. Bourgeois before they were discovered in nature. The conditions under which they are formed are indicated in Fig. 187. They are conveniently prepared by annealing the glass. C. Palache and H. E. Merwin found a snow-white mineral at Alamos, Mexico, which they called **alamosite**, and the analysis corresponded with lead metasilicate. It forms radiated fibrous aggregates with a more or less pronounced spheroidal form. Isolated fibres are colourless and transparent, and are elongated in the direction of the axis of symmetry. The monoclinic crystals resemble those of wollastonite and have the axial ratios $a:b:c=1.375:1:0.924$, and $\beta=84^\circ 10'$; but whether or not the two minerals are isomorphous has not been established owing to appreciable difference in the lengths of the a -axis, and in the cleavages. S. Hilpert and P. Weiller found the artificial crystals are biaxial and rhombic or monoclinic. The cleavage of the

mineral parallel to (011) is perfect. The sp. gr. of the mineral is 6.488, and the hardness 4½. S. Hilpert and P. Weiller gave 5.93 for the sp. gr. of the artificial silicate glass, and 6.36 for the crystals. K. Schulz gave 0.07886 for the sp. ht. of the glass; and 0.07807 for the crystals between 20° and 100°. The rate of crystallization of the metasilicate was found by S. Hilpert and R. Nacken to be slower than that of the orthosilicate; it is greatest at about 100° below the m.p. H. E. Merwin found that the optical axial angle $2V=65^\circ$ for Na-light, and the indices of refraction $\alpha=1.947$, $\beta=1.961$, and $\gamma=1.960$. P. Weiller gave for the glass 1.96. The birefringence is strong, the optical character is negative. H. C. Cooper and co-workers gave 766° for the m.p. of the metasilicate; and S. Hilpert and co-workers, 766° . The mineral dissolves in nitric acid with the separation of gelatinous silica. For the action of acids, etc., on the metasilicate, *vide supra*. It has been shown that C. Simmonds's experiment from which he inferred that lead metasilicate is reduced by hydrogen to lead metasilicate admits of another interpretation, and consequently also his argument that one oxygen of lead metasilicate is attached to lead and to another oxygen atom and not to silicon $\text{Si} < \begin{smallmatrix} \text{O} \cdot \text{Pb} \\ \text{O} \cdot \text{O} \end{smallmatrix}$ is inconclusive and probably wrong. R. Schwarz and G. A. Mathis made lead metasilicate, $\text{PbSiO}_3 \cdot \text{H}_2\text{O}$, by the action of a lead salt on water-glass, and they made **lead hemiamminometasilicate**, $\text{PbSiO}_3 \cdot \frac{1}{2} \text{NH}_3 \cdot \text{H}_2\text{O}$, by the action of ammonia on the metasilicate.

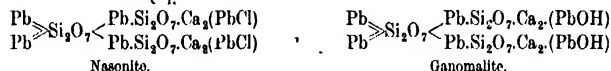

A. Sjögren and C. H. Lundström reported that white masses of a mineral with a curved lamellar structure were scattered through the iron ore along with calcite, garnet, tephroite, and galena near Pajsberg, Sweden, and the mineral was called **barysilite**. Analyses reported by A. Sjögren and C. H. Lundström, H. Sjögren, and R. Mauzelius correspond with *lead pyrosilicate*, or **lead orthosilicate**, $\text{Pb}_3\text{Si}_2\text{O}_7$, where a small proportion of the lead may be replaced by manganese, magnesium, or calcium. P. Groth said that barysilite can be regarded as the normal salt of hexabasic disilicic acid, $\text{H}_6\text{Si}_2\text{O}_7$; or as a basic salt of metadisilicic acid, $(\text{Pb}_3\text{O}_2)_2\text{Si}_2\text{O}_5$. G. Cesaro regarded the water as constitutional, and assumed the silicate to be derived from $\text{H}_{10}\text{Si}_3\text{O}_{11}$. The compound was made by H. C. Cooper and co-workers, and by S. Hilpert and R. Nacken, Fig. 191. Impure crystals were also reported by E. S. Dana and S. L. Penfield, and by H. A. Wheeler occurring below the hearth of an old lead furnace. The crystals of barysilite are uniaxial and probably trigonal with the axial ratio $a:c=1:0.4863$. H. C. Cooper and co-workers said the artificial prismatic crystals belong to the dihexagonal bipyramidal class, and have the axial ratio $a:c=1:1.0216$. E. S. Dana and S. L. Penfield gave $1:1.032$. The index of refraction and the birefringence are high; and the interference figure positive and uniaxial. The crystals are pleochroic. The basal cleavage of the mineral is distinct, the prismatic cleavage less so. The sp. gr. is 6.11–6.55, H. Sjögren gave 6.72; the hardness is 3. S. Hilpert and R. Nacken found the m.p. to be 690° , as indicated in Fig. 191. The crystals may tarnish on exposure to air by the oxidation of the manganese. The mineral dissolves in nitric or hydrochloric acid with gelatinization of the silicic acid; and in the case of hydrochloric acid, with the separation of lead chloride.

C. J. Peddle⁸ studied the properties of the glasses in the ternary and quaternary systems: SiO_2 - PbO - K_2O or Na_2O ; and SiO_2 - PbO - K_2O - Na_2O —*vide glass*. Many glasses approximate in composition, $(\text{K}, \text{Na})_2\text{O} \cdot \text{PbO} \cdot 6\text{SiO}_2$. J. N. von Fuchs said that a soln. of water-glass takes up lead oxide and forms a gelatinous mass which dries in air to a product resembling opal. V. Merz made the alkali-lead-glass by melting a mixture of water-glass and red-lead. A. Gray and J. J. Dobbie gave 3.591 for the sp. gr. of a glass, $2\text{K}_2\text{O} \cdot 0.5\text{PbO} \cdot 17\text{SiO}_2$, and 3.495 for $2\text{K}_2\text{O} \cdot 0.5\text{PbO} \cdot 22\text{SiO}_2$; and W. Beetz gave 4.71 for a heavy flint glass. E. Zschimmer and H. Schulz measured the hardness of these glasses. P. Suboff gave 0.1234 for the sp. ht.; W. Beetz, 0.04313 for the thermal conductivity of heavy flint glass; A. Winkelmann, 7.44 for the dielectric constant, and A. Gray and J. J. Dobbie,

7.991 at 14° for the first of the above-mentioned glasses, and 7.966 for the second at 15°, and 7.630 at 120°. W. Beetz, and T. Gray measured the electrical conductivity, and A. Gray and J. J. Dobbie gave 35000×10^{10} for the sp. resistance of the first of the above glasses up to 135°, and 18000×10^{10} for the second up to 130°—see the glasses for the refractive indices. M. Stoemer found that no change occurs when the glass is heated in an oxidizing atm., but in a reducing atm., lead is volatilized, and the silicate is reduced. O. Anderson did not find sufficient volatilization of lead at 900°–1400° to affect the refractive index. C. Simmonds studied the reduction of lead silicates heated in hydrogen. According to E. Grieshammer, sulphur is not absorbed by the molten glass; and hydrogen sulphide attacks the glass at ordinary temp., and this the more, the greater the proportion of lead oxide. When powdered flint glass is mixed with sodium dioxide, zinc sulphide, and some potassium persulphate, J. H. Walton and H. A. Scholz found that it is decomposed when the mixture is ignited by magnesium wire as in the thermite process. T. E. Thorpe and C. Simmonds, and K. Beck and co-workers studied the action of acids—*vide supra*; and O. Inwald, the effect of phosphates. K. Beck and co-workers found the addition of 5 per cent. of borax makes lead monosilicate melt at 450°; the disilicate, at 510°; the trisilicate, at 600°; and the tetrasilicate, at 590°.

W. E. Ford and W. M. Bradley found colourless transparent crystals of a mineral from Franklin, New Jersey, which they called *margarosanite*. R. Mauzelius obtained a similar mineral near Langban, Sweden. Analyses corresponded with **lead dicalcium trimetasilicate**, $\text{PbCa}_2(\text{SiO}_3)_3$, associated with a little manganese—approximately 1.14 per cent. MnO . The lamellar masses consist of triclinic crystals which, according to R. Mauzelius, have the axial ratios $a:b:c = 0.84419:1:1.2838$, and $\alpha = 74^\circ 37'$, $\beta = 129^\circ 29'$, and $\gamma = 101^\circ 5'$. W. E. Ford and W. M. Bradley found that the plates have two good cleavages making an angle of 78° , and they are nearly perpendicular to the lamellar cleavage. The sp. gr. is 3.991, R. Mauzelius reported 4.39. The hardness is $2\frac{1}{2}$ –3. W. E. Ford and W. M. Bradley gave for the refractive indices $\alpha = 1.730$, and $\gamma = 1.795$. The mineral is decomposed by nitric acid with the separation of gelatinous silicic acid.

A. E. Nordenskjöld⁹ found prismatic grey or colourless crystals or granular masses of a plumbiferous mineral at Langban, Sweden, and in other localities; and he named it *ganomalite*—from *γάνωμα*, lustre. Analyses by J. Wiborgh, and G. Lindström corresponded with $\text{Pb}_3\text{Si}_2\text{O}_7(\text{Ca,Mn})\text{SiO}_4$. F. W. Clarke, following S. L. Penfield and C. H. Warren, represents it and nasonite as being related as indicated by the following schemes:

This makes the mineral **hexaplastic tetracalcium dihydroxytriorthosilicate**. G. Cesaro made some observations on the constitution. The tetragonal crystals of ganomalite have the axial ratio $a:c = 1:0.707$ (nearly). The (101) and (001) cleavages are distinct. G. Lindström gave 5.74 for the sp. gr., and A. E. Nordenskjöld, 4.98. The double refraction is strong, and the optical character positive. Ganomalite is readily soluble in nitric acid with the separation of gelatinous silica.

G. Flink¹⁰ described irregular, foliated, pale-green masses of a mineral which was found at Langban, Sweden, and he called it *molybdophyllite*—from *μόλυβδος*, lead; and *φύλλον*, leaf—in allusion to its structure. The analyses corresponded with $\text{PbMgSiO}_4 \cdot \text{H}_2\text{O}$, **hydrated magnesium lead orthosilicate**; or, as F. W. Clarke suggested, $(\text{PbOH})(\text{MgOH})\text{SiO}_3$, **magnesium lead dihydroxymetasilicate**. G. Aminoff gave for the formula $(\text{R}''\text{OH})_2\text{SiO}_3$. The crystals are hexagonal. G. Aminoff gives for the axial ratio $a:c = 1:0.549$, the perfect basal cleavage resembles that of mica. The thin flakes are somewhat flexible. The etching figures resemble those

of the members of the hexagonal system. G. Aminoff showed that the X-radiogram corresponds with the trigonal symmetry with $a:c$ about 1:0.549. The indices of refraction are $\omega=1.8148$, and $\epsilon=1.7611$ for Na-light. The birefringence is $\omega-\epsilon=0.0537$; and the optical character, negative. * The sp. gr. is 4.717, and the hardness is 3-4. G. Aminoff discussed the relation between the crystals of *friedelite* and *molybdophyllite*. P. A. van der Meulen reported yellow, transparent, acicular crystals of *zinc lead oxydisilicate*, $5(\text{Pb,Zn})0.2\text{SiO}_2$, of sp. gr. 6.153, in the glassy material from furnace flues.

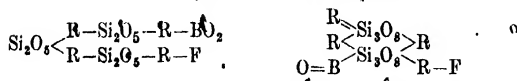

S. L. Penfield and C. H. Warren found a white mineral in granular, cleavable masses at Franklin Furnace, New Jersey; they called it *nasonite*—after F. L. Nason. Analyses correspond with $\text{Pb}_4(\text{Pb}^{(1)})_2\text{Ca}_4(\text{Si}_2\text{O}_7)_3$. F. W. Clarke's view of the composition is indicated in connection with *ganomalite*. This makes the mineral **hexaplbmic tetracalcium dichlorotriorthosilicate**, the crystals are probably tetragonal. The basal and prismatic cleavages are imperfect. The birefringence is strong and negative. The sp. gr. is 5.425, and the hardness 4. G. Lindström¹¹ found a massive mineral associated with the lead ore of Langban, Sweden; it was named *melanotecite*—from μέλας, black; and τήκειν, to melt—in allusion to its relation with *hyalotecite*. The analyses are summarized by $\text{Pb}_2\text{FeSi}_2\text{O}_6$, corresponding with the formula of the isomorphous *kentrolite*. P. Groth represented the composition **lead diferryl orthodisilicate**, $\text{Pb}_2(\text{FeO})_2\text{Si}_2\text{O}_7$. C. H. Warren gave $\text{Pb}_3\text{Fe}_4\text{Si}_3\text{O}_{16}$, which F. W. Clarke wrote $\text{Fe}(\text{SiO}_4)(\text{FeO})\text{Pb}^{1/3}$. The colour of the mineral is dark green to black. H. G. Nordenskjöld gave for the axial ratios of the rhombic mineral $a:b:c=0.6216:1:0.9041$. G. Lindström found that the massive mineral is cleavable in two directions; the sp. gr. is 5.73, and the hardness 6½. It is strongly pleochroic. H. G. Nordenskjöld measured the absorption spectrum. The mineral is decomposed by nitric acid.

A. Fouqué and A. Michel-Lévy¹² prepared a *lead-felspar*, or **lead dialumino-diorthosilicate**, $\text{PbAl}_2(\text{SiO}_4)_2$, or $\text{Pb}(\text{AlSiO}_4)_2$ —*vide* felspar. K. Beck and co-workers found that 5 per cent. of alumina raises the softening temp. of the lead silicate glasses—the monosilicate to 595°, the disilicate to 660°, and the trisilicate to 700°. The attack by dil. acids is at the same time reduced. J. Szilasi prepared *lead ultramarine blue* by heating green sodium-ultramarine and a soln. of lead nitrate under press. L. Wunder made it by heating soln. of lead nitrate and ultramarine blue containing a small proportion of silica in a wrought-iron bomb at 160°. He made *lead-ultramarine-red* by heating ultramarine-red with a conc. soln. of lead nitrate in a wrought-iron tube, at 160°; and *lead-ultramarine-violet*, by treating ultramarine-violet in a similar manner.

A. Damour,¹³ and G. vom Rath described crystals of a dark brown mineral from Southern Chile, and the mineral was called *kentrolite*—from κέντρον, a spike. Analyses were made by A. Damour, G. Flink, and D. Lovisato. The results can be represented by the formula, $\text{Pb}_2\text{Mn}_2\text{Si}_2\text{O}_6$, but if the contained manganese is quadrivalent, $\text{Pb}_2\text{MnSi}_2\text{O}_6$; on account of the isomorphism of this mineral and *melanotecite*, the former is preferred. P. Groth represented the compound as **lead dimanganyl orthodisilicate**, $\text{Pb}_2(\text{MnO})_2\text{Si}_2\text{O}_7$. The crystals are often grouped in sheaf-like forms resembling *stibite*. The mineral also occurs massive. According to G. vom Rath, the rhombic crystals have the axial ratios $a:b:c=0.6334:1:0.8830$. M. Websky drew attention to the close agreement of the angles of *kentrolite* with those of *desclowitzite*. The cleavage is prismatic and distinct. The prismatic planes are often horizontally striated. The sp. gr. is 6.19, and the hardness 5. The surface of *kentrolite* is often black owing to surface oxidation. The mineral dissolves in sulphuric acid with the separation of silica and manganese oxide; and in hydrochloric acid with the evolution of chlorine.

A. E. Nordenskjöld¹⁴ found a massive and coarsely crystalline, white or grey, mineral associated with the felspar at Langban, Sweden. It was named *hyalotecite*—υαλος, glass; and τήκειν, to melt. Analyses by A. E. Nordenskjöld, and A. Lindström corresponded with the formula $\text{R}_4\text{BFSi}_6\text{O}_{17}$, where R represents

Ba, Ca, and Pb. F. W. Clarke¹ represents its composition by two possible formulæ:

The latter agrees with lead barium calcium fluoroboryl diorthotrisilicate; and P. Groth represents it as a metasilicate, $\text{HR}_4\text{B}(\text{SiO}_3)_6$, with F replacing some of the hydroxyl. G. Casaro made some observations on this subject. According to A. des Cloizeaux, the cleavage is easy in two directions at an angle approximately 90° , and less easy in a third direction in the same zone. The crystals are optically biaxial and positive. The optic axial angle $2H = 98^\circ-99^\circ$ for the red ray. The sp. gr. is 3.81, and the hardness 5-5½.

S. L. Penfield and H. W. Foote¹² found a unique mineral at Franklin Furnace, New Jersey, which they called *schlingite* after W. A. Roebling. It occurs in white aggregates of prismatic crystals and massive. The composition corresponds with a mixture of $5\text{CaH}_2\text{SiO}_4 + 21\frac{1}{2}\text{OCa}(\text{SO}_4)$, or calcium lead sulphatohydroxysilicate. The sp. gr. is 3.433, and the hardness 3.25. It readily dissolves in dil. acid, yielding gelatinous silica on evaporation. The *wilkeite*, $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{Ca}(\text{CO}_3) \cdot 3\text{Ca}_3(\text{SiO}_4)(\text{SO}_4)$, of A. S. Eakle and A. F. Rogers is probably a mixture. The hexagonal prism has its axial ratio $a:c = 1.073$; the hardness is 5; the sp. gr. 2.234 at 25° ; the index of refraction 1.640; and the birefringence, $c. 0.004$.

§ 51. The Manganese Silicates

W. A. Lampadius,¹ P. Berthier, and N. G. Sefström tested the fusibility of various mixtures of manganese oxide and silica— $\text{MnO}:\text{SiO}_2=4:1, 2:1, 1:1$, and $1:2$ —in their studies on slags. Various mixtures of these two constituents with magnesia, lime, ferrous oxide, and alumina were also tried. R. Riecke measured

the fusibility of mixtures of clay and manganese oxide. S. Avery showed that the manganiferous glasses become strongly coloured when exposed to sunlight, the ultra-violet rays, or radium radiations—*vide glass*. I. Bang prepared a manganese blue by calcining an intimate mixture of manganese oxide, silica, and baryta or soda-lime. According to A. I. Walcker, aq. soln. of manganese sulphate and sodium silicate give a white precipitate, which has not been closely examined. For colloidal manganese silicate, *vide water-glass*. F. Dörinckel investigated mixtures of manganous oxide and 20–60 molar per cent. of silica fused in a platinum crucible; mixtures with more manganese oxide attacked the platinum, and those with more silica only fused above the m.p. of platinum. The mixtures are melted a second time to ensure a complete reaction. The resulting curves, Fig. 193, show that a manganous orthosilicate is formed at 1323° between some primary crystals and the liquid; and that with mixtures containing 40–60 molar per cent. of silica, primary crystals rich in silica react with the liquid at 1215° to form manganous metasilicate. The eutectic between these two silicates is at 1190°, with 45 molar per cent. of silica. R. Akerman measured the heats of solidification of a number of manganese calcium silicate slags.

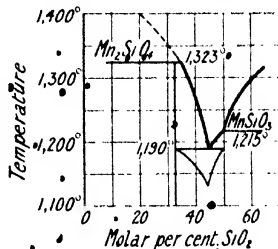

FIG. 193.—Freezing Points of Mixtures of Manganous Oxide and Silica.

A. Breithaupt² applied the term **tephroite**—from *τεφρος*, ash-coloured—to an ash-grey manganous silicate which he examined. Specimens have been found in various other localities. A variety from Langban, Sweden, was called by H. Sjögren *microtephroite*—*μικροτεφρος*, bitter—in allusion to the magnesian content. Analyses were reported by G. J. Brush, W. G. Mixter, G. C. Stone, A. Damour, L. J. Igelström, J. Wiborgh, F. Pisani, G. Paykull, A. des Cloizeaux, C. F. Rammelsberg, T. Thomson, J. H. L. Vogt, H. Sjögren, and J. C. H. Mingay and co-workers. In the idealized case, tephroite corresponds with **manganese orthosilicate**, Mn_2SiO_4 ; but there is usually some magnesia present, 1.38–18.60 per cent.; and 0–11.61 per cent. of zinc oxide; as well as a small proportion of ferrous oxide and lime. Usually, tephroite is regarded as a mixture, $n\text{Mn}_2\text{SiO}_4 \cdot \text{Mg}_2\text{SiO}_4$, with n greater than unity. P. Berthier, and L. Bourgeois obtained crystals of tephroite by fusing the component oxides in the right proportions; and A. Gorgeu, by passing hydrogen or carbon dioxide sat. with steam over a heated mixture of manganese chloride and silica; rhodonite is formed unless the action is continued for a long time. The presence of alkali chloride accelerates the formation of tephroite. J. H. L. Vogt, and J. H. Whiteley and A. F. Hallimond found tephroite and rhodonite crystals in some steel converter slags.

Crystals of tephroite are rare; the mineral usually occurs in crystalline masses; the colour is grey, greyish-red, flesh-red, reddish-brown, and rose-red. The colour often darkens on exposure to air. The crystals belong to the rhombic system, and, according to H. Sjögren, have the axial ratios $a:b:c=0.46004:1:0.59389$; G. Flink gave $0.4621:1:0.5914$. The crystals are isomorphous with olivine. Observations were also made by A. des Cloizeaux. E. Kittl found that manganese orthosilicate glass has a smaller number of centres of crystallization than other orthosilicates, and unlike them forms radiating groups of crystals. The cleavage is distinct in two directions at right angles to one another. A. des Cloizeaux, and G. Flink gave for the optic axial angles $2H_a=81^\circ 4'$, $2H_o=112^\circ 16'$, and $2V_a=76^\circ 6'$ for the yellow ray; $2H_a=84^\circ 4'$, and $2E=161^\circ 48'$ for the red ray; and $2H_a=82^\circ 59'$ and $2E=156^\circ 35'$ for the blue ray. The sp. gr. is 3.95–4.15; F. M. Jäger and H. S. van Klooster gave 4.044 at $25^\circ/4^\circ$ for the sp. gr. The hardness is 6–7. E. Kittl, and F. M. Jäger and H. S. van Klooster, 1290°–1300°, gave 1170°–1200° for the m.p. The last-named found that the index of refraction exceeds 1.739;

the birefringence is strong; and the optical character negative. S. E. Larsen gave for the indices of refraction $\alpha=1.759-1.767$, $\beta=1.785-1.792$, and $\gamma=1.797-1.805$. The crystals are strongly pleochroic. Manganese orthosilicate is decomposed by hydrochloric acid without the evolution of chlorine, but with the separation of gelatinous silicic acid. A. Gorgeu also found that chlorine water, or a soln. of sodium hydrocarbonate, readily attacks this silicate; when melted with manganese chloride and silica with the exclusion of air and water vapour, the metasilicate is formed.

L. J. Igelström³ applied the term *hydratophroite* to what appeared to be a hydrated tephroite from Pajsberg, Sweden. The composition approximated *tridachydrated manganese orthosilicate*, $3(\text{Mn,Mg})_2\text{SiO}_4 \cdot 2\text{H}_2\text{O}$; the colour was pale red; and the hardness 4. It is decomposed by acids with the separation of gelatinous silica. He also applied the term *epgentite* and *neotesite* to other analogous forms approximating *hydrated manganese orthosilicate*, $(\text{Mn,Mg})_2\text{SiO}_4 \cdot \text{H}_2\text{O}$. It is decomposed by acids without the gelatinization of the silica. M. H. Klaproth analyzed another hydrate from Klapperud which had the composition *dihydrated manganese orthosilicate*, $\text{Mn}_2\text{SiO}_4 \cdot 2\text{H}_2\text{O}$. A. H. Phillips described needle-like crystals of a mineral from Franklin, New Jersey, which had a composition corresponding with $(\text{Mg,Mn,Zn})_2\text{SiO}_4 \cdot 2\text{H}_2\text{O}$, and which he called *gagerite*—after R. B. Gage. Bementite—*vide infra*—can be regarded as *manganese dihydro-orthosilicate*, MnH_2SiO_4 . S. L. Penfield and C. H. Warren described a pale purple-red mineral from Franklin Furnace, New Jersey, which they called *leucophoenicite*—from λευκός, pale; and φοινίξ, purple-red. The composition corresponds with $\text{Mn}_2(\text{MnOH})_2(\text{SiO}_3)_2$, *manganese dihydroxy-orthosilicate*. It is considered to resemble a humite with all the fluorine replaced by hydroxy. The crystals are monoclinic. The sp. gr. is 3.848, and the hardness 5½–6. It is slightly pleochroic. It readily dissolves in hydrochloric acid yielding gelatinous silica on evaporation. The water is expelled at a red heat. F. W. Clarke considers both gagerite and leucophoenicite to be members of the humite group, and, writing R for Mg, Zn, Mn, uses graphic formulae of the type:

S. L. Penfield and C. H. Warren described some delicate bluish-green, prismatic crystals which they found at Franklin Furnace, New Jersey, to which they applied the name *glaucochroite* from γλαυκός, blue-green; and χροά, colour. The composition approximates to an isomorphous mixture of *calcium and manganese orthosilicates*, $(\text{Ca,Mn})_2\text{SiO}_4$, with the ratio Ca:Mn=1:1. The rhombic crystals have the axial ratios $a:b:c=0.440:1:0.566$; twinning plane is (011), and the vertical axes cross at $58^\circ 31'$. The optic axial angle $2V=40^\circ 51'$. The indices of refraction are $\alpha=1.679-1.686$, $\beta=1.716-1.722$, and $\gamma=1.729-1.735$; and the birefringence $\gamma-\alpha=0.049$. The sp. gr. is 3.407, and the hardness 6. The mineral is soluble in hydrochloric acid.

C. Palache and W. T. Schaller⁴ found a bright pink or reddish-brown mineral in monoclinic crystals at Franklin Furnace, New Jersey; they called it *hodgkinsonite*. The analyses correspond with *manganese zinc dihydroxyorthosilicate*, $\text{Mn}(\text{ZnOH})_2\text{SiO}_4$. The axial ratios are $a:b:c=1.539:1:1.1165$, and $\beta=84^\circ 33\frac{1}{2}'$. The mean refractive index is 1.73. The mineral decrepitates when heated, and fuses to a brown enamel; no water is lost at 110° . It is readily soluble in acids with the separation of gelatinous silica. S. G. Gordon made some observations on this mineral.

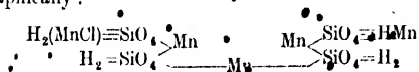

A. Schneider⁵ reported small prismatic crystals of a mineral in the manganese mines at Nanzénbach, Germany, which he called *inesite*—from ινες, flesh fibres—in allusion to the colour and structure; and G. Flink found some in the mine at Harrtig, Sweden, which he called *rhodolite*—from ρόδον, rose; and τῆλος, fibre—and later, he established its identity with inesite. A. Hamberg said that the *manganocalcite* described by A. des Cloizeaux, and P. Groth and J. A. Krenner was an inesite. A. Schneider represented his analyses by $(\text{Mn,Ca})(\text{MnOH})_2\text{Si}_3\text{O}_8 \cdot \text{H}_2\text{O}$, in agreement with the fact that part of the water persists at 300° . Analyses were also made by A. Hamberg, O. C. Farrington, and C. Flink. G. Flink gave the formula $(\text{Ca,Mn})\text{SiO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$; O. C. Farrington, $\text{H}_2(\text{Mn,Ca})_6\text{Si}_6\text{O}_{19} \cdot 3\text{H}_2\text{O}$;

F. Zambonini, $\text{H}_2(\text{Mn,Ca})_2\text{Si}_2\text{O}_7 \cdot \frac{3}{2}\text{H}_2\text{O}$, **hydrated manganese calcium orthosilicate**. F. W. Clarke gave $\text{Mn}_2\text{Si}_2\text{O}_7(\text{Mn,Si}_2\text{O}_7,\text{MnH}_3)_2 + 2\text{H}_2\text{O}$, plus $\text{Ca}_2\text{Si}_2\text{O}_7(\text{Ca,Si}_2\text{O}_7,\text{H}_3)_2 + 2\text{H}_2\text{O}$, where Si_2O_7 is the sixvalent radicle of orthodisilicic acid. A. Hamberg showed that the amount of moisture varies markedly with the humidity of the air; and F. Zambonini found that 1.98 per cent. of water is lost at 110° , and 5.98 per cent. at 310° . The dehydration curve consists of two parts: the part up to 200° does not correspond with any perceptible change in the mineral, while above that temp. the nature of the mineral is changed. A. Schneider found that 4.54 per cent. of water was lost at 110° ; and 0.48 at 200° ; 2.23 at 300° ; 0.62 at 440° ; and 1.35 on ignition—total loss, 9.22 per cent.

The colour of the mineral is rose-red or flesh-red, and on exposure, this coloration disappears. The crystals usually occur in fibrous masses, often radiated and spherulitic. The prismatic crystals, according to R. Schiebe, and A. Schneider, belong to the triclinic system, and have the axial ratios $a:b:c=0.975266:1:1.32078$, and $\alpha=92^{\circ} 18' 12''$, $\beta=132^{\circ} 55' 51''$, and $\gamma=93^{\circ} 50' 42''$. The cleavage parallel to (010) is perfect, less so when parallel to (100) and still less to (110). The sp. gr. approximates 3.03, and the hardness 6. F. Ulrich gave 3.03 for the sp. gr.; and $a=1.618$, $\beta=1.6369$, and $\gamma=1.644$ for the indices of refraction. R. Schiebe found the optic axial angle $2G$ to be 64° for Li-light, $63^{\circ} 28'$ for the Na-light, and $62^{\circ} 51'$ for the Ti-light. The index of refraction is 1.7782. The optical character is negative; the crystals are faintly pleochroic.

D. F. Hewett and E. V. Shannon⁶ reported rhombic crystals of a mineral from Costa, Oriente Province, Cuba, and he called it *orientite*. The composition approximates $4(\text{Ca}0.2\text{Mn}_2\text{O}_3.5\text{SiO}_2.4\text{H}_2\text{O})$, or, with manganese tervalent, $(\text{Ca}_4\text{Mn}_4(\text{SiO}_4)_6.4\text{H}_2\text{O})$. The sp. gr. is 3.05, and the hardness 4.5-5.0. The biaxial crystals have the refractive indices α 1.758, β 1.776, and γ 1.795. The mineral is not attacked by cold hydrochloric acid, but is readily dissolved by the hot acid with the separation of flocculent silica, and the evolution of chlorine; it is partly decomposed by moderately conc. sulphuric acid; and is almost insoluble in conc. nitric acid.

E. Bertrand ⁷ found a manganese silicate in the mines at Aderville, Hautes Pyrénées, and he named it **friedelite**—after C. Friedel. Analyses were made by E. Bertrand, A. Gorgeu, C. Palache, H. Lienau, G. Lindström, L. J. Igelström, and A. Hoffmann and F. Slavik. Formulas have been proposed by C. F. Rammelsberg, E. S. Dana, R. Zambonini, and A. Hoffmann and F. Slavik. P. Groth, and F. W. Clarke give $H_7Mn_4(Mn^{VI})_2(SiO_4)_4$, **manganese chloroheptahydrotetrorthosilicate**, or graphically:

which is analogous with the formula for diopside when MnCl is replaced by hydrogen, and manganese by copper. C. Palache gave: $\text{H}_9\text{Mn}_7(\text{MnCl})(\text{SiO}_4)_6$, and $\text{H}_{20}\text{Mn}_{14}(\text{MnCl})_2\text{Si}_{12}\text{O}_{49}$; G. Aminoff, $\text{H}_2\text{R}'(\text{O}(\text{HCl})_2)(\text{SiO}_3)_2$; and F. Zamboni, $\text{H}_{16}\text{R}'_4(\text{MnCl})_2(\text{SiO}_4)_{10}$. The rose-red crystals are commonly tabular, and the mineral also occurs massive with a saccharoidal structure and distinct cleavage, passing into compact masses with indistinct cleavage. The crystals belong to the trigonal system with the axial ratio $a:c=1.05624$; G. Aminoff obtained $1:0.532-0.562$, and this agreed with the X-ray diagrams. The faces $(10\bar{1}0)$ and $(10\bar{1}1)$ are often striated. The $\{0001\}$ cleavage is perfect; the sp. gr., 3.07; the hardness, 4-5; the double refraction is strong; and the optical character, negative. The mineral dissolves in hydrochloric acid with the separation of gelatinous silicic acid. G. Aminoff discussed the relations between the crystals of molybdomphylite and friederlite.

According to J. F. L. Hausmann,⁸ J. Clason and H. Gahn discovered in the iron mines of Bjelkegrura, Sweden, hexagonal prisms of a ferruginous silicate which they

called *pyrodmalite*—from *πῦρ*, fire; and *ὀσμή*, odour—in allusion to the odour when heated; D. L. G. Karsten altered the term to **pyrosmalite**. R. J. Häy, and J. A. H. Lucas called it *fer muratā*. Analyses were made by J. Lang, E. Ludwig, F. Wöhler, W. Hisinger, N. Engström, A. Gorgeu, and F. Zambonini; and attempts to deduce a formula were made by C. F. Rammelsberg, E. Ludwig, F. W. Clarke, G. Tschermak, F. Zambonini, and A. Gorgeu. The isomorphism of the mineral with *friedelite*, and the similarities in the properties of the two minerals show that the constitution and composition are the same except that much of the manganese of *friedelite* is replaced by ferrous iron. This makes pyrosmalite **manganese ferrous chloroheptahydrotetrorthosilicate**, $H_7(Mn, Fe)_5Cl(SiO_4)_4$. The crystals are thick and prismatic, or else they are tabular. The mineral also occurs massive and foliated. The colour is greenish-black, pale liver-brown, grey, or green. The crystals are often brown externally, and light yellowish-green internally. Observation on the crystals were made by J. F. L. Hausmann, W. Haidinger, G. Flink, R. J. Häy, and H. J. Bröcke. According to A. E. Nordenskjöld, the axial ratio of the trigonal crystals is $a:c=1:0.5308$. G. Aminoff found the X-radiogram agreed with the relations of this mineral with *friedelite* and *molybdophyllite*. The cleavage parallel to (0001) is perfect, and imperfect parallel to (1010). The sp. gr. is 3.06–3.19, and the hardness 4–4½. E. S. Larsen gave $\omega=1.675$, and $\epsilon=1.636$. G. Flink also showed that ω and ϵ were respectively 1.768 and 1.644 for red light; 1.687 and 1.649 for yellow light; and 1.686 and 1.651 for green light. The double refraction is strong, and the optical character negative. P. E. W. Oeberg gave 0.1978 for the sp. ht. F. Zambonini found that there is a change when the mineral is heated to 200°; and that a large proportion of the water is lost at about 400°. The mineral is decomposed by acids with the separation of gelatinous silica.

J. Jakob⁹ observed a **manganese tetramesosilicate**, $3MnO.4SiO_2.3H_2O$, from Val d'Err, Graubünden. He called it **parsettensite** from the occurrence at Alp Parsettens. The copper-red mineral occurs massive, it is uniaxial, and probably pseudo-hexagonal. Its sp. gr. is 2.590, and its indices of refraction $\omega=1.576$ and $\epsilon=1.546$. Part of the water is expelled at 100°, and the remainder at dull redness. In the oxidizing flame it fuses to a brownish-black glass. It is decomposed by hot hydrochloric acid with the separation of silica. A variety of parsettensite with an extra $Mn(OH)$ group was called **errite** after its occurrence at the Val d'Err. Errite is brownish-red, and has the sp. gr. 2.681, and the indices of refraction $\omega=1.575$, and $\epsilon=1.547$.

G. Flink¹⁰ reported colourless rhombic dodecahedra of a mineral, which he called **harstigitite**, among the garnets at a Harstig mine, Pajsberg, Sweden. The analysis approximates $H_7(Ca, Mn)_{12}Cl_3Si_{10}O_{40}$; and F. W. Clarke represents the analysis $H_4Ca_5Mn_2Al_2(SiO_4)_6$,* making harstigitite **calcium dimanganous dialuminium tetrahydrohexorthosilicate**. The small prismatic crystals belong to the rhombic system, and have the axial ratios $a:b:c=0.71479:1:1.01495$. No cleavage was reported. The optic axial angles are $2H_a=57^\circ 50'$ for red light, $57^\circ 56'$ for yellow light, and $58^\circ 8'$ for green light; $2V=90^\circ 27'$. W. Ramsay gave for the indices of refraction with Na-light, $\alpha=1.6782$, and $\gamma=1.68308$. The optical character is positive. The sp. gr. is 3.049, and the hardness 5½. The ignited powder readily dissolves in hydrochloric acid with the evolution of chlorine.

In the eighteenth century, there were many references to *Rothbraunstein*, *Rothstein*, and *Rothspath*. A sample of this mineral from Kapnik, Hungary, analyzed by A. von Ruprecht,¹¹ was called by J. J. N. Huot, *kapnikite*; by D. L. G. Karsten, *Kapnik felspar*; and by A. G. Werner, *manganese-spar*. According to E. F. Germar, C. F. Jasche suggested the term **rhodenite**—from *ῥόδον*, a rose—in allusion to the beautiful red colour. The term rhodonite was adopted by F. S. Beudant, J. F. L. Hausmann, and most subsequent writers.

R. J. Häy called the mineral *manganèse oxydée rose silifère*; C. C. von Leonhard, *Kieselmangan*; M. H. Klaproth, *Schwarzbraunsteinerz*; F. S. Beudant, *opéimose*—from

δψμος, late; E. F. Glocker, *manganolite*; and more or less impure or altered varieties have received various names. They were analyzed by A. Schneider, E. Schweizer, etc. P. Berthier called a more or less oxidized form from St. Marcel, Piedmont, *marceline*. J. J. N. Hüt's *pesillite* from Pesillo, and J. von Jewreynoff's *heterocline*, analyzed by J. J. Berzelius, are probably mixtures of a hydrated silicate, silica, and wad. C. F. Jasche, and E. F. Germar called a green magniferous earthy silicate from Schöbenholze, Harz, *allagite*—from *ἀλλας*, change—in allusion to the change of colour from green to yellowish-brown on exposure to air; it was analyzed by A. P. J. du Mênil, and shown to contain some carbonate. E. F. Germar called a rose-red sample *hydropite*—from *ὕδρωψ*, dropsy; and a yellowish carbonated variety associated with allagite was called *photcite* or, according to R. Brandes, *photizite*—from *φωτίζω*, enlightening. Photcite was analyzed by A. H. Chester, P. Berthier, A. Damour, T. Thomson, and A. P. J. du Mênil. The grey or brown *corneous manganese*—*Hornmangan*—and the *tomosite* of C. F. Jasche and E. F. Germar are of a similar nature to photcite. L. J. Igelström called a variety from Pajsberg, Sweden, *pajsbergite*. More or less oxidized and hydrated varieties are represented by *klippteginsite*—after A. von Klipstein—which is an amorphous black or brown mass from Klapperud, and was described by F. von Kobell, and J. F. Bahr. H. Fischer showed that the supposed mineral is a mixture. J. Igelström described *stratopite*—from *stratum*, and *πῶς*, a relation by affinity—occurring at Pajsberg, Sweden; J. F. Bahr, and A. E. Arppe, *wittingite*, occurring at Wittingi, Finland; and P. T. Clove, N. and A. E. Nordenaskjöld, and A. Schneider, *neotocite*—from *νεότοκος*, of recent origin—occurring at Gostrikland, Sweden, and several other places. J. T. Pardee and co-workers analyzed the neotocite from Western Washington. The three last-named varieties of altered rhodonite appear to be the same. E. T. Wherry discussed the proposal to apply the term neotocite to the amorphous or colloidal manganese silicates with the ratio $MnO : SiO_2$ approximating 1 : 1. N. Engström applied the term *hydrorhodonite* to a hydrated variety of rhodonite from Laugban, Sweden. A. Hamberg's *caryophillite*—from *κάρυον*, walnut; and *πῖλος*, felt—occurs near Pajsberg, Sweden, and consists of reniform or stalactitic nodules with felted masses of radiating fibres. The composition approximates $4MnO \cdot 3SiO_2 \cdot 3H_2O$, but the material analyzed was impure. J. T. Pardee and co-workers suggested that caryophillite is the same as bementite. According to C. Hintze, through some confusion of cummingtonite, and the rhodonite from Cummington, Mass., analyzed by R. Hermann, C. F. Rammelsberg and others have referred to a *manganese-amphibole*, which G. A. Kenngott called *hermannite*; no such amphibole is known.

Analyses of rhodonite were reported by J. J. Berzelius,¹² C. F. Rammelsberg, L. Colomba, J. J. Ebelmen, H. von Foullon, A. Hamberg, D. Fino, F. A. Römer, A. Roccati, L. J. Igelström, M. Weibull, A. H. Chester, J. D. Dana, G. Lindström, L. V. Pirsson, L. Sipocz, R. Hermann, W. Camac, C. U. Shepard, G. vom Rath, H. Hahn, F. Pisani, and F. Fromme. Analyses of the purer samples of rhodonite correspond with *manganese metasilicate*, $MnSiO_3$. A. Brongniart described a greyish-red calciferous manganese metasilicate from Mexico, and called it *bustamite*—after M. Bustamante. A. Breithaupt showed that it belongs to the pyroxene group, and J. F. L. Hausman demonstrated that it is closely related with rhodonite. Calcareous varieties were analyzed by F. Pisani, G. Lindström, G. vom Rath, J. Fromme, and B. J. Igelström. The formulae correspond with mixtures $nCaSiO_3 \cdot MnSiO_3$. E. S. Larsen and E. V. Shannon represent the composition by $CaMn(SiO_3)_2$, and consider the mineral to be a triclinc pyroxene, i.e. a sub-species of rhodonite. It has the optic axial angle $2V = 44^\circ$, and the indices of refraction $\alpha = 1.662$, $\beta = 1.674$, and $\gamma = 1.676$.

According to A. S. Ginsberg, the f.p. curve, Fig. 194, of mixtures of *calcium and manganese metasilicates*—the former with a m.p. 1512° and the latter with a m.p. 1218° —shows a minimum at 1184° corresponding with 12.8 molar per cent. of calcium metasilicate. S. Kullenberg gave 1180° for the m.p. of manganese metasilicate; and 1150° for the m.p. of the eutectic with 10 per cent. of calcium metasilicate. A. S. Ginsberg infers that wollastonite and rhodonite are isodimorphous, furnishing monoclinic mixed crystals. Wollastonite is triclinc; hence, he inferred that there must be a monoclinic variety of rhodonite. A. S. Ginsberg measured the sp. gr. and hardness of binary mixtures of calcium and manganese metasilicates. E. Kittl found the glass in crystallizing developed 120 nuclei per sq. cm. P. Lebedeff obtained the f.p. curve of mixtures of *manganese and strontium metasilicates*, but found there is a great tendency to form glasses with solid soln. near the m.p. The two silicates are isomorphous. Similarly with mixtures of

manganese and barium metasilicates. The f.p. curve has a minimum, but it was not exactly located because of glass formation. He also found that *magnesium and manganese metasilicates*, Fig. 195, form two series of solid soln., with a break in the f.p. curve at 1328° and 40 molar per cent. MgSiO_3 . The m.p. of magnesium metasilicate is 1535° , and of manganese metasilicate 1210° . The optical examination shows that the crystals at the magnesium end of the series have the properties

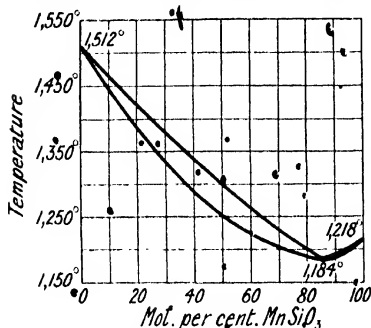

FIG. 194.—Freezing-point Curves of the Binary System: $\text{CaSiO}_3\text{--MnSiO}_3$.

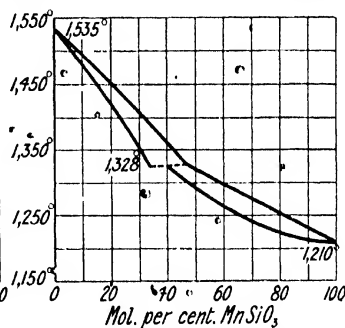

FIG. 195.—Freezing-point Curves of the Binary System: $\text{MgSiO}_3\text{--MnSiO}_3$.

of enstatite, and those at the manganese end the properties of rhodonite, confirming the representation of the system as one of two series of solid soln.

A crystalline and foliated mineral resembling red feldspar was mentioned by S. Fowler, T. Thomson, and S. Robinson as a siliceous oxide of manganese. It occurs near Sterling, New Jersey, and was called *fowlerite* by C. U. Shepard. E. F. Glocker showed that it is closely related to rhodonite; and R. Hermann found that it contained zinc, so that C. F. Rammelsberg called the zinciferous rhodonites, *fowlerite*. C. U. Shepard also called a variety of fowlerite *keatingine*. The iron-black *dyssnite* of T. Thomson was considered to be *manganese sesquisilicate*; J. D. Dana said that it is an altered fowlerite. Analyses of fowlerite were made by C. U. Shepard, C. F. Rammelsberg, W. Camac, and L. V. Pirsson. The formulæ correspond with $m\text{CaSiO}_3 \cdot n\text{ZnSiO}_3 \cdot \text{MnSiO}_3$, which appears to be a mixture of silicates in isomorphous association.

Rhodonite has been reported by F. Wiser, P. von Jeremejeff, E. Tacconi, C. W. C. Fuchs, J. H. Whiteley, and A. F. Hallimond; and J. H. L. Vogt in various iron and steel furnace-slugs. P. Berthier, N. G. Sefström, and L. Bourgeois made rhodonite by fusing a mixture of the constituent oxides. A. S. Ginsberg, and S. Kallenberg employed a similar process, and A. Gorgeu fused a mixture of silica and manganese chloride in a atm. of moist hydrogen or air. Good crystals were obtained in the presence of alkali chloride. According to S. Kallenberg, although the crystalline form of synthetic rhodonite is very similar to that of the naturally occurring rhodonites, it differs from the minerals in the positive character of its double refraction. Synthetic rhodonites containing iron and magnesium silicate are optically similar to the pure manganese silicate, but in the presence of 5 per cent. of calcium silicate the positive double refraction changes to negative. Since the natural rhodonites generally contain calcium silicate in greater proportion than this, the apparent discrepancy in the optical behaviour of synthetic rhodonite and the minerals is readily explained.

Rhodonite occurs in crystals or cleavable masses; and also in compact or granular masses. The colour ranges from a light brownish-red to flesh-red, and rose-pink; it is sometimes greenish or yellowish when impure; and sometimes black on the outside where it has been exposed to air. The fine red rhodonite stone is quarried in the Ural Mountains and used for ornamental purposes. The crystals are often large with rounded edges; commonly tabular, and spear-shaped.

As emphasized by H. Rose,¹⁴ the crystals sometimes resemble pyroxene in habit. G. Rose regarded the crystals as monoclinic, but H. Dauber showed that they are triclinic, and, according to G. Flink, have the axial ratios $a:b:c=1.07285; 1:0.62127$, and $\alpha=103^\circ 18' 7''$, $\beta=108^\circ 34' 8''$, and $\gamma=81^\circ 39' 16''$. Observations on the crystals have been made by J. D. Dana, E. S. Larsen and E. V. Shannon, A. des Cloizeaux, F. Tammann, P. Groth, N. von Kokscharoff, R. P. Greg, H. Sjögren, A. Hamberg, V. Goldschmidt, M. Wahlbüll, L. V. Pirsson, C. Anderson, W. E. Ford and R. D. Crawford, and H. L. Ungemach. C. Hlawatsch called triclinic crystals similar to but not identical with rhodonite, lining the cavities of slags, *vogtite*—after J. H. L. Vogt. The cleavage parallel to (110) is perfect, and that parallel to (001) less perfect. T. L. Walker investigated the corrosion of rhodonite. G. Flink gave for the optic axial angles $2H_a=73^\circ 25'$, $2H_0=109^\circ 56'$, and $2V_a=75^\circ 57'$ for the red Li-ray; $2H_a=79^\circ 0'$, $2H_0=108^\circ 25'$, and $2V_0=76^\circ 12'$ for the yellow Na-ray; and $2H_a=78^\circ 38\frac{1}{2}'$, $2H_0=107^\circ 13\frac{1}{2}'$, and $2V_a=76^\circ 22'$ for the green Ti-ray. A. des Cloizeaux gave for bustamite $2E=68^\circ$ for the red ray and 72° for the green ray. E. Kittl found that the glass during crystallization developed 240 nuclei per sq. cm. The sp. gr. ranges from 3.40 to 3.68. J. Jakob gave 3.416 for the sp. gr. of rhodonite; and A. S. Ginsberg found for various mixtures of calcium and manganese metasilicates, the linear relations:

MnSiO ₃	.	.	0	15	40	60	70	85	90	100 per cent.
Sp. gr.	.	.	2.910	2.992	3.080	3.180	3.219	3.302	3.313	3.390

G. Stein gave 3.44 for the sp. gr. of the artificial crystals of manganese metasilicate, and 3.36 for the sp. gr. of the glass. F. M. Jäger and H. S. van Klooster gave 3.716 for the sp. gr. of manganese metasilicate at $25^\circ/4^\circ$. The hardness of rhodonite is 5.5–6.5. A. S. Ginsberg found that with mixtures of calcium and manganese metasilicate, the relative hardness has a maximum for mixtures with 15 per cent. MnSiO₃:

MnSiO ₃	.	.	.	0	15	40	70	85	100
Hardness	.	.	.	0.041	0.045	0.055	0.058	0.061	0.048

C. Doelter gave 1170° – 1195° , and 1220° – 1240° for the m.p. of different samples of rhodonite; A. Woloskoff, 1216° ; N. V. Kultaschiff, 1180° ; A. S. Ginsberg, 1219° ; S. Smolensky, 1218° ; G. Stein, 1470° – 1500° ; F. M. Jäger and H. S. van Klooster, 1273° ; and S. Kallenberg, 1180° . For the m.p. of mixtures of manganese silicate with calcium and magnesium silicates, *vide* Figs. 194 and 195. C. Doelter gave 1140° – 1176° for the m.p. of forsterite. P. E. W. Oeberg found the sp. ht. of rhodonite to be 0.1699; U. le Chatelier gave 5.4 Cals. for the heat of formation; and S. Wologdine, 7.725 Cals. For the heat of crystallization, O. Muret gave 0.0649 Cals. per gram, or 8.52 Cals. per mol.; and for the heat of soln. of crystalline and glassy manganese silicate in 20 per cent. hydrofluoric acid, he gave respectively 53.07 and 61.59 Cals. per mol. A. Michel-Lévy and A. Lacroix gave for the mean index of refraction, $\beta=1.73$; and for the birefringence, $\gamma-\alpha=0.010$ – 0.011 . F. M. Jäger and H. S. van Klooster gave 1.739–1.733 for the index of refraction; and J. Jakob, $\alpha=1.721$, and $\gamma=1.730$. The optical character is negative. The crystals are pleochroic; this was observed by J. Jakob, G. Flink, A. des Cloizeaux, W. Ramsay, and N. von Kokscharoff.

Rhodonite usually darkens on exposure to air, sometimes becoming nearly black, owing to oxidation. The mineral is slightly acted on by acids, and the calciferous varieties often effervesce owing to the presence of calcium carbonate. The powdered mineral partly dissolves in hydrochloric acid, and the insoluble part is white. According to A. Woloskoff, the f.p. curve of mixtures of manganese metasilicate and sulphide has a eutectic with 6.85 molar per cent. of MnS. The minerals *torrensile*, $\text{MnSiO}_3 \cdot \text{MnCO}_3$; *lacroixite*, $\text{MnSiO}_3 \cdot 5\text{MnCO}_3$; *kuevite*, $3\text{Mn}_2\text{SiO}_4 \cdot 2\text{MnCO}_3$; *vick-laurite*, $2\text{Mn}_2\text{SiO}_4 \cdot 5\text{MnCO}_3$; and *chocolate-stone*, $5\text{Mn}_2\text{SiO}_4 \cdot 3\text{Mn}_3\text{O}_4 \cdot 2\text{MnCO}_3$, are considered by H. Lienau to be different stages in the weathering of rhodonite.

A. Gorgeu found that the metasilicate dissolves in melted manganous chloride and crystallizes out again on cooling; if the fusion be conducted in the vapour of water, the orthosilicate is slowly formed. A. Gautier and L. Hallopéau found that when rhodonite is treated with the vap. of carbon disulphide at a white heat, rhodonite is converted into manganese sulphide, Mn_3S_4 . Gr. A. König described a greyish-yellow mineral occurring in the zinc mines of Franklin Furnace, New Jersey. It is called *bementite*—after C. S. Bement. C. Palache said the axial angle is small, and the crystals belong to the rhombic system. Bementite is soft, with a micaceous cleavage, and sp. gr. 2.981. Its analysis corresponds with **hemihydrated manganous metasilicate**, $\text{MnSiO}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$. It dissolves in hot hydrochloric acid without the gelatinization of the silica. C. Palache's analysis corresponds with $\text{H}_2\text{Mn}_2(\text{SiO}_4)_4$. P. Groth considers it to be *manganese dihydroorthosilicate*, MnH_2SiO_4 . J. T. Pardee, E. S. Larsen, and G. Steiger represent their analyses of the mineral by $8\text{MnO} \cdot 7\text{SiO}_2 \cdot 5\text{H}_2\text{O}$; they consider caryophyllite is of the same mineral species. J. H. Collins described an amber-brown mineral from Penwith, Cornwall, which he called *penwithite*. Its analysis corresponds with **dihydrated manganous metasilicate**, $\text{MnSiO}_3 \cdot 2\text{H}_2\text{O}$.

G. Flink¹⁵ obtained columnar crystals of a light-red mineral with the habit of pectolite, to which it is related chemically. It was found at Julianhaab, Tutop Agderkøfja, and Kangerdluassuk, Greenland. It was examined by C. Wintner, O. B. Bøggild, and C. Christensen, and named *schizolite*—from $\sigma\chi\zeta\omega$, to cleave—in allusion to the marked cleavage. The composition approximates to **sodium calcium manganese hydrotrimetasilicate**, $\text{HNa}(\text{Ca}, \text{Mn})_2(\text{SiO}_3)_3$, where some ferrous iron may replace the calcium, and some titanium, the silicon. The crystals belong to the triclinic system and have the axial ratios $a:b:c = 1.10613:1:1.98629$, and $\alpha = 90^\circ 11'$, $\beta = 94^\circ 45\frac{3}{4}'$, and $\gamma = 103^\circ 7\frac{1}{4}'$. The cleavages (100) and (001) are both perfect. The optical axial angle $2E = 82^\circ 40'$. The sp. gr. is 3.048–3.089; and the hardness 5–5½. The mean index of refraction for sodium light is 1.632; and the birefringence on (100) is 0.0271. The crystals are optically positive. A. Breithaupt¹⁶ referred to flesh-red or rose-red radiating fibrous masses of a calcareous manganese carbonate, as manganocalcite; but E. Brüssig showed that the mineral from Schemnitz is a mixture of carbonate and silicate. The silicate had a composition corresponding with $\text{H}_2\text{Mn}_3(\text{SiO}_3)_4 \cdot \text{H}_2\text{O}$, **manganese dihydrotetrametasilicate**. He called the mineral *agnolite*, from $\alpha\gamma\nu\omega\sigma\alpha$, not recognized. The mineral belongs to the triclinic system; the cleavage is parallel to the length of the fibres. The sp. gr. is 3.054–3.067, and the hardness 5. According to F. Ulrich, agnolite is identical with nesite. J. Jakob described **tinzenite** from Val d'Aire, Graubünden, as a yellow manganese silicate with the composition $2\text{CaO} \cdot \text{Mn}_2\text{O}_3 \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$, and occurring in monoclinic crystals with the indices of refraction $\alpha = 1.693$, $\beta = 1.701$, and $\gamma = 1.704$; and the optical axial angle $2V = 62^\circ 43'$.

A. G. Werner¹⁷ applied the term *carpholite* or *karpholite*—from $\kappa\alpha\rho\phi\omicron\varsigma$, straw—to straw-yellow crystals of a mineral he obtained in the tin mines of Schlackenwald, Bohemia. Analyses were reported by A. Steinmann, L. de Koninck, K. A. Lossen, F. Stromeyer, and G. A. Kenngott. The analyses correspond with $(\text{Mn}, \text{Fe}, \text{Mg})\text{O} \cdot (\text{Al}_2, \text{Fe}_2)\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, or, in the idealized case, $\text{H}_4\text{CaAl}_2\text{Si}_2\text{O}_{10}$. Carpholite is considered to be isomorphous with lawsonite (*q.v.*), and to have the same constitution, making **manganese dialuminium tetrahydroxydimetasilicate**, $(\text{HO})_4\text{MnAl}_2(\text{SiO}_3)_2$. P. Groth wrote the constitutional formula $\text{Mn}[\text{Al}(\text{OH})_{\frac{1}{2}}(\text{SiO}_3)_{\frac{1}{2}}]$; and F. W. Clarke gave a formula like that for lawsonite with manganese in place of calcium.

A. Miché-Lévy and A. Lacroix said that the crystals belong to the rhombic system like lawsonite; H. Fischer said they belong to the monoclinic system. The crystals were also examined by P. Groth, G. A. Kenngott, O. Mügge, and W. Haidinger. The crystals appear in radiated or stellated tufts and groups of acicular forms. The turning plane is (100). The optic angle is $2V = 60^\circ$ approx.

There is a distinct pleochroism. The sp. gr. is 2.876–2.935, and the hardness 5–5½. The birefringence is $\gamma - \alpha = 0.022$; and the optical character is negative. The water passes off at a red heat. The mineral is not decomposed by hydrochloric acid, and it is decomposed by fusion with alkali carbonates.

In 1797, M. H. Klaproth¹⁸ analyzed a garnet which he designated *granatförmiges Braunsteinerz*. It was obtained from Spessart, Bavaria, and hence F. S. Beudant called it *spessartine*, and it is now known as *spessartite* or *manganese garnet*. Several analyses have been made.¹⁹

C. F. Rammelsberg²⁰ deduced the formula $(\text{Ca}, \text{Fe}, \text{Mn})_3(\text{Al}, \text{Fe})_2(\text{SiO}_4)_3$; and in the idealized case, spessartite is **manganese dialuminium triorthosilicate**, $\text{Mn}_3\text{Al}_2(\text{SiO}_4)_3$, with isomorphous admixtures of other garnets—*vide* grossular. H. E. Bocke concluded that there is a continuous series of mixed crystals between spessartite and almandine; but there is an extended break in the series between spessartite and pyrope.

Spessartite occurs in granite, quartzite, and some schists. W. Cross reported it in rhyolite rocks. A. Gorgeu obtained spessartite by fusing a mixture of pipe-clay and an excess of manganese chloride. C. Doelter and E. Hussak heated a mixture of alumina and silica in the proper proportions along with an excess of manganese chloride, and obtained tephroite, rhodonite, and manganese garnet. L. Bourgeois also reported the formation of spessartite by fusing a mixture of the constituents; this, however, is doubtful because his product was soluble in acids. He may have made manganese-leucite.

The crystallographic properties are indicated in connection with grossular. The colour is yellow, or reddish-brown. The sp. gr. ranges from 3.77 to 4.27. An increase of ferric oxide in place of alumina raises the sp. gr.; and an increase of calcium in place of manganese lowers the sp. gr.; the hardness varies from 7 to 7½. C. Doelter and E. Hussak found that manganese-garnet decomposes when melted, forming rhodonite, tephroite, anorthite, and a glass—*vide* grossular. R. C. Sabot found the indices of refraction for Li-, Na-, and the TL-light to be respectively, 1.7981–1.8099, 1.7998–1.8145, and 1.8046–1.8195. E. Raymond studied the action of chlorine and of hydrogen chloride on the mineral.

W. Haidinger²¹ described a monoclinic mineral from the auriferous sands of Olahpian, Transylvania. It was called *partschite*—after P. Partsch. A. Breithaupt previously mentioned this as an *unbekannten Mineralien*. Its composition approximates to that of spessartite, $(\text{Mn}, \text{Fe})_3\text{Al}_2(\text{SiO}_4)_3$, with which it appears to be isomeric. The axial ratios are $a : b : c = 1.266 : 1 : 0.817$. The sp. gr. is 4.006; W. E. Ford gave 4.180. The hardness is 6½–7.

A. Hamberg,²² obtained foliated or micaceous brown crystals of a mineral from the mine at Harstig, Sweden; he regarded it as a *mangano-zeolite*, and called it *ganophyllite*—from *γάνος*, lustre; *φύλλον*, leaf—in allusion to the high lustre on the cleavage plates. The analyses correspond with $7\text{MnO} \cdot \text{Al}_2\text{O}_3 \cdot 8\text{SiO}_2 \cdot 6\text{H}_2\text{O}$, which F. W. Clarke formulated

It is probably a mixture of several silicates. The short prismatic crystals belong to the monoclinic system, and have the axial ratios $a : b : c = 0.4130 : 1 : 1.9309$, and $\beta = 86^\circ 39'$. The basal cleavage, like that of mica, is perfect. The percussion figure is a six-rayed star. The optic axial angle is $2E = 41^\circ 19'$ and $2V = 23^\circ 36'$ for the red ray, and $2E = 41^\circ 53'$ and $2V = 23^\circ 52'$ for the yellow ray. The indices of refraction are for the red ray, $\alpha = 1.6941$, $\beta = 1.7250$, and $\gamma = 1.7264$; and for the yellow ray, $\alpha = 1.7046$, $\beta = 1.7287$, and $\gamma = 1.7287$; E. S. Larsen and E. V. Shannon gave $\alpha = 1.563$ 1.573; $\beta = 1.593$ 1.603; and $\gamma = 1.593$ –1.604. The optical character is negative. The sp. gr. is 2.84, and the hardness 4–4½.

§ 52. Iron Silicates

W. A. Lampadius,¹ N. G. Sefström, W. S. Patterson and P. F. Summers, and P. Berthier made a number of observations on the fusibility of ferrous silicates, and artificial products containing $4\text{FeO} \cdot \text{SiO}_2$, *ferrous orthosilicate*, $2\text{FeO} \cdot \text{SiO}_2$, or Fe_2SiO_4 , and *ferrous metasilicate*, $\text{FeO} \cdot \text{SiO}_2$, or FeSiO_3 . They also made *ferric orthosilicate*, $2\text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2$, or $\text{Fe}_4(\text{SiO}_4)_3$, and *ferric metasilicate*, $\text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2$, or $\text{Fe}_2(\text{SiO}_3)_3$, and tested the fusibility of various other combinations, $\text{Fe} : \text{CaO} : \text{SiO}_2 = 1 : 1 : 1$, $4 : 2 : 3$, and $1 : 1 : 2$; $\text{Fe}_2\text{O}_3 \cdot 3\text{CaO} \cdot 3\text{SiO}_2$; $2\text{FeO} \cdot 8\text{MgO} \cdot 5\text{SiO}_2$; $3\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$, and $\text{Fe}_2\text{O}_3 : \text{Al}_2\text{O}_3 : \text{SiO}_2 = 1 : 1 : 3$,

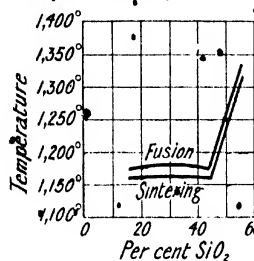

FIG. 196.—Formation Temperatures of Ferrous Silicates.

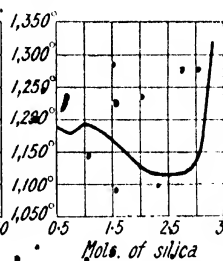

FIG. 197.—Formation Temperatures of $2\text{FeO} \cdot \text{CaO} \cdot n\text{SiO}_2$.

and $1 : 1 : 6$. P. Berthier said that the two ferrous silicates melted easily giving a mass containing rectangular prismatic crystals. The molten silicate readily penetrated a clay crucible. There was no evidence of the formation of the two ferric silicates, and P. Berthier assumed that the ferric oxide was reduced to ferrous oxide by the gases of the furnace. J. Percy also recorded some observations on these products. J. W. Mellor found that the softening temp. of clay was lowered from 1710° – 1160° by the introduction of 28 per cent. of ferric oxide. R. Riecke investigated the fusibility of clay and ferrous oxide in a neutral atm. H. O. Hoffman, and H. Steffe measured the temp. of formation of the ferrous silicates and calcium ferrous silicates, and the results by the latter are illustrated on Figs. 196 and 197. The latter diagram refers to the $\text{FeO} : \text{CaO} = 2 : 1$, in admixture with varying proportions of silica. M. Rüger observed no formation of the ferrous silicates between 900° and 1200° . The results for the system $\text{FeO}-\text{CaO}-\text{SiO}_2$ were plotted by L. Babu, and H. E. Ashley on a triangular diagram. For colloidal iron silicates, *vide water-glass*. A. W. Thomas and L. Johnson studied the mutual precipitation of ferric hydroxide and silicic acid from colloidal soln.

J. H. Whiteley and A. F. Hallimond studied the formation of iron silicates in the slags from acid hearth steel furnaces, and they deduced a possible equilibrium curve for the f.p. of binary mixtures of ferrous oxide and silica. This is shown by dotted lines in Fig. 198. The results observed by O. von Kell and A. Dammann, with mixtures containing up to 40 per cent. silica, are shown by continuous lines in the same diagram—*vide supra*, Fig. 198.

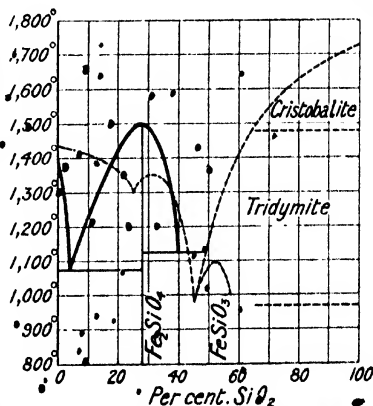

FIG. 198.—Freezing Points of Mixtures of Ferrous Oxide and Silica.

C. G. Gmelin² found nodules of a black mineral in the volcanic rocks at Fayal, Azores, and he called it *fayalite*. The same mineral has been found in a few other localities—Slievecarrach, Ireland; the Yellowstone National Park; Cheyenne Mountain, Colorado; Lipari, Iceland; Cerro de las Navajas, Mexico; etc. Analyses were reported by C. G. Gmelin, C. F. Rammelsberg, R. van Fellenberg, T. Thomson, A. E. Delesse, F. A. Gooch, A. Schertel, E. Classen, E. Mitscherlich, J. H. B. Vogt, F. Bothe, B. Kosmann, H. Laspeyres, G. O. Smith, S. Weidman, S. L. Penfield and E. H. Forbes, K. Busz and F. W. Rüsberg, A. Harpf, W. E. Hidden, J. B. Mackintosh, D. Lavisato, M. Kispatic, and J. Söllner. The results show that in the ideal case, the mineral is *ferrous orthosilicate*, Fe_2SiO_4 . In some cases ferric oxide is present. The so-called *manganese-fayalites* have up to about 9 per cent. of MnO , probably in solid soln. as manganese orthosilicate; those with zinc orthosilicate are called *zinc-fayalites*—*vide infra*. The occurrence of fayalite in slags and other furnace products has been frequently recorded.³ Thus, N. Sokoloff found fayalite in roasted siliceous earths, in blast furnace slags, in slags from cupolas, in converter slags, and in slags from copper furnaces.⁴ Observations on this subject have been made by F. Mitscherlich, C. W. C. Fuchs, J. J. Nöggerath, C. T. Jackson, W. H. Miller, F. Bothe, M. Dondorff, B. Kosmann, J. J. Ebelmen, A. E. Arnold, C. O. Trechmann, H. Laspeyres, A. W. Stelzner, G. Bellinzona, and J. H. L. Vogt. A. Lacroix observed that a slag was formed during the eruption of Mt. Pelée, Martinique, by the melting together of the andesite walls and the iron contents of a warehouse. The slag contained fayalite, magnetite, and glass. By heating a mixture of ferrous chloride and silica in a current of hydrogen charged with steam, A. Gorgeu obtained crystals of fayalite.

Fayalite occurs in minute crystals of tabular habit, and also massive. The colour is light yellow and transparent, becoming opaque and dark brown to black, and often iridescent on the surface owing to oxidation. The crystals belong to the rhombic system, and, according to S. L. Penfield, have the axial ratios $a:b:c=0.4584:1:0.5793$; J. Söllner gave $0.4600:1:0.5811$. Observations on the crystals were made by M. Bauer, and many of those who studied the fayalite in slags. The cleavage (010) is distinct; (100) is less so. H. Michel studied the zonal structure in some artificial crystals of fayalite. J. Söllner found the optic axial angle $2V=51^\circ 1' 35''$. S. L. Penfield and E. H. Forbes gave $2H=51^\circ 27'$ for the Li-ray, $56^\circ 32'$ for the Na-ray, and $55^\circ 2'$ for the Ti-ray. The reported values for the sp. gr. of fayalite range from 3.90–4.24, and the hardness from $6\frac{1}{2}$ –7. According to C. Doelter, the m.p. of fayalite is 1055° – 1075° ; O. Keil and A. Dammann gave 1500° (Fig. 198). B. Kittl found that the glass developed 220,000 nuclei per sq. cm. in crystallizing. V. Pöschl measured the sp. gr. and m.p. of mixtures of fayalite, Fe_2SiO_4 , and of forsterite, Mg_2SiO_4 , and found

Fayalite	0	10	20	30	40 per cent.
Sp. gr.	3.11	3.16	3.30	3.36	3.46
	1600°	1330°	1315°	1305°	1290°
M.p.	—	1370°	1360°	1340°	1320°

He also studied the ternary system: forsterite-fayalite-lime olivine. J. Söllner gave for the indices of refraction for the yellow Hg-line, $\alpha=1.8044$, $\beta=1.8382$, and $\gamma=1.8462$; and S. L. Penfield and E. H. Forbes gave $\alpha=1.8236$, $\beta=1.8642$, and $\gamma=1.8736$; and for the strong birefringence $\gamma-\alpha=0.050$. The optical character is negative. Fayalite dissolves in hydrochloric acid with the separation of gelatinous silica. This subject was investigated by J. M. Thiele.

J. J. Bernhardt and R. Brandes³ referred to a compact greenish-yellow mineral with an opal-like appearance which they called *chloropal*—from $\chi\lambda\omega\rho\acute{o}\varsigma$, green; and opal.

The mineral was obtained from Ungvár, Hungary, and was hence called *ungwarite* by E. F. Glocker; P. Berthier called a yellow or greenish-yellow variety with an unctuous feel, *nantropite*, from Nontron, Dordogne, France, where it was found. A. Breithaupt called a

greenish variety with a soft soapy feel, *pinguite*—from *pinguis*, fat—it was analyzed by C. M. Karsten. It was obtained from Wolkenstein, Saxony. J. C. Freiesleben called a liver-brown variety from Halsbrücke, Freiberg, *Felsöl*; and A. Krantz, C. Bergemann, and A. H. Church called a grass-green variety *gramenite*—from *gramen*, grass—it was analyzed by C. Bergemann. A. Knop described a brownish-yellow imperfectly characterized silicate occurring in cavities in the limburgite of Sadtach, Kaiserstuhl. It was called *glasurite* in allusion to its occurring in layers glazing the interior of the cavities. He described another leek-green variety occurring under similar conditions as *protonontbronite*. J. F. L. Hausmann described a fibrous yellow mineral from Antonio Pereira, Mines Gnaes, Brazil, as *anthosiderite*—*ἄνθος*, flower; and *σπρος*, iron. G. F. E. Schnedermann's analysis agrees with the formula $2\text{Fe}_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; F. W. Clarke gave $\text{Fe}_4(\text{Si}_2\text{O}_4)_3 \cdot 2\text{H}_2\text{O}$. F. Zambonini applied the term *müllerite*—after H. Müller—to a massive yellowish-green mineral from Nontron, Dordogne, France, with a lower proportion of water than chloropal or nontronite; otherwise it closely resembles this mineral. Analyses were also reported by C. F. Rammelsberg, and M. Weibull. The formulae are mullerite, $\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; and nontronite, $\text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. F. W. Clarke suggests that mullerite is *ferric metasilicate*, $\text{Fe}_2(\text{SiO}_3)_2 \cdot 2\text{H}_2\text{O}$. Since the name mullerite had been previously given for another mineral, M. Bauer proposed the term *zamboninite*. F. Katzer described a green granular or scaly earth from Kritz, Bohemia; it was named *hoeferite*—after H. Hoefer. It closely resembles chloropal or nontronite. Its composition approximates $\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$. F. Katzer said that hoeferite is *das reinste bis jetzt bekannte natürliche Eisenoxyldihydrosilicat*. The sp. gr. is near 2.4, and its hardness 1-3.

Analyses were reported by J. J. Bernhardt and R. Brandes, F. Hiller, T. Thomson, C. von Hauer, P. Berthier, P. A. Dufrenoy, V. A. Jacquelin, E. Biewand, C. M. Karsten, J. H. Collins, H. Mehner, A. Schrauf, A. H. Church, M. Weibull, F. von Kobell, A. Liversidge, E. F. Smith, L. N. Chapell, H. Müller, H. Stoddlar, C. von John, F. Kovar, E. Weinschenk, G. Steiger, etc. The results are not very concordant. The silica ranges from 36.90-48.59; the ferric oxide from 11.04-36.41, and the alumina from 0.75-25.95; water from 15.71-25.41 per cent. along with a little ferrous oxide, magnesia, and lime. The mineral appears to be related to kaolinite, with ferric oxide in place of alumina. F. W. Clarke gave for chloropal $\text{Fe}_2(\text{SiO}_4)_3\text{H}_6$. Idealized nontronite, according to E. Weinschenk, and E. T. Wherry and G. V. Brown, has the composition $\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$; although usually the actual composition is often nearer F. von Kobell's $\text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, which resembles that of mullerite—*vide infra*. T. E. Thorpe gave for nontronite $\text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2 \cdot 5\text{H}_2\text{O}$; and A. Bergéat, $2\text{Fe}_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 4\text{H}_2\text{O}$. These minerals range in composition between ferric kaolinite and a ferric halloysite. A. Lacroix described a mineral, *faratsihite*, $(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, from Faratsiho, Madagascar, with refractive indices rather higher than those of kaolinite. Chloropal is an earthy mineral, or compact-like opal; it has a light green colour which becomes dark chestnut brown when the water is expelled. There is no evidence of crystallization. The sp. gr. varies from 1.727-2.105; and the hardness 2½-3½. E. T. Wherry and G. V. Brown gave for the refractive indices $\alpha=1.595$, $\beta=1.595$, and $\gamma=1.620$. It is partly decomposed by hydrochloric acid. C. Simmonds found that chloropal is completely reduced by heating it to redness in hydrogen. J. W. Mellor found the heating curve gave a terrace at about 150°, and he inferred that nontronite probably breaks down at that temp. into free silica, free ferric oxide, and water; G. Tammann and C. E. Grevenmeyer also came to the same conclusion, and added that nontronite became yellow at 100°, brownish at 350°, brown at 800°, and reddish-brown at 800°-900°. It lost 78 per cent. of its water at 100°, none at 100°-200°, and the remaining water was lost continuously between 300° and 600°. Ten per cent. sulphuric acid dissolved out 0.01 per cent. of iron at 20°, and 1.73 per cent. in the mineral calcined at 1000°. H. von Wartenberg represented the action of chlorine on the heated mineral by $3\text{Fe}_2\text{SiO}_4 + 3\text{Cl}_2 = \text{Fe}_4(\text{SiO}_4)_3 + 2\text{FeCl}_3$.

J. E. Spurr⁴ classed a mineral as glauconite which C. K. Leith, and H. N. Winchell, and F. W. Clarke found to be free from potassium and the chemical composition to approximate $\text{FeSiO}_3 \cdot n\text{H}_2\text{O}$. The colloidal mineral was called *grenaite*. C. R. van Hise and C. K. Leith showed that a similar product is obtained by reactions between soln. of ferruginous salts and the hydrosol of silicic acid. A little ferric iron is present in both the natural and artificial products. A black or dark brown compact earthy mineral found in various

parts of Norway and other countries was called *hisingerite*—after W. Hisinger—by J. J. Berzelius.⁶ It was analyzed by P. T. Cleve, A. F. Thoreld, C. F. Rammelsberg, F. W. Clarke, G. M. Schwartz, M. Weibull, P. Sustschinsky, A. H. Church, A. Nikolajeff, and L. J. Iwanoff. The formula approximates to $\text{H}_2\text{Fe}_2\text{Si}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$, or $\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 4\text{H}_2\text{O}$; E. S. Simpson represented it $\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$ + adsorbed water. The index of refraction is 1.40–1.53. A variety occurring at Degëro, Finland, was called *degeröite* by H. J. Holmberg; a variety from Wilmington, Delaware, was called *canbyite* by A. C. Hawkins and E. W. Shannon—half the water being lost at 110°, the analysis was summarized by $\text{H}_2\text{Fe}'''\text{Si}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$; the indices of refraction were $\alpha=1.562$, $\beta=1.580$, and $\gamma=1.582$, but marked variations were observed; the optic axial angle was small and the optical character negative; a dark green or black variety with rather less water than hisingerite, was called *skotiolite*—from *σκότιος*, dark—by A. E. Alppe. A non-homogeneous earth containing about 16.5 per cent. MnO, and occurring at Vestra Silfberg, Sweden, was called *mangan-hisingerite* by M. Weibull. An earthy mineral from the gilling mine, Södermanland, Sweden, was called *gillingite* by W. Hisinger. It was analyzed by C. F. Rammelsberg. A variety from Bodenmais, Bavaria, *thraulite*—from *θραυλός*, fragile—by F. von Kobell; another variety from the same locality was called *jollyite*—after G. Jolly—by F. von Kobell. J. P. Cooke called a reddish-black earth from Mineral Hill, Pennsylvania, *melanosiderite*—from *μέλας*, black, and *σίδηρος*, iron. The analysis agrees with $\text{Fe}_2\text{SiO}_4 \cdot 6\text{H}_2\text{O}$. F. A. Genth suggested that melanosiderite is a variety of limonite with colloidal silica or silicic acid as an impurity. J. Krenner described a massive black earth occurring at Avasthal, Hungary; and he called it *avasite*. The composition approximates $5\text{Fe}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 9\text{H}_2\text{O}$, and it is probably limonite admixed with silicic acid.

A. Scacchi⁶ described a mineral resembling olivine which he found in the Vesuvian lavas of 1831, near Capa di Sabataniello. Analyses show that it contains calcium and ferrous orthosilicates in isomorphous association $(\text{Ca}, \text{Fe})_2\text{SiO}_4$. The crystals were examined by E. Scacchi. E. Kittl found the glass in crystallizing developed 240 nuclei per sq. cm. Analyses were made by H. Struve, S. L. Penfield, W. G. Mixter, and C. H. Warren. S. L. Penfield and E. H. Forbes gave for the optic axial angles $2H=76^\circ 59'$ for Li-light, 76° for Na-light, and $75^\circ 46'$ for Tl-light. The sp. gr. is 3.91, and the hardness 6–7. The lime-iron-olivine of J. H. L. Vogt has a similar composition. The rhombic crystals have the axial ratios $a:b:c=0.43663:1:0.57832$. The colour ranges from colourless to pale brown. W. T. Schaller reported on a sample of a red mica-like mineral which he called *gillespite*—after F. Gillespie, who found it near Dry Delta, Alaska. Its composition approximates **barium ferrous tritertetrasilicate**, $\text{BaFe}'''\text{Si}_4\text{O}_{10}$; its sp. gr. is 3.33; its hardness 4; it is optically uniaxial; its birefringence is low; and it is strongly pleochroic. C. T. Jackson found crystals of a manganous variety, $(\text{Ca}, \text{Fe}, \text{Mn})_2\text{SiO}_4$, in some blast-furnace slags. The *hyalo-siderite* of F. A. Walehner⁷ is a mixture of **magnesium and ferrous orthosilicates** in isomorphous association, and approximately $(\text{Mg}, \text{Fe})_2\text{SiO}_4$ with $\text{Mg}:\text{Fe}=2:1$; likewise also the mineral named by G. J. Brush,⁸ *hortonolite*—after S. R. Horton—from the iron-mine at Monroe, New York. Observations by G. J. Brush, and J. M. Blake show that the mineral is intermediate in composition between olivine and fayalite, for the ratio $\text{Mg}:\text{Fe}$ is nearly 1:1. The rhombic crystals are yellow or yellowish-green, and have the axial ratios $a:b:c=0.46630:1:0.5803$. The optic axial angle $2H_\alpha=83^\circ-86^\circ$; the sp. gr. is 3.91; and the hardness 6–7. G. T. Prior found the silicate $(\text{Mg}, \text{Fe})_2\text{SiO}_4$ with $\text{Mg}:\text{Fe}=3:1$ in the meteorites of Barote, India, and Witterkrantz, South Africa.

K. Hofmann-Degen obtained a kind of olivine in cavities in the slag at the Clausthal-silver works. The composition approximates $(\text{Fe}, \text{Ca})_2\text{SiO}_4$ with about 2 per cent. of the magnesium silicate, and 5 per cent. of calcium orthosilicates. The axial ratios are $a:b:c=0.4371:1:0.5768$, and refractive indices for Na-light, $\alpha=1.6958$, $\beta=1.7340$, $\gamma=1.7430$.

J. W. Döbereiner⁹ applied the term *knebelite*—after M. von Knebel—to a mineral which, according to J. F. L. Hausmann, and G. A. Krennott, was derived from the granite of Ilmenau. It has been observed in other localities. The *iron-knebelite* or *igelströmite* of M. Weibull was obtained from Norrbärke, Dalekarlia. Analyses were reported by J. W. Döbereiner, A. des Cloizeaux, M. Weibull, A. Erdmann, and F. Kossmat and C. von John. The results show that the dominant

constituents are *manganous and ferrous orthosilicates* in isomorphous association, $(\text{Mn,Fe})_2\text{SiO}_4$. K. Busz and E. W. Rüsberg found knebelite in furnace slags. According to M. Weibull, the black rhombic crystals have the axial ratios $a:b:c = 0.467:1:-$. The crystals are pleochroic. A. des Cloizeaux gave $2E = 115^\circ - 120^\circ$ for the optic axial angle. The sp. gr. is 3.93-4.17, and the hardness 6-7. P. E. W. Oeberg gave 0.1665 for the sp. ht.

W. T. Roepper¹⁰ described an iron-manganese-zinc-chrysolite occurring at Sterling Hill, and at Franklin Furnace, New Jersey. J. D. Dana called it *roeperite*; and G. A. Kenngott, *sterlingite* (actually *stirlingite*). The analysis by W. T. Roepper corresponds with a mixture of *ferrous, manganous, zinc, and magnesium orthosilicates* in isomorphous association. The colour when fresh is pale yellow, but it darkens on exposure to air, becoming green and black. The crystals belong to the rhombic system. The (001) and (010) cleavages are distinct; (100) is splintery. The sp. gr. is 3.95-4.08, and the hardness 5½-6. The crystals are slightly negative, and they are decomposed by acids with the separation of gelatinous silicic acid. E. Kittl found the glass FeMnSiO_4 developed 10 nuclei per sq. cm. W. Stelzner observed foliated aggregates of tabular crystals of a *zinc-fayalite* in the zinc-furnace slags of Freiberg. The analysis corresponds with an isomorphous mixture of *ferrous and zinc orthosilicates*, $(\text{Zn,Fe})_2\text{SiO}_4$.

According to A. Cronstedt,¹¹ a cross made of two brown six-sided crystals of a mineral, called *lapis crucifer*, or *Basler Tauffstein* (baptismal stone) was worn as an amulet at baptisms in Basel in the eighteenth century. According to G. F. Kunz, to-day the *lapis crucifer* is worn as a charm in Brittany and other places. C. P. G. de Robien called the mineral *pietre de croix*; A. Cronstedt, and J. G. Wallerius, *basaltes crystallisatus*; J. B. L. Romé de l'Isle, *schorl cruciforme*; J. C. Delaméthèrie, *staurolite*; H. B. de Saussure, *granatite*; and R. J. Haüy, *staurolide*. The term *staurolite*—from *σταυρός*, a cross—is now generally employed. M. F. Heddle described a reddish-yellow mineral from Milltown, Scotland, as *xantholite*—from *ξανθός*, yellow—but A. Lacroix showed that this mineral is staurolite mixed with some mica. T. Thomson called it *crucile*; and G. A. Kenngott altered the term to *crucilite*.

Analyses were made by H. V. Collet-Descotils,¹² L. N. Vauquelin, M. H. Klaproth, and many others. C. W. Paykull analyzed a sample from the dolomite of Nordmark, Wermland, Sweden, and found 11.61 per cent. of Mn_2O_3 , and it was called *manganese-staurolite* or *nordmarkite*; while F. A. Genth found a sample from Georgia with 7.13 per cent. of zinc oxide, and it was called *zinc-staurolite*. From his study of the analyses, C. F. Rammeisberg assumed that the mineral was a mixture of a salt of the silicic acid, H_2SiO_6 , and a bivalent base, and a salt of the silicic acid, $\text{H}_2\text{Si}_3\text{O}_{18}$, and a trivalent base. S. L. Penfield and J. H. Pratt deduced the formula $\text{HAl}_6\text{FeSi}_2\text{O}_{13}$, or *aluminium ferroxytetraluminyldiorthosilicate*, $(\text{FeOH})(\text{AlO})_4\text{Al}(\text{SiO}_4)_2$. P. Groth gave $(\text{AlOH})(\text{AlO})_4\text{Fe}(\text{SiO}_4)_2$; and W. Friedl, $(\text{Fe,Mg})_2\text{Al}_6(\text{AlO})_{12}(\text{OH})_4(\text{SiO}_4)_{11}$. F. W. Clarke represents andalusite by the formula $(\text{Al}=\text{SiO}_4)_2:\text{Al}_2\text{SiO}_4=(\text{AlO})_3$, and for the staurolite he gives $\text{Fe}:\{(\text{SiO}_4:\text{Fe})-\text{Al}=\{\text{SiO}_4:(\text{AlO})_3\}_2\}$, in which some Fe" can be replaced by $(\text{FeOH})_2$.

Staurolite is found in many metamorphic schists—e.g. muscovite or paragonitic schist—and in some gneisses or slates. It is often associated with garnet, sillimanite, cyanite, and tourmaline. H. St. C. Deville and H. Caron¹³ obtained what they called staurolite, by the action of silicon tetrafluoride on a heated mixture of alumina and quartz; but H. St. C. Deville showed that the product really had the composition of sillimanite. P. Hautefeuille and J. Margottet also said they obtained in their work on the synthesis of phosphates a substance resembling staurolite. In neither case is the evidence sufficient to establish the claim that staurolite has been synthesized.

The colour of staurolite may be reddish-brown, yellowish-brown, or brownish-black. The crystals commonly have inclusions—quartz, garnet, cyanite, mica,

tourmaline, magnetite, rutile, carbonaceous matters, etc. The quartz inclusions, said A. von Lasaulx,¹⁴ may amount to 30–40 per cent. of the total weight of the crystals. This is sufficient to account for the great variations—amounting to 27–51 per cent.—in the proportion of silica reported in the analyses. The carbonaceous matters may be regularly arranged, producing a tessellated appearance when viewed in cross-section, and recalling the effect observed with andalusite. This subject has been studied by S. L. Penfield and J. H. Pratt, A. Lacroix, S. Webber, and C. T. Jackson. Euhedral crystals occur in short prisms, crystals also occur with rounded edges but seldom in anhedral grains. W. Phillips gave measurements from which A. des Cloizeaux calculated for the axial ratios of the rhombic crystals, $a:b:c=0.4734:1:0.6828$. Observations on the crystals were made by M. J. Aekner, G. Primics, C. F. Peters, N. von Kokscharoff, J. R. Blum, E. J. Chapman, G. A. Kenigöft, A. des Cloizeaux, B. Studer, A. von Lasaulx, P. Termier, O. Luedecke, G. Gürlich, E. S. Pana, C. F. Rammelsberg, F. A. Genth, V. von Zepharovich, P. Groth, and Comte de Limur. The crystals commonly occur as cruciform twins; when the twinning plane is (032), the twins cross nearly at right angles; when it is (232), the twins cross at nearly 60°; and in the rarer case, when it is (230), the *b*-axes make an angle of 70° 45'. Sometimes the twinning does not affect the outward form of the crystals, and the optical properties alone show that twinning has taken place. Trillings sometimes occur. The cleavage parallel to (010) is distinct but interrupted; traces occur parallel to (110). A. Michel-Lévy and A. Lacroix gave for the optic axial angles with red light, $2H_a=113^\circ 10'$, and $2V_a=88^\circ 46'$; F. Hörner gave $2V=82^\circ 2' - 89^\circ 45'$. A. des Cloizeaux gave $2H_0=117^\circ 52'$, and $2V_0=91^\circ 39'$. The last-named found that by raising the temp., the optic axial angles are perceptibly diminished. The sp. gr. of staurolite ranges from 3.4–3.8; F. Hörner, using E. Clerici's liquids, obtained 3.753–3.778; and C. F. Rammelsberg, 3.654–3.660. The hardness is 7 or over 7. R. Cusack, gave 1115° for the m.p.; and A. L. Fletcher, 1165°. G. Spezia made some observations on this subject. The indices of refraction are high. A. Michel-Lévy and A. Lacroix gave for red-light $\alpha=1.736$, $\beta=1.741$, $\gamma=1.7466$; W. H. Miller gave $\beta=1.7526$; A. des Cloizeaux, 1.749; and F. Hörner, $\alpha=1.7344$ –1.7640; $\beta=1.7399$ –1.7660; and $\gamma=1.7033$ –1.7733. The birefringence is low. A. des Cloizeaux gave $\gamma-\alpha=0.010$, and $\gamma-\beta=0.003$. The optical character is positive. The pleochroism is distinct and was studied by H. Rosenbusch.

Staurolite is imperfectly decomposed by sulphuric acid. Staurolite alters into muscovite. C. Simmonds found that staurolite does not show any definite reduction by hydrogen at a red heat. The alteration of staurolite in nature has been discussed by J. R. Blum,¹⁵ A. Pichler, H. Rosenbusch, and C. R. van Hise. According to F. W. Clarke, the alleged alteration of staurolite into steatite is questionable. J. Lemberg studied the action of soln. of sodium silicate at 200° for 586 hrs.—part was transformed into analcite, and part into a hydrated sodium silicate.

Pliny in his *Historia naturalis* (37. 25) refers to various kinds of carbunculi; and added that the Alabandic stones from Orthosia, Caria (Asia Minor), were cut and polished at Alabanda. The stone from Alabanda appears to be the common, syrian, oriental or precious garnet, and, in the Middle Ages, the name Albanda came to be applied to a costly stone—the garnet, ruby, topaz, and hyacinth. The term was corrupted and appears in various forms in the writings of the Middle Ages—*alamandina*, *alavandina*, and *almardina*; U. F. B. Brückmann,¹⁶ indeed, attempted to derive the term from Allemandy. D. L. G. Kartsen applied the term **almandine** to the ferrous garnet, and J. J. Berzelius, *Fahln Granel*.

Numerous analyses have been reported; ¹⁷ and from them C. F. Rammelsberg,¹⁸ and J. Uhlig deduced the formula $(\text{Fe}, \text{Mg})_3(\text{Fe}, \text{Al})_2(\text{SiO}_4)_3$. In the idealized case almandine is regarded as **ferrous dialuminium triorthosilicate**, $\text{Fe}_3\text{Al}_2(\text{SiO}_4)_3$, and the presence of magnesium and ferric iron are supposed to be due to isomorphous admixture with magnesia-garnet and a ferric-garnet—*vide* grossular. Almandine occurs in granitic rocks, gneisses, etc.

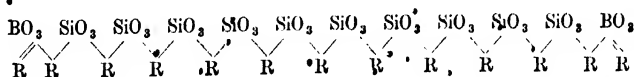

The properties of the crystals have also been discussed in connection with grossular. Almandine is coloured various shades of red, brownish-red, and rarely black. The sp. gr. ranges from 4.1–4.3. M. Seebach found the sp. gr. of a sample crystallized and fused were respectively 4.04, and 3.09 at ordinary temp.; another sample gave respectively 4.025 and 3.240. W. E. Ford gave 4.250 for the sp. gr., and P. J. Holmquist, 4.039–4.201; and for the hardness on the (111)-face, 1058 (quartz on the (0001)-face, 1000); on the (110)-face, 1159; and on the (100)-face, 1246. The hardness is 7–7½ on Mohs' scale. J. Joly gave for the m.p. 1175°; R. Cusack, 1265°; A. L. Fletcher, 1313°, 1318°; A. Brun, 1070°; and C. Doelter, 1110°–1215°. There is no true m.p. because, as C. Doelter and E. Hussak showed, the mineral decomposes when it is melted—*vide* grossular. A. des Cloizeaux found 1.7716 for the index of refraction. H. Rosenbusch gave for Li-, Na-, and Ti-light respectively 1.8022–1.8052, 1.8078–1.8107, and 1.8125–1.8250; C. Schmidt, 1.7958, 1.8017, and 1.8062; A. Brun, 1.787–1.795, 1.791–1.800, and 1.805; and M. Seebach, 1.7722–1.7883; 1.7778–1.7936, and 1.7858–1.7866. W. E. Ford gave 1.830. The alterations which almandine undergoes in nature have been discussed by J. R. Blum,¹⁹ J. Roth, E. Helland, C. W. Paikkul, and H. G. T. Wachtmeister. The action of chlorine and hydrogen chloride on the heated mineral was studied by E. Reymond.

J. B. L. Romé de l'Isle²⁰ referred to *une espèce de schorl violet* from St. Cristophe, Dauphiny; A. G. Werner called a variety from Thum, Saxony, *Thunstein*, a name later changed to *thumite*; J. F. Blumenbach called it *Glasschorl*; J. C. Delamétherie, *yanolite*—from *ἰανθον*, violet; A. Estner, *Afterschorl*; M. H. Klaproth, *Glasstein*; and R. J. Haüy, *axinite*—from *ἀξίνη*, an axe—in allusion to the broad acute-edged form of the crystals.

Analyses were made by M. H. Klaproth,²¹ L. N. Vauquelin, W. Hisinger, and many others. C. F. Rammelsberg attempted to deduce a formula and obtained $H_4R''_8R'''_8Si_{11}O_{44}$, supposed to be a complex, containing $H_4SiO_4 + 4R''_2SiO_4 + 2R'''_4SiO_8$. Empirical formulæ were also proposed by J. E. Whitfield, O. Lueddecke, W. E. Ford, P. Jannasch and J. Locke, etc. H. Sjögren gave $R''_4(SiO_3)_5 : Al_2BO_3$; and P. Groth, $(Ca, Mn, Fe, Mg, H_2)_7B_2(Al, Fe)_4(SiO_4)_8$. G. Cesaro regarded axinite as a combination of diortho- and meta-silicates or else a basic triple metasilicate with B_2O replacing some silicon. W. T. Schaller concluded that axinite is really an isomorphous mixture of two components: *ferro-axinite*, $Al_2BHCa_2Fe(SiO_4)_7$, and *mangano-axinite*, $Al_2BHCa_2Mn(SiO_4)_4$. If the boron be basic and eq. to aluminium, these two axinites are to be regarded respectively as *calcium dialuminium ferrous boratotetrorthosilicate*, and *calcium dialuminium manganous boratotetrorthosilicate*; but if the boron be acidic, as it usually is, F. W. Clarke considers it to be a mixed ortho- and tri-silicate:

T. L. Walker and A. L. Parsons' analyses correspond with $13RO \cdot B_2O_3 \cdot 10SiO_2$, thus making axinite a *calcium ferrous manganese aluminium boratosilicate*:

Axinite occurs in cavities in granite and diabase—*e.g.* Striegau, Silesia, and Mt. Monzoni, Tyrol. It is probably formed as a contact mineral in the presence of calcium aluminosilicates. The mineral has not been synthesized. C. Doelter²² found that if melted and slowly cooled, crystals resembling *aegirine* are formed. It might possibly be obtained in a dry melt if the right *agent mineralisatorum* were present; and possibly also in a hydrothermal way.

Axinite occurs crystalline and massive in lamellæ or granules. The colour is

clove-brown, plum-blue, pearl-grey, honey-yellow, greenish-yellow, and peach-blossom-red. K. von Kraatz-Koschlaw and L. Wöhler²³ could not satisfy themselves that manganese is the cause of the colour. The euhedral crystals are usually broad and acute-edged, and rarely prismatic. The anhedral crystals are lamellar or granular. The crystals belong to the triclinic system; according to A. Schrauf, the axial ratios are $a:b:c=1.5542:1:0.86415$, and $\alpha=96^\circ 57'$, $\beta=98^\circ 52'$, and $\gamma=103^\circ 2'$; and, according to A. Schmidt, $a:b:c=1.14936:1:0.86501$, and $\alpha=96^\circ 57' 52''$, $\beta=98^\circ 53' 39''$, and $\gamma=102^\circ 51' 55''$. Observations were made by V. Goldschmidt, G. vom Rath, A. des Cloizeaux, O. Luedecke, M. Websky, F. C. Neumann, C. F. Naumann, F. A. Quenstedt, A. Lévy, K. H. Solby, B. W. Frazier, H. Buttgenbach, W. H. Miller, F. Hessenberg, J. D. Dana, W. T. Schaller, H. Sjögren, A. Offret, and F. Gonnard, E. T. Wherry, K. Zimanyi, G. Annoff, E. M. Poitevin, and A. Franck. The cleavages parallel to (010), (001), and (130) are distinct; the cleavage parallel to (111) less so; and the cleavages parallel to (110) and (021) are in traces. Some faces are often striated. A. des Cloizeaux found the optic axial angles somewhat variable even in sections of the same crystal. He found, for red-light, $2H=71^\circ 38'$ to $87^\circ 49'$; $2V=71^\circ 38'$ to $74^\circ 17'$; and $2E=153^\circ 46'$ to $158^\circ 13'$; while for blue-light, $2H=83^\circ 28'$ to $87^\circ 47'$; $2V=71^\circ 39'$; and $2E=159^\circ 49'$ to $172^\circ 10'$. A. Krejci gave $2V=c. 70^\circ$. The change with variations of temp. between 21° and 171° was found to be very slight; J. Beckenkamp also found only about half a minute variation in the axial angles between 20° and 200° .

The sp. gr. of axinite, according to C. F. Rammelsberg, is 3.294, and after fusion, 2.812; W. Haidinger gave 3.271; A. Krejci, 3.22; and E. Grill, 3.314. W. T. Schaller found the sp. gr. varied with the proportion of contained manganese—per cent. MnO—

MnO . .	1.06	2.99	9.59	10.71	13.41	13.69
Sp. gr. . .	3.268	3.287	3.299	3.302	3.306	3.358

Iron oxide probably also has a great influence. R. Cusack gave 995° for the m.p. of axinite, but added that the mineral probably changes before it fuses. A. L. Fletcher gave 1045° . C. Doelter found axinite is decomposed by fusion—*vide supra*. The indices of refraction are moderately high. A. des Cloizeaux found $\alpha=1.6720$, $\beta=1.16779$, and $\gamma=1.6810$ for red-light, and $\alpha=1.6850$, $\beta=1.6918$, and $\gamma=1.6954$ for blue-light. The birefringence is low, $\gamma-\alpha=0.0090$ for red light and 0.0104 for blue-light. A. Krejci gave $\alpha=1.678$; $\beta=1.685$; and $\gamma=1.688$. The pleochroism of the crystals is well marked; it was studied by D. Brewster, W. Haidinger, A. des Cloizeaux, O. Luedecke, H. Rosenbusch, and A. Bertin. The pyroelectricity of the crystals was studied by R. J. Haüy, A. Lévy, C. P. Brard, P. Riess and G. Rose, W. G. Hankel, and G. Friedel and A. de Gramont. Axinite also becomes electrified by friction. G. A. Kenngott found that the powdered and moistened mineral has a strong alkaline reaction; after calcination, the reaction is not so marked. Acids scarcely affect axinite; but after fusion, the mineral is decomposed by hydrochloric acid with the separation of gelatinous silicic acid.

E. L. Gruner²⁴ found asbestos-like or lamellar-fibres of brown mineral, which he called *pyroxene ferrugineux*, in the metamorphic schists of Collobrières, Dept. du Var. It was named by G. A. Kenngott, **grunerite**. Analyses of grunerite from this and other localities by E. L. Gruner, S. Kreutz, and A. C. Lane and F. Sharpless show that its composition corresponds with **ferrous metasilicate**, FeSiO_3 , plus a few impurities. C. F. Rammelsberg showed that chemically, and A. des Cloizeaux that optically, grunerite is related to amphibolic hornblende. E. V. Shannon obtained the iron end-member of the anthophyllitic series of mixed crystals, $(\text{Mg}, \text{Fe})\text{SiO}_3$. He called it **iron-anthophyllite**. It occurs impure in the Cœur d'Alene district, Idaho. The colour of the mineral is white or pale brown. The plane of twinning is (100). The cleavage resembles that of hornblende. A. Lacroix found the optic axial angle to be $2E=95^\circ$. The extinction angle, according to A. Michel-Lévy and A. Lacroix,

is 11° – 15° . E. L. Gruner gave 3.713 for the sp. gr. For the synthesis of the metasilicate, *vide supra*. H. le Chatelier gave for the heat of formation $\text{FeO} + \text{SiO}_2 = \text{FeSiO}_3 + 5 \text{ Cals.}$; and $\text{FeCO}_3 + \text{SiO}_2 = \text{CO}_2 + \text{FeSiO}_3 + 7.6 \text{ Cals.}$ S. Wologdine gave $(\text{FeO}, \text{SiO}_2) = 5.905 \text{ Cals.}$ The index of refraction and birefringence were stated by A. C. Lane and F. Sharpless to be high, for the mean index of refraction is 1.7, and $\gamma - \alpha$ exceeds 0.030; A. Lacroix gave $\gamma - \alpha = 0.056$. The rhombic crystals of iron-anthophyllite have a positive elongation, and the indices of refraction $\alpha = 1.668$, and $\gamma = 1.685$. Grunerite is pleochroic.

T. G. Bonney²⁵ found a mineral resembling hornblende occurring in groups of prismatic crystals in the granite and syenite of the Island of Socotra, Indian Ocean. It has been reported by A. Harker, T. G. Bonney, G. A. Koenig, etc., in other localities. A. Sauer named it *riebeckite*—after E. Riebeck. W. C. Smith found implements made of riebeckite among relics of ancient dwellers near Jebel Katul, Soudan. Analyses were made by A. Sauer, G. A. Koenig, E. Grill, J. Orsel, C. Palache and C. H. Warren, and H. Rosenbusch. The mineral was studied by B. Gossner, A. Vendl, S. Kreutz, M. G. Murgoci, and V. de Souza-Brandao. In the idealized form it is supposed to be sodium ferric dimetasilicate, $\text{NaFe}(\text{SiO}_3)_2$, mixed with ferrous metasilicate and possibly some microcline. It approximates $2\text{NaFe}(\text{SiO}_3)_2 \cdot \text{FeSiO}_3$. Riebeckite is the amphibole representative of the pyroxene acmite or regirite. Z. Weyberg fused a mixture of silicic acid, ferric hydroxide, sodium carbonate, and a large excess of sodium chloride, and obtained crystals of sodium ferric dimetasilicate, $\text{NaFe}(\text{SiO}_3)_2$. The black prismatic crystals of riebeckite belong to the monoclinic system. The prismatic cleavage (110) is perfect. The sp. gr. is 3.33–3.49, and the hardness 5½–6. C. Palache and C. H. Warren gave 1.693 for the index of refraction with Na-light; the birefringence is feeble $\alpha - \gamma = 0.0051$ for the blue ray and 0.003 for the red ray. The optical character is negative. The mineral is strongly pleochroic. F. W. Clarke and G. Steiger found that the mineral is decomposed when heated with ammonium chloride.

M. H. Klaproth²⁶ referred to a *Blau-eisenstein* from Griqualand, S. W. Africa, and J. F. L. Hausmann called it *crocidolite*—from *κρόκος*, woof—in allusion to its fibrous structure. E. T. Wherry and E. V. Shannon called the blue pleochroic amphiboles, *glaucoamphiboles*, and described a semi-magnesian crocidolite with the composition $\text{Na}_2\text{O} \cdot \text{MgO} \cdot \text{FeO} \cdot \text{Fe}_2\text{O}_3 \cdot 6\text{SiO}_2 \cdot \text{H}_2\text{O}$. M. F. Heddle called an earthy variety from the gneiss and granite of Abriachan, Scotland, *abriachanite*. Analyses were made by M. H. Klaproth, F. Stromeyer, C. Doelter, A. Renard and C. Klement, A. H. Chester and F. J. Cairns, and A. E. Delesse. It is regarded as a fibrous variety of riebeckite, and its composition averages $\text{NaFe}(\text{SiO}_3)_2 \cdot \text{FeSiO}_3$ —*vide glaucophane*. Crocidolite occurs in long asbestiform fibres. The optical properties correspond with the monoclinic system; the cleavage is prismatic; the sp. gr. 3.20–3.30; and the hardness 4. The optic axial angle $2E = 95^{\circ}$. A. Lacroix found the birefringence $\gamma - \alpha = 0.025$, and the optical character negative. G. Hepburn described a brownish-yellow alteration product which he called *griqualandite*; it was analyzed by A. Renard and C. Klement, C. F. Rammelsberg, and F. Wibel and F. Neelsen. By the infiltration of siliceous matters, the South African mineral forms a yellowish-brown compact rock with a fibrous structure, and a chatoyant lustre, and is popularly known as *tiger's eye*, or *cat's-eye*. H. von Foullon, and A. Bukowsky described an asbestiform variety of glaucophane in which the aluminium has been partly replaced by ferric iron; and it is sometimes classed with abriachanite. It was found in Rhodes Island, and called *rhodosite*. It was analyzed by H. von Foullon, P. Tschirwinsky, W. Isküll, B. Dohr and C. Hlawatsch, M. F. Heddle, and W. Jolly, and M. Cameron. W. Isküll studied the action of hydrochloric acid on the mineral. W. F. Smeeth, and L. J. Spencer described a soda-ferric-amphibole approximating $2\text{NaFe}''(\text{SiO}_3)_2 \cdot \text{Mg}_2\text{Fe}''(\text{SiO}_3)_2$ from the Bababudan Hills, Mysore, and hence called *bababudanite*. C. Palache, and G. D. Louderback described a blue mineral occurring in lath-shaped crystals in Berkeley, California. It was called *crossite*—after W. Cross. The mineral is intermediate in composition between riebeckite and glaucophane. The sp. gr. is 3.16. It was strongly pleochroic. B. Gossner studied the chemical composition of this and related minerals.

H. Ström²⁷ mentioned the occurrence of a crystalline hornblende or schörl at Eker, Norway; and P. Ström regarded it as a definite mineral species which he named *wernerine*—after A. G. Werner. J. J. Berzelius called it *acmite*—from *ἀκμή*, a point—in allusion to the pointed extremities of the crystals. A mineral found by

J. Esmark in the Langesund fjord, Norway, was named by J. J. Berzelius ægirine, and later called ægirite—after Ægir, the Icelandic god of the sea. The crystals of acmite were shown by N. B. Möller, and W. Haidinger to belong to the augite group; and the crystals of ægirite were examined by P. Planchamp, L. J. Wallmark, and shown by T. Scheerer, A. Breithaupt, G. A. Keyngott, and M. von Hornberg to belong to the augite family, and G. Rose suggested that the two minerals belong to one species. C. F. Rammelsberg showed that acmite and ægirine have nearly the same composition. J. D. Dana, and A. des Cloizeaux regarded them as independent species, but G. Tschermak, and C. Doelter showed that the essential characters of ægirite and acmite are identical, but, as W. C. Brögger emphasized, each possesses certain peculiarities which makes it desirable to retain the names representing them as varieties of one species.

Analyses were made by P. Ström, J. J. Berzelius, A. Breithaupt, C. F. Rammelsberg, C. Doelter, F. Pisan, J. Morozewicz, F. Gutzkow, W. Ramsay, J. Machado, C. H. Smith, S. Hillebrand, A. Osann, F. W. Clarke, C. Palache and C. H. Warren. B. J. Harrington, W. A. Silbermüntz, Z. Weyberg, R. Doht and C. Hlawatsch, H. Rosenbusch, and J. Lorenzen. A. Holmes found a specimen with 0.0253 per cent. of uranium, and 0.015 per cent. of lead; and E. S. Larsen and W. F. Hunt found at Rainy Creek, Montana, a vanadiferous ægirite with up to 3.98 per cent. V_2O_5 . Attempts to represent the composition by formulæ show that idealized acmite contains sodium ferric dimetasilicate, $NaFe^{III}(SiO_3)_2$, in isomorphous association with ferrous and calcium metasilicates. It is the pyroxene equivalent of the amphibole riebeckite. Various mixture formulæ have been proposed by C. F. Rammelsberg, C. Doelter, J. Lorenzen, J. Machado, J. Morozewicz, S. Hillebrand, and C. Palache and C. H. Warren. Acmite is a mineral of eruptive rocks and is generally accompanied by leucite or nephelite; it is common in elaeolithic syenite. M. Vucnik found that when the constituent oxides are fused together, a glass containing crystals of magnetite is formed; and when acmite is fused, it also solidifies into a mixture of magnetite and glass. C. Doelter, however, observed that some acmite is formed by fusing and cooling a mixture of the constituent oxides. H. Bäckström kept a mixture of silica, ferric oxide, and sodium carbonate for 3 days at a dull red-heat, and obtained crystals of acmite; and he also obtained acmite by fusing a leucitic phonolite and very slowly cooling the glass. Z. Weyberg also obtained acmite by fusing a mixture of silica, ferric oxide, and soda with a large excess of sodium chloride. Z. Weyberg also obtained a *chromic-acmite*, or *sodium chromic dimetasilicate*, $NaCr(SiO_3)_2$, by substituting chromic oxide for ferric oxide. J. Morozewicz also observed the formation of acmite in metasilicate magmas containing less than 50 per cent. of silica. P. Niggli obtained a *potash-acmite*, *potassium ferric dimetasilicate*, $KFe(SiO_3)_2$, by the hydrothermal process at 450° .

The long prismatic crystals of acmite are coloured brown, or reddish-brown; ægirite also occurs in long prismatic crystals arranged in tufts or groups, and in fibrous forms usually dark green. V. S. Deleano and E. Dittler found the crystallizing power is not marked but the speed of crystallization is considerable. The monoclinic crystals of acmite and ægirite were found by W. C. Brögger to have nearly the same axial ratios $a:b:c=1.09957:1:0.60120$, and $\beta=73^\circ 10'$. The twinning of ægirite is not common; but acmite is commonly twinned on the (100)-plane. Polysynthetic twinning enclosing twinning lamellæ is also common. The crystals are often vertically striated or channelled; and the prisms may be bent, twisted, or broken. Inclined hemihedrism as with pyroxene is also found. The cleavage parallel to (110) is distinct, that parallel to (010) is less so. The crystals of acmite often show a zonal structure, being green within and brown outside—the green ægirite is strongly pleochroic, while the brown acmite is but feebly pleochroic. The optic axial angles are large. W. C. Brögger gave for ægirite with Na-light, $2E=134^\circ 27'$; $2H_a=63^\circ 41'$; $2H_b=117^\circ 18'$; and $2V_a=63^\circ 28'$; W. Ramsay gave $2V=63.13^\circ-66^\circ$. F. Zambonini attributed the isomorphism of diopside and

acmite to the near equality of the at. vol. and sum of the valencies of the groups CaMg and NaFe''' . R. W. G. Wyckoff studied the X-radiograms of acmite. The sp. gr. varies from 3.5–3.6, and the hardness from 6–6½. A. Brun gave for the m.p. of acmite, 970°; C. Doelter, 965°; and V. Schumoff-Deleano and E. Dittler, 960°–1030°. H. Leitmeier gave for ægirite, 940°–950°; and M. Vucnik, 970°–1010°. E. A. Wülfing found the indices of refraction to NaBe $\alpha=1.7630$, $\beta=1.7990$, and $\gamma=1.8126$ for Na-light; W. Ramsay gave $\alpha=1.777$, $\beta=1.801$; and W. F. Hunt, for vanadiferous ægirite, $\alpha=1.745$, $\beta=1.770$, and $\gamma=1.782$. H. A. Wülfing gave for the birefringence $\gamma-\alpha=0.0496$; $\gamma-\beta=0.0136$; and $\beta-\alpha=0.036$. The optical character is negative. Acmite is but slightly affected by acids. W. C. Brögger found acmite altered to analcite, and J. F. Williams, to manganeseous pectolite. F. W. Clarke and G. Steiger found no marked change when ægirite is heated in the vap. of ammonium chloride in a sealed tube.

H. Sjögren²⁸ found a mineral at Langban, Sweden, which had been confused with schafferite, and which he called *urbanite*—after Urban Hjärne; the mineral was also investigated by L. J. Igelström, who called it *indesite*. The two minerals are very much alike except that the latter has rather more manganese oxide—the highest reported for indesite is 10.97 per cent. MnO, and for urbanite, 6.71 per cent. Analyses show that it is probably a mixture of acmite and diopside. The colour is chestnut-brown to brownish-black. The monoclinic crystals belong to the pyroxene family, and have the axial ratios $a:b:c=1.1009:1:0.6058$, and $\beta=72^\circ 7'$. The habit is pyramidal; the cleavage parallel to (110) is distinct. The sp. gr. is 3.52–3.53, and the hardness 5–6. It is strongly pleochroic. It is only slightly attacked by acids. The so-called *ægirine-augites* seem to be intermediate in composition between the augites and ægirite.²⁹

In nature, wollastonite is often tinted presumably with ferrous metasilicate. The mineral *hedenbergite* was named by J. J. Berzelius³⁰ after L. Hedenberg, and was classed by R. J. Haüy among the amphiboles. C. C. von Leonhard regarded it as a ferruginous variety of augite. C. F. Rammelsberg found hedenbergite in slags. Hedenbergite appears to be one end-member of a series of solid soln. of calcium and ferrous metasilicates. The composition in the ideal case approximates **calcium ferrous metasilicate**, $\text{CaFe}(\text{SiO}_3)_2$; and there are many intermediate members of the series with the general formula $\text{Ca}(\text{Fe,Mg})(\text{SiO}_3)_2$, between it and diopside, $\text{CaMg}(\text{SiO}_3)_2$ (*q.v.*). A. Brun gave 1190° for the m.p. of hedenbergite; C. Doelter obtained numbers ranging from 1095°–1135°; and V. Pöschl, 1100°–1140°. Calcium ferrous dimetasilicate is monoclinic; sp. gr. 3.5–3.6; and hardness 5–6. In nature, the mineral is contaminated with a variable proportion of diopside, and other silicates. V. S. Deleano and E. Dittler studied the rate of crystallization of hedenbergite. G. Tamman investigated the action of ferrous aluminate, iron, manganese, and nickel, and also iron sulphide on the fused calcium ferrous dimetasilicate. C. Doelter, H. Wulf, H. Rosenbusch, E. Manasse, T. Wada, D. Lovisato, V. Pöschl, G. vom Rath, K. Busz, H. Sjögren, E. A. Wülfing, and A. H. Phillips discussed complexes which are regarded as solid soln. of hedenbergite and diopside. V. Pöschl measured the sp. gr., the m.p., and the angle of extinction of mixtures of diopside, $\text{CaMg}(\text{SiO}_3)_2$, and hedenbergite, and found:

Diopside	0	30	40	50	60	70	80	90	100 per cent.
Sp. gr.	3.53	3.26	3.16	3.01	2.98	2.96	2.90	2.87	3.03
M.p.	1100°	1175°	1185°	1210°	1215°	1236°	1235°	1245°	1300°
	1140°	1200°	1210°	1225°	1230°	1240°	1250°	1265°	1325°
Extinction	50° 30'	50°	49° 20'	47°	45° 20'	43° 40'	31°	36°	32°

A. Breithaupt called hedenbergite *bolopherit*—from *βόλος*, earth; *φορέω*, to carry; and L. J. Igelström called a variety with a stellate radiated structure, *asteroite*. M. Weibull obtained a variety rich in manganese, *manganohedenbergite*, from Vester-Silberg, Sweden. E. F. Glocker, and B. Sewerin applied the term *lotallite* to a variety of hedenbergite from Lotalla, Finland. The *violan* of A. Breithaupt is a dark violet-blue variety of hedenbergite which occurs in prismatic crystals at St. Marcel, Piedmont. It was analyzed by A. des Cloizeaux, L. Grünhut, and E. Schluttig. L. J. Igelström's *anthachroite*—from *ἀνθος*, flower; and *χρῶμα*, colour—is a rose-red or violet variety of violan. The manganeseous hedenbergites have been examined by L. L. Fermor, A. K. Coomaraswamy, T. Wada, and

L. J. Igelström. A. N. Winchell reported a *titanohedenbergite* from Pigeon Point, Minnesota, which he called *pyeonite*.

J. Palmgren²¹ found *ferroanthophyllite*, $3\text{FeSiO}_3 + \text{RSiO}_3$, in an eulysite rock from Södermanland, and E. V. Shanon found it in the Cœur d'Alene district of Idaho with the composition $(\text{Fe}, \text{Ca}, \text{H}_2, \text{Mn})\text{SiO}_3$. He regards ferroanthophyllite as the end-member of the anthophyllite series, and the magnesian end-member is called *magnesioanthophyllite*. The pyroxenic mineral *sobralite*, found by J. Palmgren, associated with ferroanthophyllite, has the composition $4\text{MnSiO}_3 \cdot 2\text{FeSiO}_3 \cdot \text{CaSiO}_3 \cdot \text{MgSiO}_3$. It is triclinic, with three cleavages. J. M. Sobral found sobralite with the optical axial angle $2V=41^\circ$; the birefringence $\beta-\alpha=0.0025$; $\gamma-\beta=0.0175$; and $\gamma-\alpha=0.0200$; and the optical character negative.

A zinciferous variety, found by W. H. Keating and L. Vanuxem,²² has been called *jeffersonite*. It is supposed to be a complex of $\text{CaMg}(\text{SiO}_3)_2$, $\text{CaFe}(\text{SiO}_3)_2$, $\text{CaMn}(\text{SiO}_3)_2$, and $\text{CaZn}(\text{SiO}_3)_2$, or a mixture of the individual metasilicates. Analyses have been reported by R. Hermann, F. Pisani, F. A. Genth, W. A. Waldschmidt, G. J. Brush, W. F. Hillebrand, and F. W. Clarke and E. A. Schneider. C. Doelter synthesized it by crystallization from a mixture of the reaction constituents. Its indices of refraction are $\alpha=1.668$, $\gamma=1.703$; and its birefringence, 0.030. A. des Cloizeaux measured the crystal constants. The sp. gr. is 3.63. V. Pöschl gave 3.53 for the sp. gr. of a sample with 25 per cent. of ferrous oxide; 1140° for the m.p., and $56^\circ 30'$ for the optic axial angle. R. Hermann, and G. A. Koenig likened it to augite; A. Breithaupt regarded it as a pyroxene.

A. Breithaupt²³ applied the term *richterite*—after T. Richter—to a yellow amphibole from Langban, Sweden, with a sp. gr. 2.826; L. J. Igelström, and G. Flink used the same term for a similar mineral, though possibly not the same, from Pajsberg, Sweden, which, according to G. A. Michaelson, had a sp. gr. 3.09. The colour is brown, yellow, or rose-red. Analyses were made by S. Kreutz, N. Engström, G. A. Michaelson, L. J. Igelström, and R. Mauzelius. The crystals were examined by G. Flink, who found the monoclinic crystals had the axial ratios $a:b:c=0.5499:1:0.2854$, and $\beta=75^\circ 46'$. It is considered to be a mixed *sodium magnesian manganese metasilicate*, or better, $(\text{Mn}, \text{Fe}, \text{Mg}, \text{Ca}, \text{Na}, \text{K})\text{SiO}_3$. G. T. Prior, P. Termier, G. M. Murgoci, and A. F. Rogers have discussed riebeckite in rocks. H. Sjögren described a coarsely crystalline columnar aggregate associated with rhodonite at Langban, and known locally as *blue rhodonite*. H. Sjögren called it *astochite*—from *astochos*, missing the mark—in allusion to the fact that it was at first regarded as a pyroxene. R. Mauzelius' analysis shows that it is not far from richterite in composition, $(\text{Mn}, \text{Fe}, \text{Mg}, \text{Ca}, \text{Na}, \text{K}, \text{H}_2)\text{SiO}_3$. The colour, said A. Hamberg, is not sufficient to distinguish it as a separate species from richterite; and H. Sjögren called it *soda-richterite*. The crystals are monoclinic; the cleavage angle is $56^\circ 27'$; the colour varies from blue to greyish-violet; and the extinction angle is $15^\circ 40' - 17^\circ 15'$. The optical character is negative. N. O. Holst described a yellow mineral occurring in fine crystalline needles at Langban, Sweden. It was named *marmatrolite*—from *marmalade*, to glisten. Its sp. gr. is 3.07; and its hardness, 5. The composition approximates to that of richterite, and E. J. Wilk suggested that marmatrolite is a massive form of that mineral. G. Brocchi²⁴ found a mineral occurring at Vesuvius and at Capo di Bove in wool-like forms, coloured dark brown. It was named *breislakite*—after S. Breislak. The greenish-grey or greyish-white hair-like crystals in the lava of Cyclops Mt. were named *cyclopent* by A. des Cloizeaux. This is not to be confounded with the lime-felspar *cyclopent* of W. S. von Waltershausen. C. F. Rammelsberg emphasized the resemblance of breislakite to hornblende; but E. J. Chapman regarded it as a variety of pyroxene. A. von Lasaulx, however, showed that its optical properties and form are like those of the amphiboles. The pleochroism is well-marked. It is considered to be a variety of richterite.

H. J. Brooke²⁵ described a mineral from Greenland which he named *arfvedsonite*, or *arfvedsonite*—after J. A. Arfvedson. According to W. Haidinger, it is a ferruginous variety of hornblende. The older analyses of T. Thomson, and J. A. Arfvedson were shown by A. Breithaupt to refer probably to aegirite (*q.v.*). The analyses quoted by C. F. Rammelsberg is also that of aegirite; and A. Lacroix showed that G. A. Koenig's analysis is probably that of riebeckite. Analyses were made by J. Lorenzen, F. Berwerth, S. Bertolli, B. Gossner, and K. Rørdam. The results show that the mineral is a *soda-hornblende*, and is a complex mixture. The main constituent may be ferrous metasilicate which is associated with sodium and calcium metasilicates, and possibly also $\text{NaFe}(\text{SiO}_3)_2$. J. Söller regards it as a complex of meta-, ortho-, and tri-silicates. The mineral occurs in black prisms or dark green plates, which, according to W. C. Brögger, belong to the monoclinic system, and have the axial ratios $a:b:c=0.55887:1:0.29781$, and $\beta=73^\circ 24'$. The twinning plane is (100); the prismatic cleavage (10) is perfect, that parallel to (010) is imperfect. The pleochroism is strongly defined. The optical character is probably positive. The sp. gr. is 3.4–3.5; and the hardness 6. The mineral is not readily attacked by acids. W. C. Brögger described an amphibole mineral, closely related to arfvedsonite, occurring near Turkevik, Norway, and hence called *barkevikite*. The prismatic crystals are deep velvet-black, and have a perfect prismatic cleavage. Analyses were made by P. Plantamour, C. F. Rammelsberg, and G. Flink. The composition is intermediate between that of hornblende and that of arfvedsonite, and it was studied by B. Gossner. The mineral is strongly pleochroic. The sp. gr. is 3.42. C. Hlawatsch described an

amphibolic mineral from Cevadaes which he named *osannite*—after A. Osann. Its composition is intermediate between that of arfvedsonite and that of riebeckite, and it was studied by B. Gossner. The sp. gr. is 3.4; hardness, 5-6; and birefringence, $\gamma - \alpha = 0.005$. A. Lacroix described a rhombic, bluish-green mineral which he called *grandidierite* and obtained from Andrahomana, South Madagascar. The composition approximated $2(\text{Na}, \text{K}, \text{H}), 0.7(\text{Mg}, \text{Fe}, \text{Ca}), 0.11(\text{Al}, \text{Fe}), \text{O}_3, 7\text{SiO}_2$, or, according to A. Lacroix and A. de Gramont, $2\text{Na}, 0.4\text{FeO}, 0.8(\text{Al}, \text{Fe}, \text{D}), \text{O}_3, 5\text{SiO}_2$. Its sp. gr. is 2.99; its birefringence is negative; and its indices of refraction $\alpha = 1.6018$, $\beta = 1.6360$, and $\gamma = 1.6385$ for Na-light. The mineral was also described by C. Hlawatsch.

A number of **magnesium ferrous metasilicates**, or magnesium ferrous manganous metasilicates, has been reported. They are probably solid soln. For example, the mineral **cunningtonite** is a magnesian amphibole which, according to A. des Cloizeaux,³⁶ is monoclinic. It was found by C. Dewey at Cummington, Mass., as a grey to brown fibrous or fibrolamellar mass. It contains about 10-30 per cent. MgO, 32-60 per cent. FeO, and 50-91 per cent. of silica with a little manganese oxide, alumina, and calcium oxide, so that its formula becomes $(\text{Fe}, \text{Mg})\text{SiO}_3$. The mean refractive index is 1.638; the cleavage angle, $51^\circ 48'$.

The term *antholite* was applied by J. D. Dana, and by G. A. Kenngott to certain asbestiform amphiboles. A kind of manganiferous cunningtonite was found by A. Erdmann at Dannemora, Sweden, and hence called *dannemorite*. It was described by J. D. Dana, and G. A. Kenngott, and represented by the formula $(\text{Fe}, \text{Mn}, \text{Mg})\text{SiO}_3$. A variety from Brunsjö which contained much iron and possessed an asbestos-like texture was called by L. J. Igelström *asbeferrite*. Analyses were also made by F. J. Wilk and A. Erdmann. Meibull called a similar mineral from Vester-Silfberget in Delarue, *silfberite*; and L. J. Igelström, one from Hillängs in Delarue, *hillängite*.

W. E. Ford and W. M. Bradley³⁷ described a mineral from Iva, South Carolina, which they called *pyroxmangite*. The analyses approximate to $(\text{Mn}, \text{Fe})\text{SiO}_3$, **ferrous manganese metasilicate**, with some calcium and aluminium silicate as impurity. The colour ranges from amber to yellowish-brown, reddish-brown, and dark brown. It is regarded as a manganese pyroxene—hence the name. The crystals are triclinic. There are cleavages parallel to the two prism faces, and one is more distinct than the other. The angle between the cleavages is $91^\circ 50'$. There is a parting plane (010). The optic axial angle $2V = 30^\circ$. The sp. gr. is 3.80, and the hardness $5\frac{1}{2}$ -6. The mean index of refraction is 1.755; and the optical character is positive. The mineral is insoluble in acids.

A. Lévy³⁸ described crystals of a mineral from Arendal, Norway, which he called **babingtonite**—after B. G. Babington. Analyses were reported by C. Palache and F. R. Fraprie, B. K. Emerson, S. Hillebrand, M. Watanabe, A. E. Arppe, T. Thomson, F. Zambonini, C. F. Rammelsberg, G. Forbes, M. F. Heddle, C. Jahn, B. Gossner, and H. Klemm. The results correspond with a mixture of **calcium manganous ferrous metasilicates**, $(\text{Ca}, \text{Mn}, \text{Fe})\text{SiO}_3$, mixed with some ferric metasilicate, $\text{Fe}_2(\text{SiO}_3)_3$. The discussion—by C. F. Rammelsberg, C. Doelter, H. S. Washington and H. E. Merwin, E. Jannetaz, G. Tschermak, C. Palache and F. R. Fraprie, P. Groth, A. Knop, F. Zambonini, and S. Hillebrand—on the nature of babingtonite has turned mainly on the components which make up the mineral. Babingtonite has not been made artificially; although M. Schläpfer and P. Niggli obtained crystals which they assumed to be babingtonite by heating in an autoclave water mixed with lime, alumina, silica, and metal chlorides. The occurrence of babingtonite in converter slags has been reported by R. Groth and H. Scheerer, G. vom Rath, L. Buchrucker, and J. H. L. Vogt.

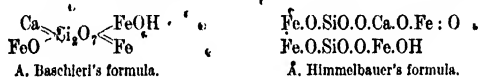

The crystals of babingtonite are small, and as emphasized by W. Haidinger, they resemble black augite or hornblende; and their colour is dark greenish-black. H. Dauber found that the triclinic crystals have the axial ratios $a:b:c = 1.06906:1:0.6384$, and $\alpha = 104^\circ 21\frac{1}{2}'$, $\beta = 108^\circ 30\frac{3}{4}'$, and $\gamma = 83^\circ 34\frac{1}{2}'$. Observations on the crystals were made by A. Lévy, A. des Cloizeaux, W. H. Miller, H. S. Washington and H. E. Merwin, G. vom Rath, E. S. Larsen, M. Watanabe, P. Groth and H. Scheerer, J. H. L. Vogt, and H. Klemm. The cleavage ($\bar{1}10$) is

perfect, (110) is less distinct. M. Watanabe gave for the indices of refraction $\alpha=1.715$, $\beta=1.725$, and $\gamma=1.740$; the crystals are biaxial and positive. A. Michel-Lévy and A. Lacroix gave for the optic axial angle $2V=60^\circ-65^\circ$; and the birefringence $\gamma-\alpha=0.032$. X-radiograms of babingtonite were reported by R. W. G. Wyckoff. The sp. gr. is 3.35-3.37, and the hardness 5.5-6.0. The crystals are pleochroic. S. Hillbrand studied the nature of the silicic acid which separates when babingtonite is decomposed by hydrochloric acid. O. B. Böggild studied the relationship of babingtonite to schizolite; and, according to H. S. Washington and H. E. Merwin, babingtonite, rhodofite, pyroxmangite, and sobralite form a group of triclinic minerals sufficiently different from the pyroxenes to be regarded as a group by themselves. J. Palmgren described a triclinic pyroxene from Söndermanland, Sweden, with the approximate composition $(\text{Mn}, \text{Fe}, \text{Ca}, \text{Mg})\text{SiO}_3$. The sp. gr. is 3.50.

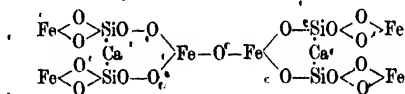

F. Katzer³⁹ found a reddish-brown amorphous ferruginous manganese silicate in the iron deposits of Vares, Bosnia, and he called it *pöchite*—after F. Pöch. The composition approximates $\text{H}_2\text{FeMnSi}_2\text{O}_8$. The sp. gr. is 3.695, and the hardness 3½-4. G. Flink⁴⁰ described a brown pleochroic mineral from Langban, Sweden, as *ektropite*. The composition approximated $12(\text{Mg}, \text{Ca}, \text{Mn}, \text{Fe})\text{O} \cdot 8\text{SiO}_2 \cdot 7\text{H}_2\text{O}$. The monoclinic crystals had the axial ratios $a:b:c=0.74:1:0.84$, and $\beta=61^\circ 5'$. The sp. gr. was 2.46, the hardness 4, and the indices of refraction $\alpha=1.62$, $\gamma=1.63$.

In 1806, C. H. de Fièvre⁴¹ obtained from the Rio la Marina, and Cape Calamita, Elba, large crystals of a mineral which was called *yenite* or *jenite* in commemoration of the battle of Jena, 1806; J. F. d'Aubuisson called it *lepor*—from *lepus*, un lièvre (a hare); H. Steffens, *ilvaite*—from the Latin name for Elba; and A. G. Werner, *lievrite*, after its discoverer. The German text-books generally employ lievrite, the American text-books, following A. des Cloizeaux, ilvaite. The black mineral found by F. von Kobell near Szurrasko, Hungary, and named *wehrlite*—after A. Wehrll—was considered by C. A. Zipser to be lievrite. It is massive and granular. Both H. Fischer, and V. von Zepharovich showed that wehrlite is a mixture of several minerals.

Analyses of ilvaite were made by L. N. Vauquelin, H. V. Collet-Descotils, F. Stromeyer, F. von Kobell, and many others.⁴² C. F. Rammelsberg⁴³ tried to work out a formula for ilvaite from the analysis and obtained $\text{R}''_{12}\text{Fe}'''_4\text{Si}_6\text{O}_{36}$. G. Städeler showed that water is probably an essential constituent; this was confirmed by L. Sipőcz, and C. F. Rammelsberg then gave $\text{H}_2\text{R}''_6\text{Fe}_2\text{Si}_4\text{O}_{18}$. P. Groth gave $(\text{FeOH})\text{Fe}_3\text{Ca}(\text{SiO}_4)_2$. A. Baschieri regarded the mineral as a salt of diorthosilicic acid, $\text{H}_6\text{Si}_2\text{O}_7$, which he isolated by the hydrochloric acid process; and he gave the accompanying formula. A. Himmelbauer by a similar method obtained metasilicic acid, and he represented the mineral by the accompanying formula.

J. E. Reynolds represented his analysis, $6\text{RO.Fe}_2\text{O}_3.4\text{SiO}_2$, by the formula :

F. Zambonini explained the difference in the results by assuming different experimental conditions; and C. Doelter, by assuming a difference in the state of hydration of the mineral owing to the difference in the climates where the samples were obtained; and G. Tschermak assumed that ilvaite, like olivine, contains two different silicic acids, since with conc. hydrochloric acid, metasilicic acid is formed, and with dil. hydrochloric acid, orthosilicic acid is produced. A. Himmelbauer

also suggested that the mineral might be an addition compound of magnetite, $\text{FeO} \cdot \text{Fe}_2\text{O}_3$, and a calcium ferrous silicate. F. W. Clarke used a formula of the same type as those employed for bertrandite, and talamine:

corresponding with **calcium diferrous aluminohydroxydiorthosilicate**. B. Bavink studied the magnetic properties of leivrite. W. Vernadsky studied the constitution and chemical relations of ilvaite. The mineral has not been synthesized. Ilvaite has been found in iron mines; it appears to have been formed by contact action,⁴⁴ say, by the action of silicates on iron oxide—e.g. magnetite—which like ilvaite contains both ferrous and ferric oxides. It has also been found in dolomite, limestone, granite, syenite, and porphyry.

Ilvaite commonly occurs in prisms with the prismatic faces striated; anhedral crystals occur in prismatic or irregularly shaped aggregates; and it also occurs in compact or columnar masses.* The colour is dark greyish-black. The crystals belong to the rhombic system, and A. des Cloizeaux⁴⁵ gives for the axial ratios $a:b:c=0.6650:1:0.44268$; J. Lorenzen gave $0.674367:1:0.448449$; and G. Flink $0.66195:1:0.43897$. The crystals have been studied by J. J. Hatiy, W. H. Miller, F. Hessenberg, G. vom Rath, A. Weisbach, G. Flink, and J. Lorenzen. The cleavages parallel to (010) and to (001) are rather distinct; those parallel to (100), (110), and to (101) are imperfect or indistinct. O. B. Böggild studied the corrosion figures and optical characters of ilvaite. J. Lorenzen found for the optic axial angle $2E$ approximately 60° . The sp. gr. ranges from 3.9-4.1, and the hardness 5-6. The index of refraction is high; E. A. Wülfing gave 1.89. The mineral is strongly pleochroic. It is decomposed by hydrochloric acid with the separation of gelatinous silica. C. Simmonds found that ilvaite is partially reduced by hydrogen at a red heat. F. W. Clarke and G. Steiger studied the action of ammonium chloride vap.

P. Hautefeuille⁴⁰ heated a mixture of silica, ferric oxide, and potassium vanadate to about 960°, and after washing away the soluble salts obtained small greenish-yellow, transparent crystals, the composition is analogous to that of leucite—*ferrie-leucite*, $\text{KFe}(\text{SiO}_3)_2$, or **potassium ferric dimetasilicate**. The icositetrahedral crystals exhibit anomalies like those of ordinary leucite. The formation of crystals of ferric-leucite requires a somewhat higher temp. than that of ordinary feldspar. When a mixture of alumina, ferric oxide, silica, and potassium vanadate is heated, it may happen that only feldspar is produced and no leucite, if the temp. be so regulated that the potassium vanadate does not attack the ferric oxide.

The term **glauconite**—from γλαυκός—bluish-green—was applied by G. Keferstein⁴⁷ to the green grains of earth in the green-sand of the chalk formation, and in other rocks. The grains are often casts of the shells of rhizopods; and they have been found in fragments of coral. G. Jenzsch applied the term **chlorophanerite** to a similar earth found in cavities in eruptive rocks. According to J. Murray and A. F. Renard, glauconite is widely disseminated upon the sea-bottom, but most abundantly in comparatively shallow waters, near the mud-line, i.e. just beyond the limits of wave and current action where the fine muddy particles commence to make up a considerable portion of the deposits. Analyses have been reported by G. H. Cook, W. B. Clark, A. J. Hoskins, L. W. Collet and G. W. Lee, W. A. Caspari, A. Lacroix, H. Wurtz, K. von Haushofer, P. Berthier, T. S. Hunt, J. Murray and A. F. Renard, M. B. Corse and C. Baskerville, A. Johnson, J. Morozewicz, L. Cayeux, G. R. Mansfield, N. Sahlbom, A. F. Hallimond, J. W. Mallet, P. N. Chirvinsky, W. van der Marck, D. H. von Dechen, W. Fischer, H. D. Rogers, E. Hitchcock, A. E. Delesse, W. S. von Waltershausen, S. Haughton, C. F. Rammelsberg, A. T. Kupffer, F. Dewalque, E. vom Bamberger, M. F. Heddele, C. W. von

Gümbel, E. Knorr and F. Schönfeld, A. des Cloizeaux, P. Schemjatschensky, W. Smirnow, G. Steiger, N. Ermola, etc. The composition is exceedingly variable, for glauconite is invariably contaminated with extraneous matters and alteration products. The iron is mainly in the ferric state, and potassium is always present; some aluminium may partly replace iron, and other bases partly replace potassium. The material used by K. Glinka for analysis was freed from impurities by heavy soln., and the analyses correspond with hydrated potassium ferric dimetasilicate, $KFe(SiO_3)_2 \cdot H_2O$. A. F. Hallimond regarded the glauconite from Lewes, Sussex, as $R_2O \cdot 4(R_2O_3 \cdot RO) \cdot 10SiO_2 \cdot nH_2O$, in which Fe_2O_3 and Al_2O_3 , and MgO and FeO , are mutually replaceable. Where potash is more or less replaced by soda, A. F. Hallimond applied the term *soda-glauconite*. F. W. Clarke said that the water is probably zoolithic, and not constitutional. According to P. Groth, glauconite may be a chlorite or a serpentine. J. Murray and A. F. Renard thus explain the origin of the glauconite now forming on the sea-bottom.

The shell is first filled with fine silt or mud upon which the organic matter of the dead animal can act. Through intervention of the sulphates contained in the sea water, the iron of the mud is converted into sulphide, which oxidizes later to ferric hydroxide. At the same time, alumina is removed from the sediments by soln. and colloidal silica is liberated. The latter reacts upon the ferric hydroxide in presence of potassium salts extracted from adjacent minerals, and so glauconite is produced. This view is sustained by other evidence, namely, the constant association of the glauconite shells with the débris of rocks in which potassium-bearing minerals, such as orthoclase and muscovite, occur.

L. Cayeux has shown that in sedimentary rocks, the glauconite has been formed subsequent to its consolidation. K. Glinka regards it as a product of the weathering of ferruginous augites and hornblendes. K. Andrée, K. C. Berz, and K. Hummel have discussed this subject. The subject has been discussed by C. W. von Gümbel, D. S. Calderon and co-workers, L. W. Collet, L. F. de Pourtales, and F. W. Clarke. W. A. Caspari described the synthesis of a compound resembling glauconite by the action of mixed soln. of potassium ferric tartrate and potassium silicate at 180° . L. W. Collet and G. W. Lee said that it is formed by the action of alkali silicates on iron sulphide or sulphate.

Glauconite is earthy or granular and massive. It sometimes resembles chlorite very closely, and it may be blackish-green, olive-green, yellowish-green, or greyish-green in colour. L. Cayeux said that the grains are biaxial and doubly refracting with the optic axial angle $2E = 30^\circ - 40^\circ$ —but sometimes nearly zero. The sp. gr. ranges from 2.2–2.6, and the hardness 2–3. D. D. Jackson and J. J. Morgan found that the vap. press. of the alkali is negligibly small below 1350° . When heated, M. W. Travers found that hydrogen and carbon monoxide are given off: $2FeO + H_2O = Fe_2O_3 + H_2$; and $2FeO + CO_2 = Fe_2O_3 + CO$. C. Simmonds showed that it is completely reduced when heated to redness in a current of hydrogen. K. Glinka found a boiling soln. of potassium carbonate dissolves alumina, lime, and ferric oxide, while alkali is taken up. Dil. hydrochloric acid attacks it slowly while the conc. acid soon decomposes it completely. K. Glinka described the passage, by weathering, of glauconite into ferruginous clay; and G. Klemm, the alteration of glauconite into ferrite.

The so-called *green-earth*, or *Grunderde* is related to glauconite; it appears to be the *creta viridis* of Pliny;⁴⁸ and it was used as a pigment for painting in the mediæval times under the name *terra di Verona*. J. B. L. Romé de l'Isle, A. Estner, and C. A. S. Hofmann, speak of *la terre verte de Verone* found in cavities in the amygdaloid at Monte Baldo, Verona. The green earth also occurs in other localities, and E. F. Glocker called a variety *seladonite*, or, in French, *celadonite* in allusion to the sea-green colour—from *κελάδων*, burning; and hence the use of the term for a verdant liver. Several analyses have been reported; they average $(Fe, K_2, H_2, Mg)_3(Al, Fe)_2(SiO_3)_6 \cdot 1.24H_2O$. It is probably an impure glauconite. The sp. gr. is 2.570–2.595—A. Lacroix gave 2.907, and G. Levy, 2.78. A. Lacroix said that the mineral is pleochroic.

F. Kretschmer⁴⁹ described a green earth from Sternberg, Moravia, which he called *viridite*; its composition approximated $4\text{FeO} \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$. He also described a mineral *macksinite* from the same locality whose composition approximated $\text{Fe}_2\text{O}_3 \cdot \text{SiO}_2 \cdot 2\text{H}_2\text{O}$, or *ferryl metasilicite*, $(\text{FeO})_2\text{SiO}_3 \cdot 2\text{H}_2\text{O}$. The *hveriers* of G. Forchhammer is a ferruginous clay from Krisuvig, Iceland; similarly also with the *keffekille* of F. E. L. Fischer obtained from Krim, Sevastopol. A. Cronstedt referred to the *keffekil tartarorum* as being used as a substitute for soap. The *neuro-lite* of T. Thomson from Stanstead, Canada; the *rhodajite*—from *rodalös*, rose-coloured—of T. Thomson, and J. E. Portlock obtained in Antrim, Ireland; and the *portite* of G. Meneghini and E. Bechi, occurring at Toscana, appear to be ferruginous clays. E. Mallard described a grey clay from Noyant, France, which he named *bravaisite*—after A. Bravais. It consists of a mass of crystalline fibres. Its composition approximates $2(\text{K}, \text{Mg}, \text{Ca})\text{O} \cdot 2(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 9\text{SiO}_2 \cdot 5\text{H}_2\text{O}$. The sp. gr. is 2.6; the hardness 1–2; double refraction, strong; extinction parallel; optical character negative; and optic axial angle $2E = 40^\circ$. G. Starkl regards *bravaisite* as related with the *Wienbergerde* of Ann-Capelle, Austria.

M. F. R. d'Andrada⁵⁰ described a brown or reddish-brown manganiferous garnet from Drammen and Ferringen, Norway, which he called *allochroite*—from *αλλος*, other; *χρῶμα*, colour—the variety to which this name is now applied is apple-green. This garnet is representative of the calcium-ferric garnets to which J. D. Dana applied the term *andradite*—after M. F. R. d'Andrada.

There are many varieties to which different names have been given, and the so-called *common garnet*, and *black garnet* belong to this group. The bivalent base is almost wholly lime in the mineral topazolite which has the colour of topaz and was described by B. Bonvoisin, and C. A. S. Hofmann. N. von Kokscharoff described a grass-green or emerald-green variety which was called *demantoid* in allusion to its diamond-like lustre. It is used as a gem-stone. A coarse granular variety coloured brownish-yellow or reddish-brown, and possessing a resinous lustre, was called *colophonite* or *kolophonite*—from *κολοφῶνια*, resin—by A. G. Werner, M. F. R. d'Andrada, P. L. Simon, and J. F. L. Hausmann. Colophonite from Arendal is now considered to be a variety of vesuvianite. J. A. H. Laue called it *grénat résinite*. A similar variety was called *Pechgranat* by D. L. G. Karsten. Some so-called colophonite is vesuvianite. A black garnet of the calcium ferric type was called by A. G. Werner *melanite*—from *μέλας*, black—although varieties of other than the ferric-garnets may be black. V. Iskyul studied the action of hydrochloric acid on melanite. A. G. Werner, and C. A. S. Hofmann applied the term *pyreneite* to a greyish-black garnet found in the Pyrenees. A green garnet like *allochroite* was called *jelleite*—after A. Jellet—by J. Apjohn; and a massive garnet found by H. Piddington in India and described by W. T. Blanford and H. Söchting was called *calderite*.

The magnesium-calcium ferric garnets include the original *allochroite* of M. F. R. d'Andrada; and the similar mineral called *Granat von Langban* by E. Rothoff, and *rothofite* by J. J. Berzelius. T. Thomson's *polyadelphite*—from *πολύς*, many; *ἀδελφός*, brother—was named in allusion to its containing many bases. It came from Franklin, New York, and is a brownish-yellow variety of andradite. B. G. Bredberg's variety, from Sala was called by J. D. Dana, *Bredbergite*. R. J. Haüy named a variety from Schwarzenberg, Saxony, and Lana, Siberia, *diplome* or *haplothe*—from *ἀπλός*, simple—in allusion to the fundamental cubic form which is simpler than the dodecahedral form common to the garnets.

Numerous analyses of andradite have been made,⁵¹ and from these C. F. Rammelsberg calculated that the best representative formula for these garnets is $(\text{Ca}, \text{Fe})_3(\text{Al}, \text{Fe})_2(\text{SiO}_4)_3$; or, in the idealized case, $\text{Ca}_3\text{Fe}_2(\text{SiO}_4)_3$, or *calcium diferric triorthosilicate*, or *calcium ferric-garnet*. Some aluminium may replace the ferric-iron, and ferrous iron; magnesium, or manganese may replace the calcium. Presumably these are carried by $\text{Mg}_3\text{Al}_2(\text{SiO}_4)_3$, $\text{Fe}^{2+}\text{Fe}^{3+}_2(\text{SiO}_4)_3$, $\text{Mn}_3\text{Al}_2(\text{SiO}_4)_3$, etc., present in isomorphous admixture—*vide* grossular. L. Hezner made some observations on this subject. The analyses of J. Uhlig indicate the presence of some vanadium, cerium, and chromium which he assumed to be present respectively as $\text{Ca}_3\text{V}_2(\text{SiO}_4)_3$, $\text{Ca}_3\text{Ce}_2(\text{SiO}_4)_3$, and $\text{Ca}_3\text{Cr}_2(\text{SiO}_4)_3$. C. Bergemann reported a Norwegian garnet to contain 6.66 per cent. of yttria earths, and he called it *yttria-garnet*. Analyses by C. B. Benedicks, L. Jaczewsky, and M. Websky, indicated about 2.6 per cent. E. T. Wherry applied the at. vol. theory of isomorphism to explain the various replacements in the garnet family.

Andradite is common in granitic rocks, gneisses, etc.; and as an accessory mineral in subsilicate eruptive rocks, the leucitic, and the nephelitic rocks. It

also occurs in serpentines, beds of iron ore, and as a product of contact metamorphism associated with wollastonite and pyroxene in certain volcanic rocks. M. H. Klaproth,⁵² A. Mitscherlich, and F. von Kobell reported andradite to be formed by melting vesuvianite, but C. Doelter was unable to verify this; indeed, andradite itself decomposes when it is melted. A. des Cloiseaux', and L. Bourgeois' experiments, also, do not lend support to the validity of these early reports. F. Fouqué and A. Michel-Lévy reported that andradite is formed when nephelite and pyroxene are fused together, and C. Doelter found this to be the case when the fused mass is kept below its m.p. for some time. L. Michel produced andradite and sphene by heating a mixture of ilmenite, silica, and calcium sulphide to 1200°.

The colour of andradite may be greenish-yellow, brownish-yellow, resin-brown, brown, dark brown, and black. The differently coloured varieties have different names—allochroite is green; melanite, black; etc., as indicated above. From his observations on the action of oxidizing and reducing gases on heated garnet, W. Hermann⁵³ inferred, that iron, chromium, and manganese oxides act as tinctorial agents in garnets. The crystallographic properties are indicated in connection with grossular. The crystals were also examined by A. Bianchi. The sp. gr. ranges from 3.3–4.1. W. E. Ford gave 3.750. A. H. Church, F. von Kobell, G. Magnus, and M. Seebach found a decrease in the sp. gr. of the mineral after it had been fused. The hardness is 6½–7. The m.p. is difficult to determine since, as indicated above, decomposition occurs about that temp.—*vide* grossular. C. Doelter gave for the m.p. of melanite, 925°–950°; and V. S. Deleano and E. Dittler, 950°–1160°. For topazolite, A. Brun gave 1150°. A. Osann gave for the indices of refraction of demantoid with Li-, Na-, and Tl-light respectively 1.8780, 1.8893, and 1.9005; while H. Rosembusch gave for melanite 1.8467, 1.8566, and 1.8659. W. E. Ford gave 1.895. M. Seebach found a decrease in the index of refraction after melanite had been fused. G. A. Keringott found that powdered and moistened allochroite reacts alkaline to litmus. Both F. von Kobell, and G. Magnus found that garnets which are not attacked by hydrochloric acid, are decomposed with the separation of gelatinous silica after the mineral has been fused—pyrope and, according to P. Jannasch, other garnets are more or less exceptional. M. Seebach found great differences in the action of hydrochloric acid since demantoid gives up 0.94 per cent. to that acid, while andradite from Dognecea is almost wholly soluble.

A. Meister⁵⁴ found what appeared to be hexagonal tabular crystals in the limestone in contact with the nepheline-syenite of southern Yenisei district, near the Angara River, Siberia, and he called the mineral, *angaratite*. The black colour is due to carbonaceous impurities; the colour is bronze after heating. The composition corresponds with $2(\text{Ca}, \text{Mg})\text{O} \cdot 5(\text{Al}, \text{Fe})_2\text{O}_3 \cdot 6\text{SiO}_2$, or idealized, $\text{Mg}_2\text{Al}_2(\text{AlO})_2(\text{SiO}_2)_6$. The uniaxial crystals have the sp. gr. 2.619; the birefringence is below that of quartz; the optical character is positive.

F. Tacconi⁵⁵ reported a brownish-red mineral in the limestone of Candoglia, Tocetal, which he called *taramellite*. The composition approximates barium ferrous ferryl triferrie decametasilicate, $\text{Ba}_4\text{Fe}''(\text{FeO})\text{Fe}'''_3(\text{SiO}_2)_{10}$. The sp. gr. is 3.293, the hardness 5½, the optic axial angle $2E = 75^\circ 40'$; the index of refraction is over 1.74; and the double refraction is small. The mineral is not decomposed by the ordinary mineral acids.

§ 53. Cobalt and Nickel Silicate.

A. Breithaupt¹ applied the term *conarite* to a green mineral from a mine at Röttis, Voigtland. The name is derived from *κοννοπος*, an evergreen tree, and should be *connarite*; not *conarite*, from *κόναρος*, well fed; nor *comarita*, from *κόμαρος*, a strawberry plant—as suggested by A. des Cloizeaux. Analyses by C. Winkler corresponded with $2\text{NiO} \cdot 3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, or $\text{H}_2\text{Ni}_2\text{Si}_3\text{O}_9 \cdot \text{H}_2\text{O}$, nickel hydrotrimetasilicate;

F. W. Clarke considers it to be nickel tetrahydro-triorthosilicate, $H_4Ni_2Si_3O_{10}$. The mineral was at first regarded as a phosphate—it contains nearly 2 per cent. P_2O_5 . According to E. Bertrand, the optical character is negative; and the crystals are probably hexagonal. The sp. gr. ranges from 2.459–2.619, and the hardness is nearly 3. C. Simmonds found the nickel is reduced by heating the mineral to redness in a stream of hydrogen. A. Breithaupt's *silicie*, from Röttis, Voigtland, is considered to be the good form of connarite. R. Schwarz and G. A. Mathis made nickel and cobalt metasilicates, $NiSiO_3 \cdot H_2O$, and $CoSiO_3 \cdot 2H_2O$, by treating a soln. of water-glass with a salt of the metal. M. Rüger found that a mixture of cobalt oxide and silica in the molar proportions 1 : 2 furnishes a violet mass at 900° ; the coloring agent can be washed out by dil. acids, and it is cobalt metasilicate, $CoSiO_3$; ruby-red cobalt orthosilicate, Co_2SiO_4 , was produced by heating a mixture of the constituents in theoretical proportions for 6 hrs. at 100° , cooling quickly and dissolving free silica from the powdered product with potash-lye, and free cobalt oxide with hydrochloric acid. M. Rüger could not make nickel orthosilicate or metasilicate by the same process. L. Bourgeois claimed to have made both cobalt and nickel orthosilicates by heating the oxide or chloride and an excess of amorphous silica at a high temp. for several hours. Cobalt orthosilicate is said to be a violet powder consisting of deep violet, non-dichroic crystals resembling peridoite. The sp. gr. is 4.63. It gelatinizes with acids. Nickel orthosilicate is said to be similar, but the colour is greenish-yellow, and the sp. gr. 4.85. Polysilicates could not be made. R. Schwarz and G. A. Mathias made nickel and cobalt aminometasilicates, $NiSiO_3 \cdot NH_3 \cdot H_2O$, and $CoSiO_3 \cdot NH_3 \cdot H_2O$, by the action of ammonia on the metasilicates. R. Schwarz and H. Bausch prepared a reddish-violet non-crystalline powder of cobaltic chlorotriamminotetrerosilicate, $[Co(NH_3)_3Cl(Si_4O_9)]$, by the action of a soln. of sodium metasilicate on cobaltic chloropentamminochloride. When heated to 120° , it yields blue cobaltic tetrerosilicate, $CoSi_4O_9$; it does not react with water or cold dil. hydrochloric acid, but the hot acid decomposes it, as does also a soln. of sodium hydroxide. A soln. of cobaltic hexamminochloride reacts with one of sodium metasilicate, forming cobaltic chlorotetraminotetrerosilicate, $[Co(NH_3)_4(Si_4O_9)]Cl$, which is freed from water at 105° . When heated, it yields cobaltic tetrerosilicate. They also obtained what they regarded as cobaltic tetramminotritrerosilicometasilicate, $[Co(NH_3)_4(Si_3O_7)]_2SiO_3$, by the action of a larger proportion of sodium metasilicate on cobaltic hexamminochloride. By treating cobaltic hexamminotrihydroxide, $[Co(NH_3)_6](OH)_3$, with dioxodisiloxane, $H_2Si_2O_3$, they obtained cobaltic tetramminotetrerosilicohydroxide, $[Co(NH_3)_4(Si_4O_9)]OH$. For the colloidal cobalt silicates, *vide* water-glass.

In the so-called *nickel-gymnite* of F. A. Genth, W. Keller and H. Tiedemann. G. A. Kenngott, and W. J. Taylor, the magnesium of deweylite is in part replaced by nickel. It occurs as a green amorphous incrustation or stalactitic mass of hardness 3–4, and sp. gr. 2.409. It has been reported at Webster, North Carolina; Texas, Pa.; Michipicoten, Lake Superior; Saasthal, Valais. Analyses by F. A. Genth, T. S. Hunt, J. A. Bachmann, P. H. Walker, and F. P. Dunnington correspond approximately with $2NiO \cdot 2MgO \cdot 3SiO_2 \cdot 6H_2O$, or magnesium nickel tetrahydrotriorthosilicate, $H_4Ni_2Mg_2(SiO_4)_3$. F. W. Clarke considers the mineral to be nickel magnesium orthotrisilicate, $Mg_2Ni_2Si_3O_{10} \cdot 6H_2O$. J. D. Dana called it *genthite* after F. A. Genth.

A nickeliferous mineral from New Caledonia was described and in some cases analyzed by J. Garnier, A. Liversidge, E. Bertrand, G. vom Rath, P. C. W. Typke, A. des Cloizeaux, C. A. Münster, C. Glasser, V. Thiollère, T. S. Hunt, F. Zambonini, R. Helmhaecker, J. H. L. Vogt, W. L. Austin, etc. A similar mineral was obtained by M. Meissonnier, from Malaga, Spain; and W. Hood, F. W. Clarke, H. J. Biddle, etc., have likewise described samples from Oregon, and North Carolina. The composition is variable, but it is idealized into magnesium nickel metasilicate, $(Mg,Ni)SiO_3 \cdot nH_2O$, or magnesium nickel dihydro-orthosilicate, $H_2(Ni,Mg)SiO_4 \cdot nH_2O$. P. Kraft discussed the formation of nickel magnesium silicate gels by the weathering

of magnesian rocks in the presence of nickeliferous rocks. M. Rüger, by the method indicated above, found that zinc cobalt orthosilicate, CoZnSiO_4 , could be obtained. If stannic oxide be added to the mixtures before calcination the products are mixtures of cobalt meta- or ortho-silicate with stannic oxide. Varieties of small were obtained by fusing mixtures of cobalt oxide, silica, and stannous oxide, barium oxide, or alkali oxides.

A. Liversidge attempted to distinguish a dark green unctuous variety which he called *noumeate*, *noumeite*, or *numeite*, after Noumea, New Caledonia; and a pale green variety which adheres to the tongue and which he called *garnierite*. The term *garnierite* was employed by J. D. Dana. The sp. gr. ranges from 2.20-2.87, and the hardness is 3-4. F. Zambonini found that under a pressure of 6 mm., and over 90 per cent. sulphuric acid, the losses after the 1st, 5th, and 32nd hour were respectively 4.57, 6.98, and 7.61 per cent. The partially dehydrated mineral reabsorbs water to within 4 per cent. of its original value. When heated, water is lost:

	69°-70°	108°-110°	146°	238°	291°	367°	420°-425°	480°
Loss . . .	5.98	7.24	7.79	8.62	9.08	9.85	10.60	11.98

The grey colour of the mineral appears deeper at 146°; at 238° the colour is dirty green, and at 480°, dark grey. A. de Gramont studied the spectrum. (Simmonds found that the nickel is reduced by heating the mineral to redness in a stream of hydrogen. F. Cornu suggested the colloidal origin of garnierite, and F. Zambonini found that the contained water may be replaced by alcohol and other substances. E. Dittler observed that garnierite adsorbs aniline dyes.

In 1788, M. H. Klaproth referred to a green nickeliferous magnesium silicate called *chrysophrase earth*, which was later called *pimeite* by D. L. G. Karsten—from *πυράνη*, fatness. It was also analyzed or described by C. F. Rammelsberg, W. Baer, H. Fischer, A. Breithaupt, and E. Bertrand. C. Schmidt described a *pimeite* which E. F. Glocker found to be different, and he called it *alipite*—from *ἀλίπης*, not greasy. R. Hermann also described a nickeliferous magnesium silicate from Roldansk, Urals, and hence he called it *reflanskite*. It was analyzed by N. Besborodko. G. A. Koenig obtained a hydrated zinc nickel silicate from Franklin, New Jersey. He called it *saulskite*—after A. B. de Saules. It contained 38.22 per cent. NiO; 31.02 per cent. SiO_2 ; 4 per cent. ZnO; 9.44 per cent of water lost at 100°, and 7.14 per cent. lost between 100° and 600°.

§ 54. Silicon Fluorides

Normal silicon tetrafluoride, or *tetrafluorosilane*, SiF_4 , was discovered by C. W. Scheele,¹ in 1771, during his experiments on the action of sulphuric acid on fluorspar. He found that the volatile acid is totally different from every other in dissolving silica from glass, etc., and carrying it off in the form of vap. When the attempt was made to collect the gas over water in the pneumatic trough, pure silica was deposited as the gas came in contact with the water. F. C. Achard, A. G. Monnet, and M. Boulangé raised objections to this work (2, 17, 2), but, in 1780, C. W. Scheele completely established the validity of his former observations. J. C. Wiegand, J. C. F. Meyer, C. F. Bucholz, and G. Wenzel also showed that the silica in the gas was derived from the glass retort, and that the gas is obtained by heating a mixture of silica sand, fluorspar, and sulphuric acid. Further, the quantity of silica given up by the gas in contact with water is equal to the quantity lost by the silica in the retort. In 1775, J. Priestley repeated C. W. Scheele's experiments, and collected the gas in a dry vessel over mercury. He also made observations on the chemical properties of this gas. The nature of the gas was established by the work of J. L. Gay Lussac and L. J. Thénard, J. Davy, and J. J. Berzelius.

While the nature of silicon tetrafluoride was being established, the remarkable effect obtained by passing the gas into water was noted. J. Priestley, for example, said that the water contains an acid, and added:

By a repetition of the process, the acid liquor may be procured of a very considerable degree of strength. There seems, however, to be a limit to its strength; for the acid is exceedingly volatile, as is evident from its pungent smell; so that I thought that I gained nothing by repeating the process more than eight or ten times; because it was impossible to transfer the water from one vessel to another, but more acid would be lost by evaporation than would be acquired by another impregnation with the acid air.

The acid is the so-called *hydrofluosilicic acid*, H_2SiF_6 , and the salts *fluosilicates*, *silicofluorides*, or *silicifluorides*. The nature of the acid was made clear by J. J. Berzelius. The salts were particularly investigated by C. W. Scheele, J. J. Berzelius, and F. Stolba, and their isomorphous relationship with the fluoritanates, fluozirconates, and fluostannates established by J. C. G. de Marignac.

In addition to silicon tetrafluoride, H. St. C. Deville,² and L. Troost and P. Hautefeuille reported the formation of a lower fluoride, *silicon subfluoride*, when the gaseous tetrafluoride is passed over silicon heated to the softening point of glass and then suddenly cooled. He also obtained, at the beginning of the reaction between silicon tetrafluoride and aluminium, a small quantity of a volatile fluid which wetted glass with difficulty, and was thought to be a subfluoride. L. Troost and P. Hautefeuille, by sparking silicon tetrafluoride between silicon electrodes, obtained the subfluoride accompanied by a white sublimate of what they regarded as a subfluoride. The need for abrupt cooling is due to the decomposition which occurs at a dull red-heat. The white powder is decomposed with the evolution of hydrogen when treated with aqueous ammonia, or potash-lye; water at 0° transforms it into hydroxide; it reduces permanganate and chromate soln., but does not reduce auric chloride or selenious acid. A. Jaquero and M. Tourpaian found that when silicon tetrafluoride is passed over glass-wool at a red heat, the weight of the normal life increases from 4.693-4.820 grms., and they explain this by assuming that a subfluoride is formed. The evidence for the existence of the subfluoride is not unimpeachable; and its composition is unknown.

The preparation of silicon tetrafluoride.—Carbon tetrafluoride can be made

by the direct union of the elements, and H. Moissan³ obtained silicon tetrafluoride by the action of fluorine on crystalline or amorphous silicon, or on silica contained in a fluor spar tube. E. Vigouroux said that the reaction between fluorine and silicon is attended by incandescence. G. S. Newth also obtained the gas by the action of dry hydrogen fluoride on crystalline silicon. H. Moissan and F. Siemens found that the gas is formed when the soluble modification of silicon is digested in hydrofluoric acid. The gas is also formed when hydrofluoric acid acts on silica or a silicate; thus, the anhydrous acid becomes heated when in contact with glass, and boils up with the evolution of silicon tetrafluoride. The process of etching glass with hydrofluoric acid depends on the formation of silicon tetrafluoride when the dil. acid or the vap. is allowed to act on glass. G. Gore made the gas by heating potassium hydrofluoride with an excess of silica and sulphuric acid:

$$2\text{KHF}_2 + \text{SiO}_2 + 2\text{H}_2\text{SO}_4 = 2\text{KHSO}_4 + 2\text{H}_2\text{O} + \text{SiF}_4$$

The early workers—*vide supra*—obtained silicon tetrafluoride from a mixture of fluorspar, powdered glass or sand, and sulphuric acid. This is also a common way of preparing the gas. The mixture is heated in a dry glass flask fitted with a safety-funnel containing mercury. Water must be carefully excluded since otherwise the gas is decomposed; consequently, an excess of sulphuric acid is employed to absorb the water formed during the reaction: $\text{CaF}_2 + \text{H}_2\text{SO}_4 = 2\text{HF} + \text{CaSO}_4$; and $4\text{HF} + \text{SiO}_2 = 2\text{H}_2\text{O} + \text{SiF}_4$. This process was recommended by J. J. Berzelius, W. Hempel, etc. According to J. J. Berzelius, if the glass which comes in contact with the silicon tetrafluoride has the slightest trace of adsorbed moisture, it becomes clouded by an opaque deposit of silica which adheres tenaciously to the glass. The gas can be collected over mercury.

A thoroughly dried mixture of 4 parts of fluorspar and 2.3 parts of sand or powdered glass is put in a dried flask, and 5 parts of sulphuric acid are added. The whole is well mixed by shaking the flask, which should not be more than half filled. Heat is gradually applied, and the gaseous product collected over mercury. If passed into water as in the preparation of hydrofluosilicic acid, if the delivery tube is narrow, it soon becomes choked with silica. There are several methods of overcoming this difficulty. L. J. Thénard made the end of the delivery tube dip under mercury. Care, of course, is necessary to prevent water getting in the tube above the mercury. J. J. Berzelius, A. Maus, and L. Gmelin devised methods of passing the gas into water without choking the delivery tube; but none is so good as the mercury process.

H. Moissan recommended purifying the gas by passing it through a tube containing pieces of glass or glass-wool, and heated to redness. By cooling the gas to -60° the hydrogen fluoride is condensed; and that impurity can be removed by passing the contaminated gas through a tower packed with sodium fluoride. The gas can be condensed by cooling in liquid air, and purified by fractional distillation. As indicated above, A. Jaquerod and M. Tourpaian said that the treatment recommended by H. Moissan decomposes some of the gas. C. Truchot prepared the gas of a high degree of purity by strongly heating barium fluosilicate—30–40 grms. of the salt gave between two and three litres of gas.

L. Troost and P. Hautefeuille obtained silicon tetrafluoride by passing boron trifluoride rapidly through a porcelain tube at a red heat; H. Moissan found arsenic trifluoride likewise reacts with glass at a dull red heat; and A. Simon obtained the gas by the action of carbon tetrafluoride or phosphorus trifluoride on silica, or a silicide of iron and manganese. H. St. C. Deville noted that a little gas is formed when steam is passed over a mixture of fluorspar and sand at a red heat; and C. M. Tessié du Motay, by heating a mixture of fluorspar, silica or clay, and carbon. In the latter case, the gas is accompanied by carbon monoxide. S. S. Svendsen represented the reaction between calcium fluoride and silica: $2\text{CaF}_2 + 3\text{SiO}_2 = \text{SiF}_4 + 2\text{CaSiO}_3$; and $2\text{CaF}_2 + \text{SiO}_2 = \text{SiF}_4 + 2\text{CaO}$. If water vap. be present, the reaction may furnish hydrogen fluoride: $3\text{CaF}_2 + \text{SiO}_2 + 3\text{H}_2\text{O} = 6\text{HF} + \text{CaSiO}_3 + 3\text{CaO}$, or hydrofluosilicic acid, $3\text{CaF}_2 + \text{SiO}_2 + \text{H}_2\text{O} = \text{H}_2\text{SiF}_6 + 3\text{CaO}$, according to the proportion of water used. H. Moissan noted that silicon tetrachloride is not attacked by fluorine in the cold, yet at 40° , the fluorine burns

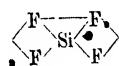

with a pale flame, forming silicon tetrafluoride; and arsenic trifluoride reacts in the cold with silicon tetrachloride, forming silicon tetrafluoride and arsenic trichloride. O. Ruff and K. Albert likewise found that antimony trifluoride reacts with silico-chloroform, SiHCl_3 , forming silicon tetrafluoride; and E. Berger prepared silicon tetrafluoride from a mixture of lead fluoride, calcium silicate, and alkali nitrate.

The physical properties of silicon tetrafluoride.—This compound at ordinary temp. is a colourless, pungent, fuming gas. J. Dalton gave for the density of the gas, 4.17; J. Davy, 5.5735; J. B. A. Dumas, 3.60; and C. Truchot, 3.6 when the theoretical value, air unity, is 3.619. A. F. O. Germann and H. S. Booth found 4.6840 grms. for the weight of a normal litre at 0° and 760 mm.; and A. Jaquerod and M. Tourpaian 4.693 grms.—*vide supra*—they estimate the coeff. of compressibility to be 0.000069, and the coefficient of expansion under constant press. between 0° and 18.17° to be $\alpha = 0.003754$; and between 0° and 30° , and a constant press. of 726 mm., $\alpha = 0.003752$. M. Faraday said that at -105.5° the gas liquefied under a press. of about 9 atm. to form a clear, transparent, colourless, mobile liquid; but it did not solidify at any temp. to which it could be subjected, he added that if the gas confined in a sealed tube be cooled to 0° by a little ice, a liquid appears, but by cooling with a mixture of ice and salt there is a greater condensation of the gas—the press. approximating 30 atm. According to H. Moissan, at -97° and under atm. press., silicon tetrafluoride forms a white amorphous solid, K. Olschewsky said -102° , and that by raising the temp. the solid vaporizes without passing into the liquid state. H. Moissan found that under a press. of .2 atm., the melting point was -77° ; the resulting colourless mobile liquid had a boiling point of -65° under a press. of 1810 mm. O. Ruff and K. Albert gave -90° for the sublimation temperature at 759 mm. press. H. Moissan gave -1.5° for the critical temperature, and 50 atm. for the critical pressure. A. Guntz, H. Hammerl, and M. Berthelot found that the heat of formation from crystalline silicon and gaseous fluorine is 239.8 Cals.; and E. Baur calculated 219.6 Cals. F. Fischer and K. Thiele found that the heat of soln. of silica is greater than that of boric acid in hydrofluoric acid. W. Herz gave 2.89 for the chemical constant. B. H. Wilsdon studied the energy involved in the motion of the electrons during the dissociation of silicon tetrafluoride.

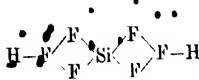

According to A. Dufour, J. Chautard, E. Demarçay, etc., the spectrum of the electrical discharge in a tube containing the gas is banded. C. Porlezza studied the regularities in the band spectrum of silicon tetrafluoride. The Zeeman effect has been studied by H. M. Reese, etc. J. Chautard showed that new lines appear when the discharge tube is placed in a magnetic field, and A. Cotton showed that the lines persist after the magnetic field is withdrawn; hence they are probably due to chemical action since the glass is attacked. The magnetic spectrum consists of diffuse rays accompanied at the red end by a background of varying intensity, the latter being often resolved into more or less widely-spaced channels. The lines may be separated into three principal groups, of which the frequencies in each group obey Deslandres' formula $N = A - (Bm + C)^2$, *vide* 4. 25, 3. In the first two groups, the Zeeman effect is abnormal, and in the third group normal. H. Ruff and A. W. Hofmann electrically heated an iron or platinum wire in an atm. of silicon tetrafluoride, but the amount of gas decomposed was scarcely perceptible; on the other hand, W. R. Hodgkinson and F. K. Lowndes similarly heated a platinum wire to its m.p. and obtained crystals of silicon at the bottom of the containing vessel. M. Berthelot, and H. Moissan found that the electrical discharge did not decompose the gas after an hour's action, but J. M. Seguin found that with the spectroscope the electric discharge furnishes a blue fluorine line—*vide supra*. L. Troost and P. Hautefeuille found that sparks from an induction coil between carbon electrodes decomposed the gas, while the silicon deposit which collected was thought to be a subfluoride—*vide supra*. If the tetrafluoride vap. be passed over heated silicon, a ring of crystalline silicon is formed in the part

of the porcelain tube just below a red heat; and similarly with the voltaic arc between silicon electrodes in an atm. of silicon fluoride, the flame has a violet glow and a brilliant envelope containing finely divided silicon, which is gradually deposited on the inner surface of the vessel. When the distance between the poles is as large as possible, the light shows a most brilliant violet colour—*vide* hexachlorodisilane. W. J. Pope gave 11.51 for the retraction equivalent of the SiF_6 -radicle.

The chemical properties of silicon tetrafluoride.—The composition of silicon tetrafluoride can be represented graphically on the assumptions that silicon is quadrivalent, and fluorine univalent $\text{F}_2=\text{Si}=\text{F}_2$, or, if fluorine be tervalent, the compositions of silicon tetrafluoride and of hydrofluosilicic acid, H_2SiF_6 , can be represented by the formulæ:

Silicon tetrafluoride.

Hydrofluosilicic acid.

J. Davy said that the gas reddens litmus even when carefully dried. Most of the metalloids are without action on silicon tetrafluoride, but when heated with the metals, the gas is decomposed. J. Davy did not detect any sign of chemical change when a mixture of silicon tetrafluoride and hydrogen is exposed to sunlight; but J. M. Seguin found that there is a reaction if the mixture be sparked. H. Moissan observed no reaction by sparking a mixture of equal vols. of oxygen and silicon tetrafluoride. The gas is not combustible, and it does not support the combustion of a taper or burning wood. The gas forms a white cloud when exposed to ordinary moist air; and the crystalline product, when washed free from acid with warm water, and dried at 130° , has, according to H. H. Laugel, the composition $\text{HSi}_2\text{O}_4\text{F}$; i.e. $\text{HF} \cdot 2\text{SiO}_2$, or **hydrofluomesodisilicic acid**, $\text{HO} \cdot \text{SiO} \cdot \text{O} \cdot \text{SiO} \cdot \text{F}$. When this product is heated by the gas-blowpipe it loses silicon tetrafluoride, water, and an acid gas. The residue appears to be silica associated with 3.06 per cent. of fluorine and corresponding with $\text{HF} \cdot 8\text{SiO}_2$ —*vide infra* the alkali oxyfluosilicates. On the assumption that the hydrofluomesodisilicic acid contains some free silica, H. Schiff and E. Bechi represent the reaction: $8\text{HSi}_2\text{O}_4\text{F} + \text{SiO}_2 = 2\text{H}_2\text{O} + 2\text{HF} + \text{SiF}_4 + 2\text{HSi}_6\text{O}_{16}\text{F}$. The hydrofluomesodisilicic acid volatilizes completely when heated with ammonium fluoride. J. J. Berzelius discussed the possibility of the existence of $4\text{HF} \cdot \text{SiO}_2$. **Water** absorbs and decomposes a large quantity of gas with the production of hydrofluosilicic acid, H_2SiF_6 , and hydrated silica: $3\text{SiF}_4 + 2\text{H}_2\text{O} = \text{SiO}_2 + 2\text{H}_2\text{SiF}_6$. C. T. Barfoed, and K. Daniel discussed the reaction from the point of view of analytical chemistry. In 24 hrs., said J. J. Berzelius, 100 parts of water absorb 140.6 parts of the gas; the absorption at first is rapid, but as the liquid becomes thickened by the precipitated silica, the absorption is much slower. According to J. Davy, one vol. of water absorbs 265 vols. of gaseous silicon tetrafluoride. The precipitated silicic acid, said J. J. Berzelius, is somewhat soluble in water, and consequently one-fourth, not one-third, of the silicon of the gas appears in the precipitate. When the precipitate is thoroughly washed, it is quite free from fluorine. Consequently, there is a marked difference in the products of the reaction between silicon tetrafluoride with an excess of water, and with a limited supply of water vap. According to A. Daubrée, water-vap. at a red heat decomposes silicon tetrafluoride, forming crystalline silica. According to A. Guntz, $2\text{H}_2\text{O} + \text{SiF}_4 = \text{SiO}_2 + 4\text{HF} - 25.8 \text{ Cals.}$, and this reaction can occur only when the temp. is high enough to prevent the secondary formation of hydrofluosilicic acid which develops sufficient heat to compensate for this absorption. According to L. Troost and P. Hautefeuille, steam above 150° is not decomposed by silicon tetrafluoride. E. Baur has shown that the condition of equilibrium of the gas phase corresponds with $\text{C}_{\text{SiF}_4} \cdot \text{C}_{\text{H}_2\text{O}} / \text{C}_{\text{HF}}^4 = 163 \times 10^7$ at 104° , and 5.4×10^7 at 270° . The equilibrium point

of the reaction favours the decomposition of the silicon tetrafluoride with rise of temp. Hence the formation of silicon tetrafluoride and water from silicic acid and hydrofluoric acid is accompanied by an evolution of heat, and from the equation $d(\log K)/dT = q/RT^2$, the heat evolution is calculated to be $\text{SiO}_2 + 4\text{HF} = \text{SiF}_4 + 2\text{H}_2\text{O} = 8.945 \text{ Cals.}$, which is about one-third the value 25.8 calculated from the thermochemical data.

Conc. aq. **hydrofluoric acid** was found by F. Kessler to absorb silicon tetrafluoride to form hydrofluosilicic acid; but **hydrogen fluoride**, according to C. Truchot, does not unite with silicon tetrafluoride at temp. down to -30° . J. Davy found that **iodine** can be sublimed in the gas without chemical change. J. Davy did not observe any reaction by heating **sulphur** in an atm. of silicon tetrafluoride; and H. Schiff and E. Bechi found that when the gas is heated with **hydrogen sulphide** there is no chemical change.

J. Davy did not observe any decomposition of silicon tetrafluoride when **carbon** is heated in the gas. According to W. Knop, absolute **alcohol**, or alcohol with 8 per cent. of water readily absorbs silicon tetrafluoride without the separation of silicic acid, and a strongly acid fluid of sp. gr. 1.044 is formed. When exposed to air, the liquid called by W. Knop *Kieselfluoralcohol*, gives off silicon tetrafluoride, and when distilled, the same gas is given off and some silicic acid first separates, and afterwards a siliciferous alcohol distils over. W. Knop also found ethylorthosilicate and hydrofluosilicic acid among the products of the action of silicon tetrafluoride on alcohol. When the Kieselfluoralcohol is mixed with a little water it gelatinizes, but with much water it forms a clear soln. Aq. ammonia precipitates silicic acid, and on addition of aq. alcohol produces a compound of the composition $(\text{NH}_4)_3\text{Si}_3\text{F}_{17}$ —*vide infra*. Many organic compounds, e.g. aniline, *o*- and *p*-toluidine, dimethylamine, dimethylaniline, *p*-chloraniline, quinoline, acetone, etc.—unite with silicon tetrafluoride, forming additive products.

According to J. Davy, dry **ammonia** reacts with dry silicon tetrafluoride forming white **silicon diamminotetrafluoride**, $\text{SiF}_4 \cdot 2\text{NH}_3$ —*vide infra*. A. Hileman showed that when the gas is passed into aq. ammonia, ammonium fluoride and silicic acid are formed. Silicon fluoride was found by J. J. Berzelius to unite with **nitric oxide**, **nitrogen trioxide**, **tetroxide**, and **pentoxide**. F. Kuhlmann showed that nitric acid absorbs silicon tetrafluoride copiously, forming a fuming liquid from which water or alkalis precipitate silicic acid. J. Davy said that the gas is not decomposed by heated **phosphorus**. A. Besson found that at -22° under a press. of 50 atm. two vols. of **phosphine** unite with 3 vols. of silicon tetrafluoride, forming white crystals of **silicon phosphinotetrafluoride**, $3\text{SiF}_4 \cdot 2\text{PH}_3$. J. Davy found that the gas is absorbed by **antimonie oxide**.

According to J. L. Gay Lussac and L. J. Thénard, and J. J. Berzelius, at ordinary temp., **potassium** has a slight action on silicon tetrafluoride; when the metal is heated in the gas it becomes white; then darkens, becoming black; then it takes fire, burning with a dark red flame, absorbing a quantity of the gas equal in vol. to that of the hydrogen which would be evolved had the metal been treated by water. The resulting gas is porous mass which remains is a mixture of potassium fluoride, potassium fluosilicate, and silicon. The behaviour of **sodium** is similar. J. Davy observed that the gas was not changed by molten **zinc**. H. St. C. Deville passed silicon tetrafluoride over heated **aluminium** and obtained a mixture of aluminium fluoride and silicon. A. F. O. Germann and H. S. Booth found that the gas had no action on **mercury**. J. J. Berzelius said that when the gas is passed through a layer of white-hot **iron** turnings, very little is absorbed, for the iron becomes covered with a thin layer of silicon and iron fluoride; E. Frémy said that when the gas is heated in the presence of iron or **platinum**, the metals are transformed into silicides, and H. Moissan said that at a red heat the gas is decomposed with the liberation of some free fluorine.

According to J. Davy, aq. soln. of the bases act like water, precipitating one-third of the silica and forming a fluosilicate of the metal, or they simply precipitate

the silica and form a fluoride of the metal. Many of the alkalis, alkaline earths, and anhydrous metallic oxides absorb silicon fluorides with the evolution of heat, sometimes with incandescence, forming a mixture of the metal fluoride and silica. According to C. Truchot, when the gas is treated with **lithium hydroxide** the alkali fluoride is formed; similar results were obtained by J. Davy, and C. Truchot with **sodium hydroxide**: $\text{SiF}_4 + 4\text{NaOH} = \text{SiO}_2 + 2\text{H}_2\text{O} + 4\text{NaF}$, but with **potassium hydroxide**, the fluosilicate was formed: $3\text{SiF}_4 + 4\text{KOH} = \text{SiO}_2 + 2\text{H}_2\text{O} + 2\text{K}_2\text{SiF}_6$. According to J. Davy, **calcium oxide** becomes red hot when immersed in the gas, and the reaction is probably eq. to $2\text{CaO} + \text{SiF}_4 = 2\text{CaF}_2 + \text{SiO}_2$. If **calcium hydroxide** be present, heat is necessary to start the reaction. J. Davy also found that **barium oxide** absorbs the gas, and the product gives off the gas when treated with sulphuric acid; according to J. B. A. Dumas, if the baryta be heated in the gas, the mass becomes incandescent, and the reaction approximates to $\text{SiF}_4 + 4\text{BaO} = 2\text{BaF}_2 + \text{Ba}_2\text{SiO}_4$. J. Davy found that silicon tetrafluoride combines with **magnesium oxide** without ignition, and the gas is also absorbed by **manganese**, and **mercuric oxides**; and copiously by **ferrie oxide**. The gas is expelled with sulphuric acid. He also found that **aluminium oxide** absorbs the gas. The action of silicon tetrafluoride on heated alumina enabled A. Daubrée to synthesize topaz, and other minerals. The reaction has been investigated by H. St. C. Deville, and A. Reich. The gas is said to be *un minéralisateur par excellence*. L. Troost and P. Hautefeuille found that red-hot alumina, and **zirconium oxide** are rapidly attacked by silicon tetrafluoride. Silicon tetrafluoride, said J. J. Berzelius, is not absorbed by **boric oxide**, but it is absorbed by **boric acid**, forming a white powder which does not fume. When the product is treated with water, part is dissolved, forming a soln. of hydrofluoboric acid, HBF_4 . A. Hileman found that when a conc. aq. soln. of **potassium chloride** is treated with silicon tetrafluoride, potassium fluosilicate and hydrochloric acid are formed. J. J. Berzelius observed that no action occurs when the anhydrous **alkali carbonates** and **alkali borates** are treated with the gas. J. Davy showed that the gas is not affected by fused **potassium chlorate**, or by heated **calcium chloride**. L. Troost and P. Hautefeuille found that at a red heat **porcelain** is slowly attacked by silicon tetrafluoride; and H. Rose, that **glass** is slowly attacked at ordinary temp.—possibly owing to a film of moisture on the glass—because A. F. O. Germann and H. S. Booth could detect no action.

According to O. Ruff and C. Albert,¹ silicochloroform does not react when heated with lead and silver fluorides; with antimony and arsenic trifluorides in a sealed tube the reaction is of the type: $3\text{SiHCl}_3 + 4\text{SbF}_3 = 3\text{SiF}_4 + 2\text{Sb} + 2\text{SbCl}_3 + 3\text{HCl}$; but with tin and titanium tetrafluorides, the reaction is of the type: $3\text{SnF}_4 + 4\text{SiHCl}_3 = 4\text{SiHF}_3 + 3\text{SnCl}_4$. The product, **silicofluoroform**, or **trifluoro-silane**, SiHF_3 , is best obtained by heating molar proportions of silicochloroform and titanium tetrafluoride in a closed copper vessel or glass tube for 18 hrs. at 100° – 120° . The vessel is then cooled in liquid air and allowed to become warm slowly, the gases evolved being condensed by means of liquid air. Silicochloroform boils at -80.2° under 758.5 mm. press., and melts at about -110° . It slowly decomposes in a sealed glass tube, even at the ordinary temp., according to the equation $4\text{SiHF}_3 = 2\text{H}_2 + 3\text{SiF}_4 + \text{Si}$, the decomposition being greatly accelerated by heat. It burns in air with a very pale blue flame, the temp. of ignition being higher than that of silicochloroform: $12\text{SiHF}_3 + 6\text{O}_2 = 3\text{SiF}_4 + 3\text{SiO}_2 + 4\text{H}_2\text{SiF}_6 + 2\text{H}_2\text{SiO}_3$. Water and sodium hydroxide decompose it thus: $2\text{SiHF}_3 + 4\text{H}_2\text{O} = \text{Si}(\text{OH})_4 + \text{H}_2\text{SiF}_6 + 2\text{H}_2$. Alcohol forms ethyl orthosilicate, $\text{Si}(\text{OEt})_4$; ether forms ethyl silico-orthoformate, $\text{SiH}(\text{OEt})_3$, and ethyl fluoride. Toluene dissolves its own vol. of silicofluoroform.

§ 55. Hydrofluosilicic Acid and its Salts

The observations of J. Priestley¹ and others on the preparation of hydrofluosilicic acid, H_2SiF_6 , have been previously indicated. The acid is known only in soln., for all attempts to make the anhydrous acid either by concentrating the aq. soln., or by the direct union of hydrogen fluoride and silicon tetrafluoride, have proved abortive. J. Priestley showed that in the former case, the acid volatilizes, after a certain conc. has been obtained. Although F. Kessler was able to prepare hydrofluosilicic acid by the action of silicon tetrafluoride on a conc. aq. soln. of hydrofluoric acid, C. Truchot observed no sign of combination in the absence of water. J. J. Berzelius obtained the acid by the action of cold dil. hydrofluoric acid on powdered quartz. The silica dissolves quietly at first, but afterwards, if the quartz be in excess, and the acid conc., silicon tetrafluoride is evolved. J. J. Berzelius' method of passing silicon tetrafluoride into water for the preparation

of hydrofluosilicic acid has already been indicated. The mixture of aq. acid and gelatinous silicic acid is separated by straining or filtration. The resulting liquid, said J. J. Berzelius, is a dil. soln. of hydrofluosilicic acid with a little silicic acid in soln. The preparation of hydrofluosilicic acid by this process was discussed by F. Stolba, W. Hempel, A. Ziegler, A. W. Hoffmann, and C. M. Tessié du Motay and E. Karcher. F. Stolba also used cryolite in place of fluorspar. A. Ziegler found the absorption of the gas is favoured by warming the water to 60°–70°. F. Stolba showed that if the sulphuric acid contains arsenic, the hydrofluosilicic acid will be contaminated with arsenious fluoride.

E. Fleischer treated a mixture of silica and cryolite with a boiling soln. of barium hydroxide, and obtained barium fluosilicate. The product was boiled with a soln. of calcium sulphate acidified with hydrofluoric acid; the soln. of calcium fluosilicate was mixed with an equal vol. or more of alcohol, and filtered from the precipitated barium sulphate; the calculated quantity of sulphuric acid was added, the calcium sulphate filtered off, and an alcoholic soln. of hydrofluosilicic acid obtained. E. Baur and A. Glassner obtained a soln. of the acid of a high degree of purity by treating purified and dry barium fluosilicate with conc. sulphuric acid in a platinum retort. A. F. Meyerhoffer used calcium fluoride. F. A. Hoppen obtained hydrofluosilicic acid as a by-product in the purification of graphite by hydrofluoric acid. For the preparation of hydrofluosilicic acid by the joint action of silica, calcium fluoride, and steam by S. S. Swendsen's process, *vide* silicon tetrafluoride. F. Halla purified the acid by the following process:

Commercial hydrofluosilicic acid may be purified by removing the arsenic with hydrogen sulphide, and the excess of gas with a current of air; precipitating the iron with potassium ferrocyanide; treating the soln. with copper sulphate, filtering, removing the excess of copper with hydrogen sulphide, and the excess of the latter with air; adding lead monosilicate to precipitate sulphuric and hydrofluoric acids, and removing the lead in a similar way to the copper. Addition of barium hydroxide to remove the hydrofluoric and sulphuric acids is not so good, as it causes a small amount of the hydrofluosilicic acid to hydrolyze.

A dil. soln. of hydrofluosilicic acid can be conc. by evaporation at a low temp., but the process cannot be carried very far because the soln. at 40° can be evaporated completely without residue. According to J. J. Berzelius, conc. hydrofluosilicic acid, exposed to the air at ordinary temp. absorbs moisture until the conc. has acquired a definite value, and a very dil. acid, on the contrary, gives off water in air until it attains the same conc. The most conc. acid J. J. Berzelius could prepare contained 42.85 per cent. of water and corresponded with $\text{H}_2\text{SiF}_6 + 6\text{H}_2\text{O}$. The phenomenon thus resembles to some extent the distillation of acids of constant composition. The hydrofluosilicic acid vaporizes with the steam, but at the same time the acid is partly dissociated into hydrogen fluoride and silicon tetrafluoride. According to E. Baur, at a press. of 720 mm., an acid containing 13.3 per cent. of hydrofluosilicic acid gives a vap., the composition of which is exactly expressed by the formula H_2SiF_6 . The distillate from more conc. acids contains silicic acid, whilst dil. acids yield a distillate containing hydrogen fluoride; further, conc. acids dissolve silicic acid when evaporated with it, whereas dil. soln. deposit this acid on evaporation. An acid containing 30.2 per cent. of hydrofluosilicic acid boils at 108.5° under 7.20 mm. press. E. Baur and A. Glassner measured the vap. density of hydrofluosilicic acid at 23°, 31.5°, and 42° at press. between 650 and 1350 mm. of mercury. Under these conditions, the mol. wt. is between 80 and 83, showing that more than half of the acid is dissociated, and at 100°, probably more than two-thirds is dissociated. C. A. Jacobsen holds that the vap. density of hydrogen fluoride agrees with the formulæ H_2F_2 and H_3F_3 , and on this assumption believed that the hydrofluosilicic acid was completely dissociated. He also showed that hydrofluosilicic acid like carbonic and sulphurous acids cannot exist in the state of vap. E. Baur studied the equilibrium con-

ditions between silicon tetrafluoride, hydrogen fluoride, water, and silicic acid—*vide supra*, silicon tetrafluoride.

Hydrofluosilicic acid has a very sour taste resembling that of hydrochloric acid, and, like that acid, it irritates the skin, and reddens lichen. According to C. Truchot, on cooling to -20° a soln. of silicon tetrafluoride in hydrofluoric acid containing one eq. of water, crystals of the monohydrate, $\text{H}_2\text{SiF}_6 \cdot \text{H}_2\text{O}$, are formed; on exposure to air, the crystals fume strongly and decompose. F. Kessler passed silicon tetrafluoride into conc. hydrofluoric acid and found no deposition of silica or absorption of excess of gas, but noted a deposition of acicular crystals in the delivery tube. The crystals were free from hydrogen fluoride, for their aq. soln. after precipitation by an excess of potassium chloride did not corrode glass; and they were free from excess of silica because the potassium fluosilicate so formed, after washing with dil. alcohol, left no trace of silica in the evaporated wash-waters. The composition of the crystals approximated to that of the dihydrate, $\text{H}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$. The crystals were very deliquescent; fumed strongly in air; melted at 19° ; and at a higher temp. they decomposed with ebullition. C. Truchot could not make the dihydrate, but on cooling at 0° a soln. of silicon tetrafluoride in 4–6 eq. of water, he obtained fuming crystals of the tetrahydrate, $\text{H}_2\text{SiF}_6 \cdot 4\text{H}_2\text{O}$. The sp. gr. was 1.7; and they readily melted to form a syrupy liquid. When heated in vacuo, they decomposed into silicon tetrafluoride, hydrogen fluoride, and water.

The sp. gr., S , of aq. soln. of hydrofluosilicic acid, determined by F. Stolba, are shown in Table XXXIV; and the results can be represented by the formula $S = 1 + 0.004n + \{n(n-3) + 2\} \times 10^{-5}$, where n represents half the percentage amount of contained H_2SiF_6 , at $17.5^{\circ}/17.5^{\circ}$. For the heat of formation, C. Truchot

TABLE XXXIV.—SPECIFIC GRAVITIES OF HYDROFLUOSILICIC ACID AT $17.5^{\circ}/17.5^{\circ}$.

Per cent. H_2SiF_6 .	Specific gravities.									
	0	1	2	3	4	5	6	7	8	9

30	1.2742	1.2846	1.2951	1.3056	1.3162	—	—	—	—	—

gave $\text{Si}_{\text{cryst.}} + 6\text{F} + 2\text{H} + \text{Aq.} = \text{H}_2\text{SiF}_6 \cdot \text{aq.} + 375.1 \text{ Cals.}$; A. Guntz gave 374.3 Cals. ; H. Hammerl, $3\text{SiF}_4 + 2\text{H}_2\text{O} + \text{Aq.} = 2\text{H}_2\text{SiF}_6 \cdot \text{aq.} + \text{SiO}_2 \cdot \text{aq.} + 67 \text{ Cals.}$; C. Truchot, $\text{SiF}_4 + 2\text{HF} + \text{Aq.} = \text{H}_2\text{SiF}_6 \cdot \text{aq.} + 33.9 \text{ Cals.}$ J. Thomsen gave for the heat of neutralization $\text{H}_2\text{SiF}_6 \cdot \text{aq.} + \text{NaOH} \cdot \text{aq.} = \dots + 13.3 \text{ Cals.}$; $\frac{1}{2}\text{H}_2\text{SiF}_6 \cdot \text{aq.} + \text{NaOH} \cdot \text{aq.} = \dots + 13.3 \text{ Cals.}$; and $\text{H}_2\text{SiF}_6 \cdot \text{aq.} + 2\text{NaOH} \cdot \text{aq.} = \dots + 26.6 \text{ Cals.}$ —*vide infra*, alkali fluosilicates. C. Truchot gave for the heat of dissolution of tetrahydrate, $+8.0 \text{ Cals.}$ W. Ostwald found the eq. conductivity, λ , at 25° for soln. with an eq. of the acid per v litrs. to be

v	2	8	32	64	128	256	512	1024	2048	4096
λ	21.5	281	324	342	358	377	415	495	652	847

The increase in the conductivity above $v=256$ is due to the hydrolysis of hydrofluosilicic acid into silicic and hydrofluoric acids. S. Arrhenius discussed the ionization of the acid in soln. W. Ramsay and F. L. Usher examined the effect of radium radiations on hydrofluosilicic acid, and claimed to have degraded silicon to carbon. This has not been verified.

According to J. Davy, if hydrogen chloride be passed into hydrofluosilicic acid, water is taken from the compound, and silicon fluoride is formed. A. Hileman found that when the acid is boiled with potassium iodide and iodate, iodine is set

free. J. Davy, and F. Stolba found that sulphuric acid behaves like hydrogen chloride gas; and that boric acid precipitates gelatinous silica from hydrofluosilicic acid, and forms hydrofluoboric acid, HBF_4 . According to J. Davy, and J. J. Berzelius, an excess of aq. ammonia, sodium hydroxide, or other salifiable base precipitates the whole of the silica, and forms a fluoride, and A. Hileman represented the reaction: $\text{H}_2\text{SiF}_6 + 6\text{KOH} = 6\text{KF} + \text{Si(OH)}_4 + 2\text{H}_2\text{O}$. A soln. of an alkali hydroxide or carbonate decomposes the fluosilicates, forming a fluoride and silicate. Consequently, when hydrofluosilicic acid is titrated with a soln. of sodium hydroxide with litmus as indicator, there are two transition points. The first corresponds with the neutralization of the original acid: $\text{H}_2\text{SiF}_6 + 2\text{NaOH} = \text{Na}_2\text{SiF}_6 + 2\text{H}_2\text{O}$; and the second with the decomposition of the fluosilicate: $\text{Na}_2\text{SiF}_6 + 4\text{NaOH} = 6\text{NaF} + \text{Si(OH)}_4$. Litmus shows the permanent excess of alkali after the completion of the second reaction, for silicic acid does not behave as an acid to litmus under these conditions. The reaction was studied by C. A. Jacobson, J. Katz, and J. G. Dinwiddie. C. R. Wagner and W. H. Ross showed that the reaction, $\text{H}_2\text{SiF}_6 + 6\text{NaOH} = 6\text{NaF} + \text{H}_2\text{SiO}_3 + 3\text{H}_2\text{O}$, occupies an appreciable time; and L. J. Hudleston and H. Bassett inferred that the reactions involved are (i) $\text{SiF}_4 + 3\text{H}_2\text{O} = \text{H}_2\text{SiO}_3 + 4\text{HF}$; (ii) $\text{SiF}_4 + 2\text{HF} = \text{H}_2\text{SiF}_6$; and (iii) $3\text{SiF}_4 + 3\text{H}_2\text{O} = 2\text{H}_2\text{SiF}_6 + \text{H}_2\text{SiO}_3$. The reactions are reversible because hydrofluosilicic acid is formed equally by the action of silicon tetrafluoride on water and of hydrofluoric acid on silica; and hydrofluosilicic acid with sufficient alkali yields sodium fluoride and silicic acid as end-products. The proportion of hydrofluoric acid in the aq. soln. was found by E. Baur, and C. A. Jacobson to be negligibly small. For the second of the above reactions, L. J. Hudleston and H. Bassett found $[\text{SiF}_4][\text{HF}]^2 = K[\text{H}_2\text{SiF}_6]$, where $K = 4 \times 10^{-5}$. They also showed that silicic acid can exist in soln. with an active mass proportional to its conc., to the extent of at least 0.003 mol. per litre at 15° . J. Katz found that pyridine fixes the acid without decomposition. A. von Berkel showed that with a soln. of calcium hydroxide, calcium fluoride, fluosilicate, and silicate, and hydrated silica are formed. According to J. J. Berzelius, ammonium, potassium, and sodium salts produce a transparent precipitate which is scarcely perceptible at first; and barium salts gave a white crystalline precipitate which becomes visible after a few seconds. For the action of hydrofluosilicic acid, vide 2, 20, 28. E. Guerry and E. Toussaint discussed the action of ammonium salts in the presence of citric acid; and A. Gawalowsky, the action of soln. of chromium salts.

W. T. Gibbs found that silicate minerals are more rapidly opened up by hydrofluoric acid if a trace of hydrofluosilicic acid be present. The reports of the action of hydrofluosilicic acid on glass, by J. J. Berzelius, and J. Davy, indicate that the acid cannot be preserved in glass bottles, but, added H. Rose, the acid slowly dissolves some alkali, lime, and ferric oxide from the glass, and precipitate these substances when alcohol is added. J. J. Berzelius also said a mixture of the acid with half its vol. of alcohol, does not attack glass. If the acid be evaporated on glass, the surface is corroded because, added J. J. Berzelius, silicon tetrafluoride is at first evolved, and the hydrofluoric acid in the residual liquor becomes more and more conc., which subsequently also evaporates. Hence, the acid attacks glass when evaporated on its surface. When evaporated over sulphuric acid in vacuo, it corrodes the glass receiver, because after the silicon fluoride has been given off, hydrofluoric acid remains to be evaporated. The work of E. Baur and A. Gaüssner, indicated above, explains the facts more clearly, for a soln. which will dissolve silica will also corrode glass, and a soln. containing hydrofluosilicic acid but no hydrofluoric acid does not etch glass. H. St. C. Deville found that hydrofluosilicic acid has a considerable solvent action on alumina forming what he regarded as a soln. of *hydrofluoaluminic acid*. A similar soln., free from silica, was obtained by treating china clay with hydrofluosilicic acid (q.v.). He added:

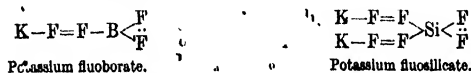

When dil. hydrofluosilicic acid is placed in contact with ignited alumina, aluminium fluosilicate is first formed. Then, when an excess of alumina is added, and the digestion prolonged, the fluosilicate is decomposed, silica is deposited, and hydrated soluble aluminium fluoride is formed.

§ 56. The Fluosilicates

The salts of hydrofluosilicic acid are called *silicofluorides*, or, in harmony with the commonly recognized name for the acid, **fluosilicates**. In general, the fluosilicates are made by dissolving the oxides, hydroxides, or carbonates in the acid; by the action of silicon tetrafluoride on the metal fluorides—solid or in soln.; by dissolving the fluoride and silica in aq. hydrofluoric acid; and in some cases by dissolving the metal in the acid. An excess of acid must always be present or the salts may be hydrolyzed. The fluosilicates usually form characteristic crystals, some are useful for identifying certain metals under the microscope. The low solubilities of the salts of potassium, sodium, and barium are noteworthy. The salts decompose with the evolution of silicon tetrafluoride when heated, and leave the metal fluoride as a residue. When a fluosilicate is warmed with sulphuric acid, hydrofluosilicic acid is given off. Nitric or hydrochloric acid partially decomposes the fluosilicates, and some of the chlorides and nitrates are partially decomposed by hydrofluosilicic acid. The reaction is therefore reversible. The fluosilicates are isomorphous with the corresponding fluoritanates, fluozirconates, and fluostannates. Graphic formulae for the fluoroborates and fluosilicates are usually based on the tervalency of fluorine:

*According to A. Werner's *Neuere Anschauungen auf dem Gebiete der anorganischen Chemie* (Braunschweig, 68, 1905), hydrofluosilicic acid is a complex acid analogous to hydrofluoboric acid, hydrochloroplatinic acid, and other halogenoacids. The silicon is considered to be the central atom with a co-ordination number 6, thus furnishing the acid $[\text{SiF}_6]\text{H}_2$.

F. Kessler¹ recommended hardening the surface of calcareous stones by means of the fluosilicates of the metals—e.g. magnesium, aluminium, or lead—which form an insoluble oxide. Carbon dioxide is given off, and calcium fluoride, silica, and alumina or lead carbonate, or, magnesium fluoride, may be formed. The fluosilicates have also been recommended as antiseptics by G. Heinzelmann, G. Jacquemin, A. Cobenzl, F. J. Homeyer, etc. E. Prior described the antiseptic properties of hydrofluosilicic acid under the trade-name *keranyl*; and H. Schnegg showed that the acid is also the active constituent in the disinfectant with the trade-name *montanin*. According to A. Cobenzl, the sodium, potassium, and ammonium fluosilicates are used in rat-poisons.

J. Davy² found that one vol. of silicon tetrafluoride unites with 2 vols. of ammonia, forming a white powder—**silicon diamminotetrafluoride**, $\text{Si}(\text{NH}_3)_2\text{F}_4$. It is decomposed by water into ammonium fluosilicate and silicic acid; and by hydrogen chloride into ammonium chloride and silicon tetrafluoride.

W. Knop mixed alcoholic soln. of hydrofluosilicic acid and ammonia, and obtained a gelatinous mass which when dried had the composition *ammonium heptafluosilicate*, $5\text{NH}_3 \cdot \text{F}_7\text{SiF}_6$, but there is nothing to show whether a mixture or compound is involved. J. C. G. de Marignac mixed normal ammonium fluosilicate with an excess of ammonium fluoride and obtained tetragonal crystals of the composition $3\text{NH}_3 \cdot \text{F}_7\text{SiF}_6$, or *ammonium heptafluosilicate*, $(\text{NH}_4)_3\text{SiF}_7$, which volatilize when heated and without melting; when treated with a soln. of ammonium carbonate, there is a period of quiescence after which bubbles of carbon dioxide are formed, and silicic acid is precipitated. H. Baker prepared the same salt.

A. Scacchi reported the occurrence of ammonium fluosilicate which he called *cryptohalite*, along with ammonium chloride in a Vesuvian fumarole. J. L. Gay Lussac and L. J. Thénard, J. Davy and J. J. Berzelius, etc., made **ammonium fluosilicate**, $(\text{NH}_4)_3\text{SiF}_7$, by neutralizing a soln. of hydrofluosilicic acid with dil. aq. ammonia; a little silicic acid is usually precipitated at first; and if an excess of ammonia is used, still more silicic acid is precipitated. F. Stolba neutralized one-third of the required amount of hydrofluosilicic acid with ammonia, and after mixing that product with the remaining two-thirds of acid, evaporated the filtered soln. for crystallization. J. J. Berzelius made this salt by heating an intimate mixture of ammonium chloride and sodium or potassium fluosilicate in a glass vessel until the required compound sublimes. F. Stolba made it by dissolving iron in hydrofluosilicic acid, treating the conc. soln. with ammonium chloride, and, on cooling the liquid, crystals of ammonium fluosilicate separated. According to J. Davy, if an aq. soln. of the salt be evaporated spontaneously, large, transparent, four-sided prisms are formed, or, according to J. J. Berzelius, six-sided prisms containing water of crystallization; but this is an error, they are anhydrous. According to A. Priess, the crystals are isodimorphous with those of the potassium salt. J. C. G. de Marignac obtained octahedral crystals of the cubic salt, and B. Gossner obtained them by evaporating the aq. soln. above 13° , while below 5° , the aq. soln. furnishes the hexagonal form. If the temp. approaches 12° both forms appear. J. C. G. de Marignac first obtained both the hexagonal and the cubic crystals side by side from a soln. containing an excess of hydrofluoric acid and ammonium fluoride. According to B. Gossner, the axial ratio of the hexagonal crystals is $a : c = 1 : 1.6552$. The symmetry deduced from the corrosion figures is that of the dihexagonal bipyramidal class. R. M. Bozorth showed that the X-radiogram of ammonium fluosilicate is analogous with those of ammonium chloroplatinate, and ammonium and potassium chlorostannates, being like that of calcium fluoride type with each fluorine replaced by an NH_4 -group, and each calcium atom by a fluosilicate group having six fluorine atoms equidistant from the silicon atom in the directions of the axes of the crystal. The length of unit cube containing four mols. is 8.38 \AA ; the shortest distances between the centres of the atoms of silicon and fluorine is 1.72 \AA . The sp. gr. of the cubic crystals is 1.970, according to H. Topsøe and C. Christiansen, and 2.011, according to B. Gossner; F. Stolba gave 1.9489 at 14° , and for the sublimed salt 1.9966 at 17.5° . B. Gossner found the

sp. gr. of the hexagonal crystals to be 2.152. J. J. Berzelius said that the salt decrepitates slightly when heated, and sublimes to form a solid crystalline mass without fusion or decomposition. The index of refraction of the cubic crystals, according to H. Töpsøe and C. Christiansen, is 1.3682 for the *C*-line, 1.3696 for the *D*-line, and 1.3723 for the *F*-line. The double refraction of the hexagonal crystals is feeble and negative. C. Trichot found for the heat of formation, H_2SiF_6 (one mol. in 10 litres of water) + $6\text{NH}_4\text{O}$ (one mol. in 4 litres of water) = $6\text{NH}_4\text{F}_{\text{soln.}}$ + $\text{Si}(\text{OH})_4$ + 56.2 Cals.; $\text{H}_2\text{SiF}_{6\text{soln.}}$ + $2\text{NH}_4\text{O}_{\text{soln.}}$ = $(\text{NH}_4)_2\text{SiF}_{6\text{soln.}}$ + 27.2 Cals.; $\text{H}_2\text{SiF}_6 + 2\text{NH}_{3\text{gas}}$ = $(\text{NH}_4)_2\text{SiF}_{6\text{solid}}$ + 66.8 Cals.; $\text{SiF}_{4\text{gas}} + 2\text{NH}_4\text{F}_{\text{soln.}}$ = $(\text{NH}_4)_2\text{SiF}_{6\text{soln.}}$ + 31.2 Cals.; $\text{SiF}_{4\text{gas}} + 2\text{NH}_4\text{F}_{\text{solid}}$ = $(\text{NH}_4)_2\text{SiF}_{6\text{solid}}$ + 36.6 Cals.; and for the heat of soln. of a mol of $(\text{NH}_4)_2\text{SiF}_6$ in 1200 mols. of water at 7°, 8.4 Cals. J. Davy, and J. J. Berzelius said that the salt is very soluble in water, but does not deliquesce in air. According to F. Stolba, 100 parts of water at 17.5° dissolve 18.6 parts of the salt, and the soln. has a sp. gr. 1.0961; 100 parts of boiling water dissolve 55.5 parts of salt; and one part of salt dissolves in 45.5 parts of 31 per cent. alcohol. J. Davy said that the salt has a strong saline taste and reddens moist litmus. When the soln. is boiled in glass vessels some silica is dissolved and precipitated when the soln. is diluted. The salt is decomposed by sulphuric acid with the evolution of silicon tetrafluoride and hydrofluoric acid; hydrogen chloride has a less energetic action; and hydrochloric acid does not affect the salt. A soln. of potassium hydroxide liberates ammonia and forms potassium fluosilicate, but does not precipitate silica; J. Davy said sodium hydroxide acts similarly, but J. L. Gay Lussac and L. J. Thénard said that all the silica is precipitated. J. Davy found that ammonia forms ammonium fluoride and precipitates all the silica, while J. J. Berzelius, and J. L. Gay Lussac and L. J. Thénard found a portion of the silica remains in soln. F. J. Faktor studied the antiseptic qualities of the salt.

E. Ehler and E. Schott³ precipitated small crystals of **hydrazine fluosilicate**, $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SiF}_6$, by adding alcohol to a mixture of equi-molar proportions of a 50 per cent. aq. soln. of hydrazine hydrate and 20 per cent. hydrofluosilicic acid. The salt melts with decomposition at 186°; it is readily soluble in water and sparingly soluble in methyl or ethyl alcohol; and when heated in vacuo, it yields silicon tetrafluoride and hydrazine dihydrofluoride. They also made crystals of **hydroxylamine fluosilicate**, $(\text{NH}_2\text{OH})_2\text{H}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$, adding 16 per cent. aq. hydrofluosilicic acid to a 25 per cent. aq. soln. of hydroxylamine and allowing the mixture to evaporate. The salt crystallizes from boiling methyl alcohol in scales, and is almost insoluble in alcohol, but dissolves readily in water.

J. J. Berzelius⁴ first prepared lithium fluosilicate by evaporating an aq. soln. of the salt obtained by the action of the acid on an aq. soln. of a lithium salt. F. Stolba evaporated a soln. of lithium carbonate or acetate in a small excess of hydrofluosilicic acid, and obtained crystals of **dihydrated lithium fluosilicate**, $\text{Li}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$; and C. Trichot obtained the same salt by the action of silicon tetrafluoride on water having lithium fluoride in suspension. The potassium salt was found by A. Cossa in the fumaroles of the Vulcano crater in one of the Lipari Islands, and he called the mineral *hieratite*—from Hieras, the Greek name of the crater. J. J. Berzelius noted that a detonation occurs when a mixture of silicon and potassium hydrofluoride is heated. He also said that molten sodium or potassium fluoride dissolves silica, but does not give off silicon tetrafluoride when heated to a high temp. Gebrüder Siemens made the alkali fluosilicates by mixing the alkali chloride and silica into a thin paste with water, and adding hydrofluoric acid. H. Howard patented the preparation of alkali fluosilicate from phosphatic rocks by treating the sulphuric acid soln. with a quantity of an alkali soln. insufficient to convert the phosphoric acid in soln. into the mono-alkali salt, and the resulting precipitate of alkali fluosilicate separated. The product is decomposed by water with the separation of silica. H. Schiff and E. Bechi obtained a glassy mass which they suggested contained *potassium oxyfluosilicate*, $2\text{KF} \cdot \text{SiO}_2$, or $\text{KF} \cdot \text{SiO}_2$.

He also said that a mixture of potassium fluoride and potassium silicate, $K_2Si_2O_5$, forms a fusible mass. C. W. Scheele made **potassium fluosilicate**, K_2SiF_6 , and **sodium fluosilicate**, Na_2SiF_6 , by crystallization from a mixture of hydrofluosilicic acid and an aq. soln. of a potassium or sodium salt. According to J. J. Berzelius, the alkali salt separates very slowly from the soln., and it is at first scarcely visible; afterwards, it produces prismatic colours in the liquid, and is finally deposited as a transparent, gelatinous, iridescent mass, which dries on the filter to a white powder. The evaporation of the sat. aq. soln. furnishes small six-sided prisms, or rhombohedral crystals. G. Cesaro observed that crystals of the hexagonal sodium salt were developed by the prolonged action of hydrofluosilicic acid on glass; and R. Kraut observed tetragonal (perhaps hexagonal) doubly refracting crystals of the potassium salt as a by-product in the preparation of perchloric acid by the hydrofluosilicic acid process. J. J. Berzelius observed that when sodium hydrofluoride, $NaHF_2$, is digested with silicic acid, sodium fluosilicate and fluoride are formed. Here is reaction between an acid and an acid salt which produces a salt with an alkaline reaction. The fluorine compounds generated during the manufacture of fertilizers are not always allowed to escape as injurious fumes from the chimney of the factory, but they are directed through a series of wooden chambers where they are exposed to a spray of water which converts the fluosilicon compounds into hydrofluosilicic acid. This is then converted into sodium fluosilicate.

F. Stolba obtained potassium fluosilicate by adding sodium fluosilicate to an aq. soln. of a potassium salt. He also found potassium fluoride is decomposed when heated with hydrofluosilicic acid; that sodium fluosilicate is formed when hydrofluosilicic acid is treated with sodium chloride; and that silicic acid does not react with a boiling soln. of potassium fluoroborate, but when a soln. of potash water-glass is mixed with hydrochloric acid and potassium fluoroborate, potassium fluosilicate is incompletely precipitated. C. Truchot obtained potassium fluosilicate by the action of silicon tetrafluoride on a soln. of potassium fluoride. A. F. Meyerhofer made it from a mixture of potassium fluoride, silica, and hydrochloric acid with or without calcium fluoride; from potassium chloride, calcium fluoride, silica, and hydrochloric acid; from potassium chloride, silicon tetrafluoride, calcium fluoride, and a small proportion of acid; or from potassium silicate, calcium fluoride, and hydrochloric acid. R. Bunsen made **rubidium fluosilicate**, Rb_2SiF_6 , as an opalescent powder by adding a hydrofluosilicic acid to a soln. of a rubidium salt; and F. Stolba, by treating an aq. soln. of rubidium alum with cupric fluosilicate, and washing the product by decantation. K. Preis obtained **cesium fluosilicate**, Cs_2SiF_6 , in octahedral crystals, by mixing an aq. soln. of cesium chloride with cupric fluosilicate, and adding alcohol; or in cubic crystals, by evaporating an aq. soln. of the salt.

Dihydrated lithium fluosilicate furnishes short prismatic crystals belonging to the monoclinic system which, according to J. C. G. de Marignac, have the axial ratios $a : b : c = 1.235 : 1 : 2.160$. The crystals of the sodium salt were stated by J. C. G. de Marignac, G. Cesaro, E. Bertrand, and F. Stolba to belong to the hexagonal system; and the first named gave for the axial ratio $a : c = 1 : 0.763$. According to K. Preis, J. C. G. de Marignac, and B. Gossner, the crystals of the potassium salt are dimorphous—cubic and hexagonal. K. Preis reported that the hexagonal crystals were found, together with calcium sulphate, as a deposit in a large basin containing phosphoric acid of sp. gr. 1.161 prepared from phosphorites in the chemical works at Pecky, Bohemia. Small, regular crystals of the same compound were found, together with the hexagonal form, with the axial ratio $a : c = 1 : 0.8898$. B. Gossner gave $1 : 1.6006$. According to K. Preis, the potassium and ammonium salts are isodimorphous. The cubic form is obtained in octahedra by slowly cooling a hot aq. soln. of the salt; as already mentioned, it also occurs in nature as the mineral *hieratite*. The cubic crystals were obtained by J. J. Berzelius; and B. Gossner obtained them in thin plates by drying the soln. at about 10° . F. Stolba obtained cubic crystals of rubidium fluosilicate having octahedral

and dodecahedral faces. B. Gossner said that the rubidium salt, like the potassium salt, occurs in two forms; the hexagonal form being obtained by drying a soln. at about 16° . K. Preis obtained octahedral crystals of the cesium salt belonging to the cubic system. H. Töpsøe gave 2.44 for the sp. gr. of lithium fluosilicate, and F. Stolba, 2.36 at 12° for the hydrate, and 2.88 at 12° for the anhydrous salt. He also gave 2.7547 at 17.5° for the sodium salt. B. Gossner gave 2.746 for the sp. gr. of the cubic crystals of the potassium salt, and 3.081 for the hexagonal crystals. F. Stolba gave 2.665 for the sp. gr. of the cubic potassium salt at 17.5° , and 3.338 for the rubidium salt at 20° . K. Preis gave 3.3756 for the sp. gr. of the cesium salt at 17° . F. Stolba and J. C. G. de Marignac observed that dihydrated lithium fluosilicate loses water when heated in air, and it becomes anhydrous at 100° . F. Stolba found that below red heat, the lithium salt gives off silicon tetrafluoride; or, if steam be present, hydrofluosilicic acid. J. J. Berzelius saw that both the sodium and potassium salts fuse at a red heat, and decompose at a higher temp.; the former more readily than the latter. The evolution of silicon tetrafluoride is attended by the boiling of the fused mass, which becomes more and more refractory, until, after a prolonged ignition, there remains potassium fluoride holding some silica in soln. According to F. Bothe, the decomposition into silicon tetrafluoride and alkali fluoride is incomplete. The heats of formation estimated by C. Truchot are: $\text{SiF}_{4\text{gas}} + 2\text{LiF}_{\text{soln.}} = \text{Li}_2\text{SiF}_{6\text{soln.}} + 27 \text{ Cals.}$; $\text{SiF}_{4\text{gas}} + 2\text{LiF}_{\text{solid}} = \text{Li}_2\text{SiF}_{6\text{solid}} + 25.16 \text{ Cals.}$; $\text{SiF}_{4\text{gas}} + 2\text{NaF}_{\text{soln.}} = \text{Na}_2\text{SiF}_{6\text{solid}} + 36.6 \text{ Cals.}$; $\text{SiF}_{4\text{gas}} + 2\text{NaF}_{\text{solid}} = \text{Na}_2\text{SiF}_{6\text{solid}} + 25.4 \text{ Cals.}$; $\text{H}_2\text{SiF}_{6\text{soln.}} + 2\text{LiOH}_{\text{soln.}} = \text{Li}_2\text{SiF}_{6\text{soln.}} + 28.6 \text{ Cals.}$; $\text{H}_2\text{SiF}_{6\text{soln.}} + 6\text{NaOH}_{\text{soln.}} = 6\text{NaF}_{\text{solid}} + \text{Si(OH)}_4\text{solid} + \text{Aq} + 66 \text{ Cals.}$; A. Guntz gave $\text{H}_2\text{SiF}_{6\text{soln.}} + 2\text{NaOH} = \text{Na}_2\text{SiF}_{6\text{solid}} + 31.6 \text{ Cals.}$; J. Thomsen found that the heat of neutralization of hydrofluosilicic acid by sodium hydroxide is nearly the same as that of hydrochloric acid. C. Truchot found $\text{SiF}_{4\text{gas}} + 2\text{KF}_{\text{soln.}} = \text{K}_2\text{SiF}_{6\text{solid}} + 22.8 \text{ Cals.}$; $\text{SiF}_{4\text{gas}} + 2\text{KF}_{\text{solid}} = \text{K}_2\text{SiF}_{6\text{solid}} + 26.4 \text{ Cals.}$; $\text{H}_2\text{SiF}_{6\text{soln.}} + 2\text{KOH}_{\text{soln.}} = \text{K}_2\text{SiF}_{6\text{solid}} + 22 \text{ Cals.}$; $3\text{SiF}_{4\text{gas}} + 4\text{KOH}_{\text{soln.}} = 2\text{K}_2\text{SiF}_{6\text{solid}} + \text{Si(OH)}_4\text{solid} + 82.9 \text{ Cals.}$ The heat of soln. of anhydrous lithium fluosilicate is +1.840 Cals. G. Cesaro gave for the indices of refraction of dihydrated lithium fluosilicate $\omega=1.300$ and $\epsilon=1.296$. For sodium fluosilicate, L. Raiteri gave 1.3112 for $\lambda=677$; 1.3125 for $\lambda=589$; 1.3132 for $\lambda=535$; and 1.3146 for $\lambda=458$; and for potassium fluosilicate, 1.339 for $\lambda=677$. B. Gossner found the cubic form of potassium and rubidium fluosilicates singly refracting, and the hexagonal form had a feeble negative double refraction. The electrolysis of fused potassium fluosilicate was found by F. Ullik to give amorphous silicon.

H. Behrens and P. D. C. Kley recommended the ready formation of crystals of sodium and potassium fluosilicates as microchemical tests for the alkalis in question. J. C. G. de Marignac found the solubility of the dihydrated lithium fluosilicate in 100 parts of water at 17° to be 75 parts; and C. Truchot, 52.6 parts. J. J. Berzelius said that the sodium salt is much more soluble in water, particularly hot water, than the potassium salt; and F. Stolba found 100 parts of water at 17.5° dissolve 0.70 part of salt, and 2.46 parts in boiling water; supersaturation readily occurs. It will be observed that the fluosilicates of cesium, rubidium, potassium, sodium, and barium are but sparingly soluble in water, the others are fairly soluble;

Ca_2SiF_6	Rb_2SiF_6	K_2SiF_6	Na_2SiF_6	Li_2SiF_6	$(\text{NH}_4)_2\text{SiF}_6$
0.60	0.16	0.12	0.65	73	18.6

J. J. Berzelius said that an excess of acid does not increase the solubility of the sodium salt; and C. Truchot that this salt is not soluble in a soln. of sodium fluoride. F. Stolba also found the solubility is much reduced in the presence of sodium chloride. C. W. Scheele, and J. E. Gay Lussac and L. J. Thenard said that potassium fluosilicate is sparingly soluble in cold water, but is more freely dissolved by hot water. F. Stolba found that 100 parts of water dissolve 0.12 part of the potassium salt at 17.5° , and 0.96 part in boiling water. The presence of potassium chloride, sulphate, or nitrate lowers the solubility, and this the more the greater the pro-

portion of foreign salt. Aq. soln. of ammonium chloride and hydrochloric acid augment the solubility of potassium fluosilicate. F. Stolba found that 100 parts of water dissolve about 0.16 part of rubidium fluosilicate at 20°, and 1.37 parts in boiling water. He added that the salt is more soluble in acidulated water. K. Preis found that 100 parts of water dissolve 0.60 part of caesium fluosilicate, and more is dissolved by boiling water. F. Stolba said lithium fluosilicate is soluble in aq. alcohol; 100 parts of 46 per cent. alcohol dissolve 4 parts of the dihydrated fluosilicate, and 100 parts of 79 per cent. alcohol, 0.4 part. M. Pierrat found for solubility in

Alcohol	94.7	42.4	27.3	15.9	8.7	0 per cent.
Salt	0.0096	0.05	0.09	0.21	0.46	0.9 grm. per litre

H. Rose said that alcohol precipitates sodium or potassium fluosilicate completely from its aq. soln.; and K. Preis, that caesium fluosilicate is not soluble in alcohol. M. Pierrat measured the electrical conductivity of aq. soln. of the potassium salt.

The aq. soln. of lithium fluosilicate has an acid reaction. According to J. J. Berzelius, potassium fluosilicate is decomposed by treatment with cold potassium hydroxide or carbonate; but when boiled with the latter, carbon dioxide is evolved and the salt is decomposed with the deposition of gelatinous silica and the formation of potassium fluoride. F. Stolba showed that the reaction: $\text{K}_2\text{SiF}_6 + 4\text{KOH} = 6\text{KF} + \text{Si(OH)}_4$ is quantitative and can be used for the volumetric determination of the alkali hydroxide, or the alkali fluosilicate, or even hydrofluosilicic acid. The process has been discussed by L. Schucht, and S. Kohn. If an acid be added to the mixture of potassium fluoride and silicic acid, the potassium fluosilicate is regenerated. C. W. Scheele found that every trace of lime can be removed from a soln. of calcium hydroxide by treatment with potassium fluosilicate; and F. Stolba showed that when a soln. of the potassium salt is boiled with calcium carbonate the reaction is symbolized: $\text{K}_2\text{SiF}_6 + 2\text{CaCO}_3 = 2\text{KF} + 2\text{CaF}_2 + \text{SiO}_2 + 2\text{CO}_2$, and if an excess of the alkali salt be present, some potassium carbonate is formed. When a soln. of potassium fluosilicate is boiled with an eq. amount of magnesium oxide, the reaction is symbolized: $\text{K}_2\text{SiF}_6 + 2\text{MgO} = 2\text{KF} + 2\text{MgF}_2 + \text{SiO}_2$, and if an excess of magnesia is used, some potassium hydroxide is formed. J. J. Berzelius found that with sulphuric acid, potassium fluosilicate furnishes silicon tetrafluoride, and hydrogen fluoride. An aq. soln. of boric acid precipitates silica, but the reaction is far from complete. J. J. Berzelius said that when heated with potassium, silicon and potassium fluorides are formed; and with iron at a white heat, potassium and iron fluorides and iron silicide are formed; while, according to H. N. Warren, with aluminium in the presence of potassium chloride and carbonate at a white heat, graphitic silicon is formed. M. A. Razukin studied the reversible adsorption of sodium fluosilicate by charcoal, colloidal silica, and alumina; and he measured the electrical conductivity of aq. soln. of the salt. R. T. Thomson, and A. W. M. Robson examined the antiseptic properties of sodium fluosilicate; and S. Marcovitch, its use as an insecticide.

J. J. Berzelius⁶ prepared cuprous fluosilicate, Cu_2SiF_6 , by the action of hydrofluosilicic acid on cuprous oxide. F. Stolba obtained this compound when hydrofluosilicic acid is heated in a copper vessel in the preparation of cupric fluosilicate—*vide infra*. According to J. J. Berzelius, the product resembles red cuprous fluoride, and when exposed to moist air it is decomposed, forming cupric fluoride and cuprous hydroxide, and finally cupric oxyfluoride. When strongly heated, it fuses, and gives off silicon tetrafluoride. J. J. Berzelius also found that when a soln. of cupric oxide in hydrofluosilicic acid is evaporated spontaneously in air, transparent octahedra and six-sided prisms of hexahydrated cupric fluosilicate, $\text{CuSiF}_6 \cdot 6\text{H}_2\text{O}$, are formed; or, according to J. C. G. de Maignac, by cooling a fairly conc. soln. F. Stolba gradually added cupric carbonate to hydrofluosilicic acid, heated in a copper vessel; the soln. was conc. a little, and filtered so as to remove the separated silica; the filtrate was evaporated almost to dryness; and washed with a little

water. The product was dissolved in water and evaporated at 10° – 22° in a platinum dish, or in a glass or porcelain dish coated with paraffin wax. W. Knop and W. Wolf passed silicon tetrafluoride into 93 per cent. alcohol, carrying in suspension precipitated cupric hydroxide. The product was washed a few times with alcohol. If the cupric hydroxide be in excess, an insoluble green basic salt is formed. F. Stolba, and L. Balbiano boiled a mol of barium fluosilicate with a soln. containing a mol of cupric sulphate, and in about 15 mins. added a little more barium fluosilicate to make up for that which is entangled with the precipitated barium sulphate. The filtrate was then evaporated as previously indicated for crystallization. A. G. Betts made cupric fluosilicate by treating finely divided copper with ferric fluosilicate, or with hydrofluosilicic acid and lead peroxide.

The deep blue octahedral or prismatic crystals were found by J. C. G. de Marignac to belong to the trigonal system, and to have the axial ratio $a : c = 1 : 0.5395$, and $\alpha = 110^{\circ} 34'$. H. Töpsøe and C. Christiansen gave 2.207 for the sp. gr.; B. Gossner gave 2.222; and F. Stolba, 2.1576 at $19^{\circ}/19^{\circ}$. J. A. Groshens made some observations on the density of this salt. H. Töpsøe and C. Christiansen found the indices of refraction $\omega = 1.4071$ and $\epsilon = 1.4062$ for the C-line; $\omega = 1.4092$ and $\epsilon = 1.4080$ for the D-line; and $\omega = 1.4138$ and $\epsilon = 1.4124$ for the F-line. The double refraction is feeble and negative. J. J. Berzelius observed that the crystals effloresce on exposure to air, becoming light blue and opaque and forming the tetrahydrate by the loss of 2 mols of water. F. Stolba showed that in moist air, the crystals are deliquescent; and when heated to 100° , the salt gradually loses 14.5 per cent. of water in 24 hrs.; at 125° , the salt loses 56.3 per cent. of water and silicon tetrafluoride in 4 hrs., and the residue is no longer completely soluble in water. J. C. G. de Marignac found that after calcination, 29.25 per cent. remains probably as oxyfluoride. L. Balbiano found that the hexahydrate loses 2 mols of water at 90° or in vacuo over sulphuric acid, and is decomposed at 130° – 140° : $\text{CuSiF}_6 \cdot 6\text{H}_2\text{O} = \text{SiF}_4 + \text{HF} + 5\text{H}_2\text{O} + \text{Cu}(\text{OH})\text{F}$. J. J. Berzelius said that the fluosilicate is readily soluble in water, and F. Stolba found that 100 parts of water dissolve 233.6 parts of salt at 17° . At 20° , 100 parts of 62 per cent. alcohol dissolve 5.56 parts of salt; 100 parts of 85 per cent. alcohol, 0.667 part of salt; and 100 parts of 92 per cent. alcohol, 0.162 part of salt. F. Stolba measured the sp. gr. of soln. of cupric fluosilicate. When the sat. soln. in dil. alcohol is warmed, or mixed with conc. alcohol, a heavy, blue, oily liquid separates; and when shaken with an excess of conc. alcohol, a light blue salt approximating $\text{CuSiF}_6 \cdot 5\frac{1}{2}\text{H}_2\text{O}$ separates. J. Schröder said that cupric fluosilicate is insoluble in pyridine. W. Knop and W. Wolf found that when the aq. soln. is treated with zinc or iron, metallic copper is first deposited and hydrogen then appears owing to the decomposition of the silicon tetrafluoride. S. H. C. Briggs showed that with cupric chromate, a soln. is obtained which, on evaporation, gives a mixture of the fluosilicate and oxochromate. As just indicated, tetrahydrated cupric fluosilicate, $\text{CuSiF}_6 \cdot 4\text{H}_2\text{O}$, is formed by driving two mols of water from the hexahydrate; or, according to J. C. G. de Marignac, by evaporating the aq. soln. at 50° . The monoclinic prismatic crystals have the axial ratios $a : b : c = 0.7604 : 1 : 0.5519$, and $\beta = 105^{\circ} 37'$. They are isomorphous with the tetrahydrated cupric fluostannate. According to L. Balbiano, the tetrahydrate absorbs ammonia, but no ammino-derivative of hydrofluosilicic acid is formed. On treating the bright blue product of the reaction with water, a blue mass is left undissolved, consisting of silica and cupric diamminohydroxyfluoride; the latter is soluble in dil. ammonia, and on heating this soln., cupric oxyfluoride is deposited. The action of ammonia on the fluosilicate is therefore: $\text{CuSiF}_6 \cdot 4\text{H}_2\text{O} + 7\text{NH}_3 = \text{CuF} \cdot \text{OH} \cdot 2\text{NH}_3 + 5\text{NH}_4\text{F} + \text{SiF}_2 + \text{H}_2\text{O}$. T. E. Thorpe and J. W. Rodger found that when a soln. of copper sulphate is added to a soln. of the compound of ammonia and thiophosphoryl fluoride, the filtrate from the copper sulphide deposits crystals of copper phosphatofluosilicate, $\text{Cu}_3(\text{PO}_4)_2 \cdot \text{CuSiF}_6$.

According to J. J. Berzelius, the evaporation of a soln. of silver oxide in hydrofluosilicic acid yields crystals of tetrahydrated silver fluosilicate, $\text{Ag}_2\text{SiF}_6 \cdot 4\text{H}_2\text{O}$.

S. Kern obtained the salt as a greyish-white precipitate on adding silver nitrate to hydrofluosilicic acid. J. C. G. de Marignac said that the crystals are rectangular octahedra which melt below 100° , and at the same time lose water with decomposition. J. J. Berzelius said that the crystals deliquesce on exposure to air, and when a soln. of the salt is treated with aq. ammonia, a light yellow, basic salt is precipitated which passes into silver silicate when treated with an excess of ammonia. M. Löb and W. Nernst measured the electrical conductivity of the aq. soln.; and K. Eisenreich found that on electrolysis, rather more silver is deposited than corresponds with the electrochemical eq. H. Hetsch examined the bactericidal action of the salt which has the commercial name *isotachiol*. A number of calcium fluosilicates or calcium aluminium fluosilicates has been reported: for instance, the *zeophyllite* of A. Pelikan⁷ and F. Cornu; with the composition $H_4Ca_4Si_3O_{11}F$, *apophyllite*, *cuspidin*, *lepidolite*, etc. There is the product approximating $CaO.3SiO_2.6CaF_2$, obtained by H. St. C. Deville by heating calcium oxide in a stream of silicon tetrafluoride; and the products obtained in the attempt to synthesize the fluoriferous silicate minerals (*q.v.*) J. J. Berzelius made the normal salt by digesting levigated fluorspar and finely divided silica in hydrofluoric acid, or, according to F. Stolba, in hydrochloric acid. J. J. Berzelius also obtained the salt by saturating hydrofluosilicic acid with calcium carbonate, and evaporating the filtered soln. for crystallization. F. Stolba preferred to use about two-thirds this quantity of carbonate so that some free acid is present; otherwise the calcium fluosilicate is unstable. E. Fleischer obtained calcium fluosilicate from cryolite *vide supra*, hydrofluosilicic acid. The four-sided, obliquely truncated crystals, as J. J. Berzelius described them, are those of **dihydrated calcium fluosilicate**, $CaSiF_6 \cdot 2H_2O$. J. J. Berzelius, and F. Stolba made **dihydrated strontium fluosilicate**, $SrSiF_6 \cdot 2H_2O$, in a similar manner. J. L. Gay Lussac and L. J. Thénard made **barium fluosilicate**, $BaSiF_6$, as a precipitate by mixing hydrofluosilicic acid and barium chloride. At first the soln. remains clear, but small crystals are soon deposited. F. Stolba used a similar process. J. J. Berzelius found that nearly all the barium is precipitated. If the soln. are mixed at a boiling heat, the crystals are somewhat larger, but they are still microscopic. According to E. Fleischer, barium acetate or butyrate precipitates a mixture of barium fluoride and fluosilicate from hydrofluosilicic acid. A mixture of silica and barium fluoride is transformed by hydrobromic acid into barium fluosilicate, and conversely, hydrobromic acid and barium fluosilicate furnish hydrofluosilicic acid. E. Fleischer made barium fluosilicate from cryolite—*vide supra*, hydrofluosilicic acid.

J. J. Berzelius described the crystals of the barium salt as prisms with acute summits, and those of the dihydrated strontium salt as "rhombohedral prisms with dihedral summits resting on the two acute lateral edges." K. Haushofer said that the crystals of the barium salt are rhombohedral; and H. Bohrens uses the crystals in his microchemical test. J. C. G. de Marignac said that the dihydrated strontium salt shows monoclinic prisms with axial ratios $a : b : c = 1.179 : 1 : 1.232$ and $\beta = 110^{\circ} 22'$, and he added that the crystals of the dihydrated calcium salt are probably similar. K. Haushofer said the six-sided plates of dihydrated calcium fluosilicate are probably isomorphous with the dihydrated strontium salt. F. Fouqué and A. Michel-Lévy made some observations on the crystals. H. Töpsøe gave 2.252 for the sp. gr. of the hydrated calcium salt; F. Stolba, 2.99 at 17.5° for the hydrated salt; and 4.277 at 21° for the anhydrous barium salt. When heated, these fluosilicates lose their combined water and become opaque, and, as shown by J. J. Berzelius, C. Truchot, and others, on calcination silicon tetrafluoride is evolved and the fluoride remains. Calcium fluosilicate is partly dissolved and partly decomposed by water, forming a precipitate of silicic acid and calcium fluoride, and a soln. of hydrofluosilicic acid. As J. J. Berzelius showed, the salt is soluble in hydrofluosilicic acid without decomposition, and the soln., on evaporation, yields crystals of the original salt. L. Schucht and W. Möller showed that some colloidal calcium fluoride and silicic acid remain in the liquid when calcium fluosilicate is decomposed

by water. J. J. Berzelius noted that strontium fluosilicate is also partially decomposed by water, forming a basic salt, and a liquid containing an excess of acid. F. Stolba said that cold water dissolves the salt completely but not without decomposition, and, added J. C. G. de Marignac, the soln. when heated furnishes some strontium fluoride. J. J. Berzelius said that barium fluosilicate is very sparingly soluble in cold water, but dissolves more freely in hot water. C. R. Fresenius found that at ordinary temp., 100 parts of water dissolve 0.0263 part of salt. F. Stolba found that 100 parts of water dissolve 0.0268 part of salt at 17.5° ; 0.0302 part at 21° ; and 0.0351 part at the boiling temp. J. J. Berzelius said that hydrochloric acid dissolves calcium fluosilicate without decomposition, but when the soln. is evaporated, hydrofluosilicic acid is given off, and calcium chloride is formed; and when the soln. is treated with aq. ammonia, calcium fluoride and silica are precipitated, while ammonium chloride and fluoride remain in soln. C. F. Rammelsberg said that the precipitate might be a fluoxysilicate, $3\text{CaF}_2 \cdot \text{SiO}_2$. J. J. Berzelius said that strontium fluosilicate is readily soluble in acidulated water without decomposition, and, added C. R. Fresenius, hydrochloric acid augments the solubility of strontium fluosilicate, and that hydrofluosilicic acid does not interfere. J. J. Berzelius said that hydrochloric acid does not increase the solubility of barium fluosilicate, but this is not right, since C. R. Fresenius found that 100 parts of water acidulated with hydrochloric acid dissolve 0.136 part of barium fluosilicate at ordinary temp., and some barium chloride is formed; and F. Stolba, that 100 parts of 4.25 per cent. hydrochloric acid at 22° dissolve 0.205 part of barium fluosilicate. C. R. Fresenius said that the solubility of barium fluosilicate is increased in the presence of nitric acid, and F. Stolba found that 100 parts of 8 per cent. nitric acid dissolve 0.368 part of salt at 22° . E. Fleischer said that calcium fluosilicate readily dissolves in 60 per cent. alcohol; and C. R. Fresenius, that the strontium salt is soluble in alcohol, and this the more the less conc. the alcohol. The latter also said that the barium salt is almost insoluble in alcohol, so that the properties have been employed in the separation of barium and strontium. G. Tammann found that 100 parts of 50 per cent. alcohol dissolve 0.00256 part of barium fluosilicate, and, added C. R. Fresenius, the presence of hydrochloric acid diminishes the solubility, so that the addition of hydrofluosilicic acid precipitates some barium fluosilicate from an alcoholic or acidic soln. J. W. Mallet found that 100 parts of a sat. soln. of ammonium chloride dissolve 0.234 part of barium fluosilicate, and the solubility is diminished by diluting the soln. F. Stolba found that at 22° , 100 parts of a sat. soln. of ammonium chloride dissolved 0.327 part of the barium salt; and 100 parts of a 15 per cent. soln., 0.277 part. He also found that 100 parts of a boiling sat. soln. of sodium chloride dissolved 0.177 part of barium salt; a boiling 10 per cent. soln., 0.286 part, and a 10 per cent. soln. at 20° , 0.0458 part. When the boiling sat. soln. is cooled, some sodium fluosilicate crystallizes out. G. Tammann said that acetic and butyric acids have scarcely any action on barium fluosilicate at 100° ; ammonium phosphate forms some ammonium fluosilicate and barium phosphate. T. Scheerer and E. Drechsel found that when a mixture of calcium fluosilicate, calcium chloride, and water is heated in a sealed tube at 250° , crystals of calcium fluoride are formed. J. J. Berzelius showed that when a mixture of barium salt and sulphuric acid is heated barium sulphate is formed; and F. Stolba, that when mixed with ammonium chloride and calcined, a mixture of barium chloride and fluoride remains; and that a soln. of potassium hydroxide decomposes the soln. easily, and the solid salt with difficulty; soln. of sulphates decompose barium fluosilicate completely; and alkali carbonates form barium carbonate.

According to J. J. Berzelius,⁸ the evaporation of an aq. soln. of beryllium oxide in hydrofluosilicic acid furnishes a syrupy liquid which becomes opaque and white, and if an excess of acid is used, the product which remains after the volatilization of the acid is a hard, white, porcelainic mass readily soluble in water. The beryllium fluosilicate so obtained is decomposed by heat. J. C. G. de Marignac, and A. Atterberg also obtained the salt as an uncrystallizable syrup. C. Chabrie

obtained crystals of the salt by the prolonged boiling of a soln. of 0.5 gm. of freshly precipitated beryllium hydroxide in a large excess (200 grms.) of hydrofluosilicic acid, and cooling.

A number of fluobiferous magnesium silicates occur in nature—e.g. humite, preectite, chondrodite, clinohumite, etc.; and A. Duboin,⁹ by fusing a mixture of silica, magnesia, and potassium fluoride obtained two products which he regarded as *potassium magnesium fluosilicates*, $\text{Mg}_2\text{SiO}_2\text{F}_4 \cdot 4\text{K}_2\text{MgSi}_3\text{O}_8$, and $\text{K}_4\text{SiO}_2\text{F}_4 \cdot \text{Mg}_3\text{K}_4\text{Si}_{10}\text{O}_{25}$, but there is little evidence of the chemical individuality of these substances.

J. J. Berzelius obtained a transparent, yellowish, gum-like mass by evaporating a soln. of magnesia in hydrofluosilicic acid. The composition corresponded with **magnesium fluosilicate**, MgSiF_6 . F. Stolba made crystals of **hexahydrated magnesium fluosilicate**, $\text{MgSiF}_6 \cdot 6\text{H}_2\text{O}$, by adding hydrofluosilicic acid to a slurry made by rubbing magnesia with water; evaporating to a syrupy mass; dissolving in water; filtering; and evaporating spontaneously in a platinum dish. He also mixed a conc. soln. of magnesium acetate with hydrofluosilicic acid and alcohol, and quickly filtered the soln., since on standing silica is deposited. P. Engelskirchen said that to obtain good crystals it is necessary to finish the evaporation of the conc. soln. in a desiccator at ordinary temp. A. F. Meyerhofer made the fluosilicate from a mixture of silica, calcium fluoride, magnesium sulphate, and sulphuric acid. F. Stolba, and H. Topsøe and C. Christiansen described the crystals as transparent colourless rhombohedra belonging to the trigonal system with the axial ratio $a:c=1:0.5174$, and $\alpha=112^\circ 9'$; and, added P. Engelskirchen, isomorphous with the corresponding fluostannate and flustitanate. F. Stolba gave $n_D^{17.8} 1.788$ for the sp. gr. at 17.5° , and H. Topsøe, 1.761. The indices of refraction by H. Topsøe and C. Christiansen are $\omega=1.3427$ and $\epsilon=1.3587$ for the *C*-line; $\omega=1.3439$ and $\epsilon=1.3602$ for the *D*-line; and $\omega=1.3473$ and $\epsilon=1.3634$ for the *F*-line. The double refraction is positive. F. Stolba found the crystals effloresce in dry air or over sulphuric acid; at $100^\circ\text{--}120^\circ$, water and almost all the silicon tetrafluoride are expelled. He also noted that 100 parts of water at 17.5° dissolve 64.8 parts of salt to form a liquid of sp. gr. 1.235; when warmed, the soln. becomes opalescent owing to the separation of colloidal silica, but on cooling, the soln. becomes almost clear again. P. Engelskirchen found that hydrofluoric acid decomposes the salt into magnesium fluoride and hydrofluosilicic acid.

J. J. Berzelius¹⁰ evaporated a soln. of zinc oxide in hydrofluosilicic acid, and obtained transparent, colourless, prismatic crystals of **hexahydrated zinc fluosilicate**, $\text{ZnSiF}_6 \cdot 6\text{H}_2\text{O}$. J. J. Berzelius' analysis gave $7\text{H}_2\text{O}$. The trigonal crystals, according to J. C. G. de Marignac, have the axial ratio $a:c=1:0.5173$, and $\alpha=112^\circ 10'$; and, according to B. Gössner, they are isomorphous with the corresponding compounds of chromium, cobalt, and nickel, and with the nickel salt, zinc fluosilicate forms a continuous series of mixed crystals. W. Stortenbeker also found that the hexahydrated zinc fluosilicate and fluostannate form mixed crystals. The sp. gr. found by H. Topsøe is 2.104, and by B. Gössner, 2.139. H. Topsøe and C. Christiansen gave for the indices of refraction $\omega=1.3808$ and $\epsilon=1.3938$ for the *C*-line; $\omega=1.3824$ and $\epsilon=1.3956$ for the *D*-line; and $\omega=1.3860$ and $\epsilon=1.3992$ for the *F*-line. The double refraction is positive. J. J. Berzelius said that the salt is permanent in air and easily soluble in water. When heated in air, G. Gallo found that silicon fluoride escapes, and anhydrous zinc fluoride remains. The corresponding **hexahydrated cadmium fluosilicate**, $\text{CdSiF}_6 \cdot 6\text{H}_2\text{O}$, was obtained by J. J. Berzelius in long, transparent, colourless prisms by a process similar to that employed for the zinc salt. P. Engelskirchen evaporated a soln. of cadmium carbonate in hydrofluosilicic acid, and obtained the salt by precipitation with alcohol, or by spontaneous evaporation. The hexagonal crystals are easily soluble in water, and in 50 per cent. alcohol; they effloresce in warm air, but in ordinary air they are fairly stable.

J. J. Berzelius¹¹ dissolved freshly precipitated and moist mercurous oxide in hydrofluosilicic acid, and on evaporating the pale yellow liquid obtained small

crystals of **dihydrated mercurous fluosilicate**, $\text{Hg}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$. R. Finkener, and C. Lemaire crystallized a soln. of mercurous carbonate in hydrofluosilicic acid, washed the crystals with a little water; pressed them between bibulous paper, and dried them over sulphuric acid. The clear crystals dissolve sparingly in water without decomposition. J. J. Berzelius said the crystals dissolve more readily in acidulated water, and that the salt is precipitated by hydrochloric acid. J. J. Berzelius obtained crystals of what was probably **hexahydrated mercuric fluosilicate**, $\text{HgSiF}_6 \cdot 6\text{H}_2\text{O}$, from a conc. soln. of mercuric oxide in hydrofluosilicic acid, by evaporating until crystals begin to appear, and continuing the evaporation at 15° . The colourless rhombohedral crystals were found by R. Finkener to be very unstable. They deliquesce in air, and effloresce over sulphuric acid. They are almost completely soluble in water, and, as shown by J. J. Berzelius, and C. Lemaire, the crystals are resolved by water into an acid soln., and a yellow basic salt, which, according to R. Finkener, corresponds with **trihydrated mercuric oxyfluosilicate**, $\text{HgO} \cdot \text{HgSiF}_6 \cdot 3\text{H}_2\text{O}$. The basic salt, said J. J. Berzelius, is blackened by ammonia, and afterwards restored to a lighter colour by water; the salt is completely soluble in acidulated water, forming an acid soln. which by spontaneous evaporation forms a syrupy liquid, but does not crystallize until it has been evaporated by heat.

A number of fluoriferous aluminium silicates occur in nature—e.g. topaz, lepidolite, zunyite, etc. J. J. Berzelius¹² dissolved hydrated alumina in hydrofluosilicic acid, and obtained a gelatinous mass of presumably **aluminium fluosilicate**, $2\text{AlF}_3 \cdot 3\text{SiF}_4$, or $\text{Al}_2(\text{SiF}_6)_3$. H. St. C. Deville dissolved calcined alumina and obtained a similar product. C. Chabrie found that by the prolonged boiling of 0.5 gm. of aluminium chloride or the recently precipitated hydrate, with 200 grms. of the acid, a distinctly crystalline fluosilicate separates on cooling, which does not alter on drying at 100° . Aluminium fluoride treated by this method yields a similar compound. H. St. C. Deville said that the addition of an excess of alumina to the soln. results in the precipitation of silica; and with sodium chloride, sodium fluosilicate and aluminium chloride are formed. A. Frank recommended this salt for use in the sterilization of potable waters.

The **rare earth fluosilicates** are obtained as gelatinous precipitates on adding an alkali fluosilicate to a neutral soln. of a rare earth salt; but in the presence of mineral acids, they are not precipitated in the cold, and on boiling, the metals cerium and scandium are precipitated as fluorides owing to the hydrolysis of the fluosilicates: $\text{Sc}_2(\text{SiF}_6)_3 + 6\text{H}_2\text{O} = 2\text{ScF}_3 + 3\text{SiO}_2 + 12\text{HF}$. The yttrium elements are held in soln. by the mineral acid. Thus, J. J. Berzelius showed that **yttrium fluosilicate** is insoluble in water, but is dissolved by water containing hydrochloric acid, and on evaporating the liquid, the fluosilicate is again precipitated. F. Stolba prepared **cerium fluosilicate**, **lanthanum fluosilicate**, and **didymium fluosilicate** in this manner. He said that the precipitates are very sparingly soluble in water, acetic and fluosilicic acids, but are readily dissolved by mineral acids. The precipitates are also insoluble in alcohol. R. J. Meyer¹³ based a method for separating scandia from the rare earths on the property possessed by **scandium fluosilicate** of decomposing and precipitating as scandium fluoride when the soln. is boiled.

By evaporating a soln. of thallous carbonate in hydrofluosilicic acid, F. Kuhlmann¹⁴ obtained crystals of **dihydrated thallous fluosilicate**, $\text{Tl}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$; G. Werther likewise obtained regular octahedra, or six-sided plates. J. Nickles also obtained the salt by the action of hydrochloric acid, containing some silica, on thallium. The salt is soluble in water, the soln. has an acid reaction, and slowly deposits silica. The evaporation of the aq. soln. gives the original salt. When aq. ammonia is added to the aq. soln., there is formed a precipitate which soon becomes crystalline, and which cannot be freed from thallium by washing with aq. ammonia. G. Werther thinks that the precipitate is a basic fluosilicate or an amino-compound.

P. Engelskirchen¹⁵ found that freshly precipitated titanium hydroxide readily

dissolves in hydrofluosilicic acid, and on evaporating the soln., a syrupy liquid which does not crystallize is obtained. The product may be an impure **titanium fluosilicate**. J. J. Berzelius obtained white pearly crystals of **zirconium fluosilicate** from a soln. of the hydroxide in hydrofluosilicic acid. M. Weibull, and P. Engelskirchen made observations on the product, but without establishing definitely the nature of the compound. J. J. Berzelius said that it is very soluble in water, and that the soln. becomes turbid on boiling owing to the decomposition of part of the solute. P. T. Cleve reported a basic salt, **thorium dihydroxyfluosilicate**, approximating $\text{Th}(\text{OH})_2\text{SiF}_6$, by the action of hydrofluosilicic acid on thorium hydroxide. A pulverulent mass of needle-like crystals is formed which gives off acid vapours when dried over sulphuric acid.

J. J. Berzelius reported the formation of long prisms of **stannic fluosilicate** by evaporating a soln. of stannous oxide in hydrofluosilicic acid, and he said that the stannous oxide is converted into stannic oxide and precipitated along with the silica. J. J. Berzelius first assumed that the stannous salt is formed, but later regarded it as a stannic salt. P. Engelskirchen also prepared an impure salt from a soln. of stannous hydroxide in hydrofluosilicic acid.

J. J. Berzelius said that a soln. of lead oxide in hydrofluosilicic acid dries up to a transparent gum of **lead fluosilicate** which is readily soluble in water. A. and L. Lefranc and A. Vivien obtained the fluosilicate by dissolving lead in the acid; W. Mills dissolved lead oxide or hydroxide in the acid, and mixed the filtered soln., which was slightly acid, with lead nitrate. The precipitated fluosilicate was washed and dried. T. Cobley mixed hydrofluosilicic acid with lead acetate or other lead salt and obtained lead fluosilicate; and the same salt was made by the action of hydrofluosilicic acid—gas or aq. soln.—on lead silicate; or by heating a mixture of lead silicate, calcium fluoride or cryolite, and sulphuric acid. J. C. G. de Marignac obtained the *dihydrate*, $\text{PbSiF}_6 \cdot 2\text{H}_2\text{O}$, and by evaporating the soln. at ordinary temp. in air, he obtained the *tetrahydrate*, $\text{PbSiF}_6 \cdot 4\text{H}_2\text{O}$. F. Fischer and K. Thiele added lead carbonate to hydrofluosilicic acid, filtered the soln. to remove lead fluoride and lead sulphate if present, evaporated the clear soln.; by neutralizing the acid soln. with lead carbonate, they obtained a basic salt; and by electrolyzing the neutral soln. in a cell with lead anodes, they also obtained lead fluosilicate. K. Elbs and R. Nübling obtained the dihydrate by electrolyzing a conc. soln. of sp. gr. 1.30, or very dil. hydrofluoric acid in a cell with lead electrodes and a diaphragm using a current of anode density 1–3 amps. per sq. dm. If the electrolyte be sat. with lead fluosilicate, and allowed to stand for some days, the tetrafluoride is formed. According to J. C. G. de Marignac, the dihydrate forms monoclinic prisms, of axial ratios $a : b : c = 1.4220 : 1 : 1.4306$, and $\beta = 103.44^\circ$; and the tetrahydrate forms similar crystals but with the axial ratios $a : b : c = 1.5772 : 1 : 0.9735$, and $\beta = 91.30^\circ$. The dihydrate loses hydrogen fluoride and water when heated; at 300° , lead fluoride remains; the tetrahydrate melts below 100° , loses water and silicon tetrafluoride; and according to K. Elbs and R. Nübling, it readily passes into the dihydrate. F. A. Patterson measured the electrical conductivity of the soln. F. Fischer and co-workers reported crystals of an acid salt.

J. J. Berzelius slowly evaporated a soln. of antimonous oxide in hydrofluosilicic acid, and obtained prismatic crystals of **antimony fluosilicate** which crumble to powder when dried in air, and readily dissolve in water containing an excess of acid. According to J. J. Berzelius, when a soln. of vanadic oxide, VO_3 , in hydrofluosilicic acid is rapidly evaporated, blue **vanadyl fluosilicate** is formed which at a moderate heat swells up into a pale blue porous mass; but if the blue soln. evaporates spontaneously, it acquires a green colour, and forms a syrupy liquid containing crystals. According to A. Guyard, if the soln. be evaporated to dryness a grey deliquescent mass is obtained which is completely soluble in water. J. J. Berzelius found that vanadic acid, V_2O_5 , dissolves in hydrofluosilicic acid, forming a red soln., which, on evaporation, yields an orange-yellow uncrystallizable mass of **vanadium fluosilicate**. It is partially soluble in water, forming a yellow soln.

The undissolved dark green portion forms a red soln. with sulphuric acid and gives off silicon tetrafluoride. The columbium silicate minerals, chalcocamprite and epistolite, are fluoriferous.

J. J. Berzelius¹⁷ obtained a transparent green mass of **chromium fluosilicate** by evaporating a soln. of chromic oxide in hydrofluosilicic acid. The product is deliquescent, and when it contains an excess of acid, it swells up like an alum when heated, and the residue again deliquesces if exposed to air. S. M. Jørgensen made **chromic chloropentamminofluosilicate**, or *chromic purpureofluosilicate*, $[\text{Cr}(\text{NH}_3)_5\text{Cl}]\text{SiF}_6$, by adding hydrofluosilicic acid to a soln. of a soluble chloropentamminochromic salt. The dark rose-red rhombic crystals are isomorphous with the corresponding cobalt salt. He also made **chromic chlorooctetramminofluosilicate**, or *chromic roseofluosilicate*, $[\text{Cr}(\text{NH}_3)_4(\text{H}_2\text{O})\text{Cl}]\text{SiF}_6$, by treating the soluble chloride with a conc. soln. of zinc fluosilicate in hydrofluosilicic acid. The precipitate is washed with ice-cold hydrofluosilicic acid until free from zinc; it is then washed with alcohol until free from acid. The carmine-red rhomboidal plates are soluble in water; when the salt has been dried over sulphuric acid it does not lose weight by heating to 100° . According to J. J. Berzelius, a soln. of molybdic oxide, Mo_2O_3 , in an excess of hydrofluosilicic acid does not dry up when exposed to air at ordinary temp., but when heated, the excess of acid is expelled, and a black neutral compound of **molybdenum fluosilicate** is formed which redissolves in the aq. acid. When the acid liquid is spontaneously evaporated, it acquires a bluish tinge and yields a black uncrystallizable mass from which water extracts the blue salt, and leaves a neutral black powder. The product is resolved by the prolonged action of water into a soluble acid salt and an insoluble basic salt. Aq. ammonia converts it into molybdenum silicate; and it dissolves in acidulated water without decomposition. When the yellow soln. obtained by dissolving molybdic acid in hydrofluosilicic acid is evaporated, a lemon-yellow opaque substance is formed which is decomposed by water forming a yellow soln. and a small quantity of an insoluble basic compound.

According to C. F. Rammelsberg,¹⁸ when uranium chloride, UCl_4 , is mixed with hydrofluosilicic acid, a bluish-green gelatinous precipitate is formed. If an excess of acid be present, the soln. retains the bluish-green colour. When the precipitated **uranium fluosilicate** is heated out of contact with air, it is decomposed, forming water, hydrofluoric acid, and silica. It is but slightly affected by a boiling soln. of potassium hydroxide; and after drying it is but sparingly soluble in acids. F. Stolba prepared **uranyl fluosilicate** soluble in water and in alcohol.

J. J. Berzelius¹⁹ obtained long, regular, six-sided prisms of **hexahydrated manganese fluosilicate**, $\text{MnSiF}_6 \cdot 6\text{H}_2\text{O}$, from a soln. of manganese oxide in hydrofluosilicic acid, and short prisms and rhomboidal crystals by the slow evaporation of the soln. F. Stolba evaporated at room temp. a soln. of manganese carbonate in hydrofluosilicic acid; and also mixed-barium fluosilicate with a soln. of manganese sulphate. The rose-red, hexagonal, prismatic crystals belong to the trigonal system, and, according to J. C. G. de Marignac, have the axial ratio $a : c = 1 : 0.5043$, and $\alpha = 112^\circ 30'$. The crystals are isomorphous with the corresponding fluosilicates of the manganese family. F. Stolba gave 1.9038 for the sp. gr. at 17.5° , and H. Töpsøe, 1.858. H. Töpsøe and C. Christiansen found the indices of refraction to be $\omega = 1.3552$ and $\epsilon = 1.3721$ for *C*-light; $\omega = 1.3570$ and $\epsilon = 1.3742$ for *D*-light; and $\omega = 1.3605$ and $\epsilon = 1.3774$ for *F*-light. The double refraction is positive. The salt is stable in air, and when heated, J. J. Berzelius found that the water is first given off; then silicon tetrafluoride, and manganese fluoride remains. F. Stolba found that all the silicon tetrafluoride is not expelled after 40 hrs.' heating at 100° , and after slowly heating to 200° , a little silicon tetrafluoride still remains. The salt is readily soluble in water; F. Stolba found that 100 parts of water at 17.5° dissolve 140 parts of the salt, and the soln. has a sp. gr. 1.44825; the solubility is augmented by raising the temp. The solubility in alcohol is greater the less the conc. of the alcohol. F. Stolba found that a soln. of the salt is decomposed when

evaporated in the presence of conc. hydrochloric or nitric acid. Alkali fluosilicates are almost insoluble in a soln. of manganese fluoride, so that when alkali salts are added to a soln. of manganese fluosilicates these fluosilicates are almost quantitatively precipitated.

J. C. G. de Marignac could not make a fluosilicate with a higher proportion of manganese fluoride. T. L. Phipson found that when an aq. soln. of potassium fluoride, potassium permanganate, and nitric acid is allowed to stand for some days, crystals containing fluorine, manganese, potassium, and silica are produced—the latter is derived from the glass containing vessel.

According to J. J. Berzelius,²⁰ when a soln. of iron in hydrofluosilicic acid is evaporated in an iron dish, exposed to the air, pale, bluish-green, six-sided, prismatic crystals of what H. Dufet showed to be **hexahydrated ferrous fluosilicate**, $\text{FeSiF}_6 \cdot 6\text{H}_2\text{O}$, are formed. F. Stolba prepared the salt by evaporating on a water bath the soln. acidified with a few drops of hydrofluosilicic acid; he also evaporated the soln. containing a little free hydrofluosilicic acid until a crust began to form. Conc. alcohol was added so long as a precipitate was produced. The salt was collected by filtration, and washed by suction with conc. alcohol, and dried on a porous tile. According to H. Dufet, the crystals belong to the trigonal system, and have the axial ratio $a : c = 1 : 0.5033$, and $\alpha = 112^\circ 32'$. F. Stolba gave 1.961 for the sp. gr. at 17.5° . The indices of refraction were found by H. Dufet to be $\epsilon = 1.3823$ and $\omega = 1.3619$ for Li-light; $\epsilon = 1.3848$ and $\omega = 1.3638$ for Na-light; and $\epsilon = 1.3867$ and $\omega = 1.3656$ for Ti-light at 20.5° . The crystals are oxidized in moist air, and F. Stolba found that 100 parts of water at 17.5° dissolve 128.2 parts of the salt. J. J. Berzelius also prepared what was once thought to be **ferric fluosilicate**, $\text{Fe}_2(\text{SiF}_6)_3$, by evaporating a soln. of hydrated ferric oxide in hydrofluosilicic acid. It appeared as a yellowish jelly which, after complete drying, appeared as a translucent gum-like mass, soluble in water. It is doubtful if normal ferric fluosilicate can exist under these conditions since when the attempt is made to prepare it by saturating the acid with ferric oxide, or by double decomposition, it breaks down at once: $2\text{FeF}_3 \cdot 3\text{SiF}_4 \rightarrow 2\text{SiF}_4 + 2\text{FeF}_3 \cdot \text{SiF}_4$ —the silicon fluoride is decomposed by water. When the soln. is slowly evaporated, a colourless syrup is obtained containing $\text{FeF}_3 \cdot \text{SiF}_4$ in aq. soln.; by further evaporation, this compound decomposes—silicon fluoride escapes and hydrated ferric fluoride remains.

• J. J. Berzelius evaporated a soln. of cobalt carbonate in hydrofluosilicic acid and obtained pale red rhombohedra, and six-sided prisms of what J. Grailich and others showed to be **hexahydrated cobalt fluosilicate**, $\text{CoSiF}_6 \cdot 6\text{H}_2\text{O}$; J. J. Berzelius considered the salt to be a heptahydrate. F. Stolba also made the salt by acting on barium fluosilicate with a boiling soln. of cobalt sulphate; and by the method employed for the ferrous salt. J. Grailich found the trigonal crystals have the axial ratio $a : c = 1 : 0.5219$, and $\alpha = 112^\circ 4'$. B. Gossner gave 2.807 for the sp. gr. H. Töpsöe, 2.067; and F. Stolba, 2.113–2.121 at 19° . J. A. Groshans studied the mol. vol. and sp. gr. of the salt. H. Töpsöe and C. Christiansen gave $\omega = 1.3817$ and $\epsilon = 1.3872$ for the indices of refraction with the C-line; the double refraction is positive. B. Gossner studied the isomorphism of the corresponding cobalt, copper, nickel, and zinc salts. There is a limited miscibility between the cobalt and copper fluosilicates. P. Engelskirchen found that ammonium and cobalt fluosilicates do not form a double salt, but the ammonium salt separates first when a mixed soln. of the two salts is concd. by evaporation. F. Stolba found that 100 parts of water at 21.5° dissolve 118.1 parts of salt; and more at a higher temp.

A. Molati and G. Rossi obtained **cobaltic hexamminofluosilicate**, or **cobaltic luteofluosilicate**, $[\text{Co}(\text{NH}_3)_6]\text{F}_4 \cdot 2\text{SiF}_6$, as a yellow crystalline powder by the action of hydrofluosilicic acid on a soln. of the carbonate in hydrofluoric acid. S. M. Jørgensen obtained **cobaltic nitropentamminofluosilicate**, or **cobaltic xanthofluosilicate**, $[\text{Co}(\text{NH}_3)_5\text{NO}]\text{SiF}_6$, by the action of hydrofluosilicic acid on the chloride of the base. W. Gibbs, and S. M. Jørgensen prepared **cobaltic chloropentamminofluosilicate**, or **cobaltic chloropurpureofluosilicate**, $[\text{Co}(\text{NH}_3)_5\text{Cl}]\text{SiF}_6$, by a cold soln. of chloropentamminocobaltic salt to an excess of

hydrofluosilicic acid. W. Gibbs regarded the salt as a trihydrate. S. M. Jørgensen made **cobaltic chloroaquatetramminofluosilicate**, $[\text{Co}(\text{NH}_3)_4(\text{H}_2\text{O})\text{Cl}]\text{SiF}_6$, in violet crystals by the action of hydrofluosilicic acid on a soln. of the chloride of the base. The crystals were washed with alcohol. S. M. Jørgensen made dark violet, rhombic, tabular crystals of **cobaltic bromopentamminofluosilicate**, or **cobaltic bromopurpureofluosilicate**, $[\text{Co}(\text{NH}_3)_5\text{Br}]\text{SiF}_6$ by heating the nitrate or chloride of the base with hydrofluosilicic acid, and washing the product with water and alcohol. The crystals are isomorphous with the analogous chloro-compound. S. M. Jørgensen made **cobaltic tetramminodiaquodiamminofluosilicate**, $[(\text{NH}_3)_2(\text{H}_2\text{O})_2\text{Co}(\text{OH})\text{O}.\text{Co}(\text{NH}_3)_4](\text{SiF}_6)_2.2\text{H}_2\text{O}$, in hexagonal prisms, by treating a soln. of the chloride of the base with hydrofluosilicic acid.

J. J. Berzelius evaporated a soln. of nickel carbonate in hydrofluosilicic acid and obtained green rhombohedral and six-sided prismatic crystals of what were shown by J. Grailich and others to be **hexahydrated nickel fluosilicate**, $\text{NiSiF}_6.6\text{H}_2\text{O}$. J. J. Berzelius supposed the salt to be a heptahydrate. F. Stolba employed the method used for the ferrous salt. J. C. G. de Marignac showed that the trigonal crystals have the axial ratio $a:c=1:0.5136$ and $a=1.2516'$. H. Töpsöe gave 2.109 for the sp. gr. V. von Lang measured the heat conductivity; and H. Töpsöe and C. Christiansen found the indices of refraction to be $\omega=1.3876$ and $\epsilon=1.4036$ for the *C*-line; and $\omega=1.3910$ and $\epsilon=1.4066$ for the *D*-line; and $\omega=1.3950$ and $\epsilon=1.4105$ for the *F*-line. J. J. Berzelius said that the salt is very soluble in water.

J. J. Berzelius²¹ found that the yellow soln. of hydrated platinum oxide in hydrofluosilicic acid dries to a yellow gum-like mass of **platinic fluosilicate**, which is decomposed by water, forming a brown insoluble basic salt. J. Wöhler showed that the salt is readily hydrolyzed and a great excess of hydrofluosilicic acid is needed to prevent hydrolysis. The subject was also investigated by O. Ruff. By adding hydrofluosilicic acid to an aq. soln. of a tetramminopalladous salt, H. Müller obtained **palladous tetramminofluosilicate**, $[\text{Pd}(\text{NH}_3)_4]\text{SiF}_6$. The colourless crystals are sparingly soluble in cold water; easily soluble in hot water; insoluble in alcohol; decomposed at 160° ; and, when treated with hydrochloric acid, give a precipitate of the chloride. S. M. Jørgensen prepared **rhodic chloropentamminofluosilicate**, $[\text{Rh}(\text{NH}_3)_5\text{Cl}]\text{SiF}_6$, in yellow rhombohedra by adding hydrofluosilicic acid to a cold soln. of the chloride of the complex base.

57. Silicon Chlorides

* In 1823, J. J. Berzelius¹ discovered **tetrachlorosilane**, or **silicon tetrachloride**, SiCl_4 , when he showed that this compound is formed by the direct union of the elements silicon and chlorine. In addition, the derivative **trichlorosilane**, or **silicochloroform**, SiHCl_3 ; **dichlorosilane**, SiH_2Cl_2 ; and **monochlorosilane**, SiH_3Cl , have been made. In addition, the members of the homologous series, **hexachlorosilicethane**, or **hexachlorodisilane**, Si_2Cl_6 ; **octochlorosilicopropane**, or **octochlorotrisilane**, Si_3Cl_8 ; **decachlorosilicobutane**, or **decachlorotetrasilane**, $\text{Si}_4\text{Cl}_{10}$; **dodecachlorosilicopentane**, or **dodecachloropentasilane**, $\text{Si}_5\text{Cl}_{12}$; and **tetradecachlorosilicohexane**, or **tetradecachlorohexasilane**, $\text{Si}_6\text{Cl}_{14}$, have been prepared. Some chlorobromo- and chloriodo-silanes are known—*vide infra*.

When silicon is heated in chlorine gas, it ignites and burns, forming the vap. of silicon tetrachloride which condenses to a liquid on cooling. If any air or oxygen is present some silica or, according to L. Troost and P. Hautefeuille, an oxychloride is formed. According to W. Hempel and H. von Haasy, the reaction between silicon and chlorine begins at 280° , and it proceeds with incandescence at 480° . If the silicon contains sodium fluoride, A. F. Holleman and H. J. Slijper showed that silicon tetrachloride is not obtained by heating it in chlorine, on account of the reaction: $\text{SiCl}_4 + 4\text{NaF} = \text{SiF}_4 + 4\text{NaCl}$. H. C. Ørsted made the tetrachloride by passing chlorine gas over an intimate mixture of silica and charcoal at a red heat. H. Buff and F. Wöhler, J. J. Ebelmen, and H. Schnitzler made the gas by this process, which may be conducted in the following manner:

An intimate mixture of precipitated silica and finely ground willow charcoal is made into a stiff paste with oil; rolled into balls; ignited in a closed crucible; and loosely packed in a wide porcelain tube. A stream of chlorine is passed through the tube heated to bright redness. The condensed liquid is at first colourless, but it soon acquires a yellow colour owing to the absorption of chlorine. To remove the colouring, J. J. Ebelmen, and J. B. A. Dumas allowed the yellow liquid to stand in contact with mercury or

with copper turnings. The liquid can then be rectified by fractional distillation. According to J. J. Ebelmen, the yield with natural silica—amorphous or crystalline—is not so good as with precipitated silica.

According to the *Konsortium für elektrochemische Industrie*, the temp. of the reaction can be lowered some 800° to about 900°, by adding chlorides of the alkalis or alkaline earths, manganese or aluminium, or of mixtures of chlorides. R. Weber found that if the temp. is raised high enough silica reacts with chlorine in the absence of carbon. H. St. C. Deville showed that hydrogen chloride also furnishes silicon tetrachloride when passed over a mixture of carbon and silica, but the temp. must be higher than is required with chlorine. A. Faure made silicon tetrachloride by passing a mixture of hydrogen chloride and a hydrocarbon gas over red-hot silica. C. W. Watts and C. A. Bell were not very successful in the attempt to make silicon tetrachloride by the action of carbon tetrachloride, chloroform, or a mixture of carbon monoxide, and chlorine on red-hot silica. According to L. Tréost and P. Hautefeuille, if chlorine be passed over a mixture of silicon with one-tenth of its weight of boron, the latter generates so much heat in reacting with the chlorine that the temp. of reaction of silicon with the chlorine is attained; boron trichloride also reacts with silica at a bright red-heat forming silicon tetrachloride: $4\text{BCl}_3 + 3\text{SiO}_2 = 3\text{SiCl}_4 + 2\text{B}_2\text{O}_3$; if unglazed porcelain be used instead of silica, some aluminium chloride is formed; and with glazed porcelain, some potassium aluminium chloride is formed. R. Weber, and A. Dauriac found that when amorphous silica, powdered quartz, or a powdered silicate, is strongly heated in the vapour of phosphorus pentachloride, some phosphorous oxychloride and silicon tetrachloride are formed. P. Didier found some silicon tetrachloride is produced when cerium trichloride and silica are heated in the presence of a feeble oxidizing agent. C. Maignon and P. Bourion showed that when a mixture of chlorine and the vapour of sulphur chloride is passed over silica at about 450°, silicon tetrachloride is formed. E. Baudrimont said that a mixture of potassium chlorate and silica at a temp. exceeding 360°, furnishes oxygen, chlorine, and a little silicon tetrachloride, but G. Rauter observed that no silicon tetrachloride is formed when silica is heated with the chloride of potassium, sodium, silver, chromium, sulphur, manganese, or iron. E. Jüngst and R. Mewes obtained metal silicides and silicon tetrachloride by heating a mixture of a metal chloride and silicon. R. Weber found that when a mixture of trichlorosilane and chlorine is heated, tetrachlorosilane is formed; H. Buff and F. Wohler, and C. Friedel and A. Ladenburg noted that when silicochloroform is heated it forms the tetrachloride. W. Hempel and H. von Haasy obtained the tetrachloride in the reaction between chlorine and the sulposilicates; H. N. Stokes, in the reaction between the aromatic silicon esters and phosphorus oxychloride; and A. Colson, in the reaction between mercuric chloride and silicon sulphide.

H. N. Warren, and F. de Carli made silicon tetrachloride by passing chlorine over heated ferrosilicon; and L. Gattermann used magnesium silicide obtained by heating a mixture of silica and magnesium. The best yield was obtained by working at 300°–310°. The product of the reaction contained about 80 per cent. of silicon tetrachloride; 20 per cent. of hexachlorosilicethane; and 0.5–1.0 per cent. of octochlorosilicopropane. The distillate was separated into its components by fractional distillation. G. Rauter used copper silicide in place of ferrosilicon; O. Hutchins, silicon carbide; and E. Vigouroux, aluminium silicide. G. P. Baxter and co-workers describe the purification of silicon tetrachloride for their work on the at. wt. of silicon. G. Martin's directions for making silicon tetrachloride from ferrosilicon are as follows:

The chlorine cylinder *A*, Fig. 199, delivers gas into the washbottles *B*, connected with an iron tube fitted with iron caps *cc*, and heated to 180°–200° in the tube-furnace *C*. The iron tube is packed with coarsely crushed ferrosilicon. The liquid products of the reaction collect in the flask which has an exit-tube connected with the inverted condenser *E*, and an exit leading into the fume chamber. A force-pump, *K*, drives air, as required, through

the mercury bottle *J*, up the drying tower *I*, and so forces the liquid as required from *D* into the fractionating flask *F*, fitted with Young's still-head. The distillation flask *F* is connected with the condenser *G* and receiver *H*, which has an exit-tube leading into the fume chamber. The manometer and safety-tube *M* contain mercury and sulphuric acid in order to prevent an explosion if the tubes get blocked and the press. rises too high. The flask *F* is heated on a water-bath; and the bottles *H* of crude silicon chloride are stoppered and removed as they are filled. When the flask *F* is nearly full of high-boiling residues, the water-bath is replaced by an oil-bath, and silicon hexachloride distils over

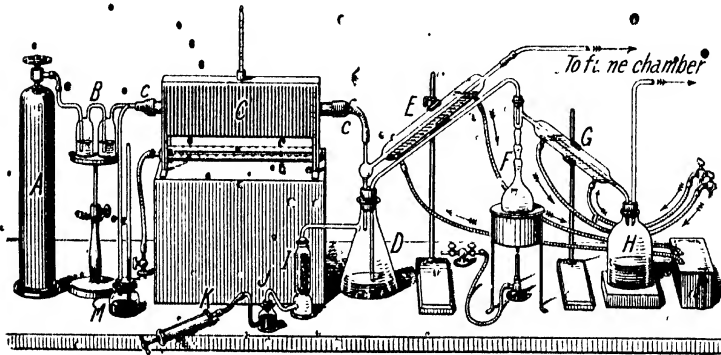

FIG. 199.—The Preparation of Silicon Chlorides.

between 147° and 149° . In this way, 143 kgrms. of chlorine gas passed over 50 kgrms. of 50 per cent. ferrosilicon furnished 54 kgrms. of silicon tetrachloride, 3 kgrms. of silicon hexachloride, and 500 grms. of a residue which yielded nearly 200 grms. of silicon octochloride. If the furnace be heated to 300° – 310° , the iron tube is quickly corroded by the chlorine, but at 180° – 200° , this action is too slow to be troublesome. If the temp. is 170° , the action of chlorine on the ferrosilicon is too slow for effective work. If the temp. be 300° – 310° , the yield of the disilicon hexachloride is about 4 per cent.; if 250° – 260° , the yield is 4.6 per cent.; and if 180° – 200° , the yield rises to 8.6 per cent. The crude products must be further rectified by fractional distillation. Great care must be taken that the apparatus is thoroughly dried before the silicon chloride is introduced. The attachment *IJK* enables the chlorides to be transferred from one vessel to another without contact with undried atm. air.

The formation of more complex chlorides during the reaction between chlorine and the metal silicide is attributed by L. Gattermann and K. Weinlig to a secondary reaction between the tetrachloride and silicon: $3\text{SiCl}_4 + \text{Si} = 2\text{Si}_2\text{Cl}_6$; but at the temp. of the reaction, silicon tetrachloride does not react with silicon to produce an appreciable amount of the hexachloride. Consequently, G. Martin suggested that the mols. of the element silicon are 'chains of atoms, and the first action of chlorine on silicon is not to break the chains of atoms into single atoms, but rather to form complex chlorination products, which, reacting with more and more chlorine, break down into simpler and simpler chlorides: e.g. $\text{Si}_2\text{Cl}_6 + \text{Cl}_2 = 2\text{SiCl}_4$. Instead of regarding silicon tetrachloride as the first product of the reaction, it is considered to be the end-product of a process which progresses in a series of stages: The complex chlorides obtained in the receiver are supposed to have escaped destruction owing to their having been removed from the seat of the reaction and quickly cooled.

The physical properties of silicon tetrachloride.—Silicon tetrachloride at ordinary temp. is a transparent, colourless, fuming liquid. J. J. Berzelius² said that when exposed to the air the liquid evaporates as a white cloud leaving a residue of silica; the vapour has a suffocating odour and reddens litmus. L. Köster gave for the **specific gravity** of the liquid 1.54; J. I. Pierre, 1.52371 at 0° ; D. I. Mendeleëff, 1.50068 at 10.98° , 1.4928 at 15° , and 1.4829 at 99.9° ; C. Friedel and J. M. Crafts, 1.522; A. Stiefelhagen, 1.524 at 16° ; O. Ruff and C. Albert, 1.4933 at 15° ; G. Abati, 1.47556 at 22° ; O. Haagen, 1.4878 at 20° ; and T. E. Thorpe, 1.52408 at 4° . J. B. A. Dumas gave for the **vapour density**, 5.939; and H. V. Regnault,

5.86 when the calculated value for SiCl_4 is 5.868. The vap. shows no signs of dissociation at the softening temp. of porcelain. W. Ramsay and J. Shields found for the **surface tension** 16.31 dynes per cm. at 18.9° and 13.66 dynes per cm. at 45.5° ; and for the **specific cohesion** at these temp., 2.21 and 1.95 sq. mm. respectively. P. Walden gave for the surface tension, σ , at θ° , $\sigma = 18.20(1 - 0.00548\theta)$, and for the sp. cohesion $\sigma^2 = 2.731(1 - 0.00461\theta)$; D. I. Mendeléeff gave 15.13 for the surface tension of the liquid at the b.p. The **association factor**, according to G. G. Lozinescu, is unity; and observations on this subject were made by W. Ramsay and J. Shields, I. Traube, P. Vaubel, and L. Henry. I. Traube estimated a at 273°K . in J. H. van der Waals' equation to be 121×10^6 ; and b at 273°K . to be 88.5; $v - b = 23.1$; and $a/v^2 = 890$ atm.

The coefficient of **thermal expansion** of the liquid at 20° was found by J. I. Pierre to be 0.001430; and 0.001446 by T. E. Thorpe. The former found unit vol. at 0° becomes $1 + 0.001294119069\theta + 0.002184143631\theta^2 + 0.000740864220\theta^3$ at θ° ; and the latter, $1 + 0.001330916\theta + 0.00280978\theta^2 + 0.000215657\theta^3$. J. J. Saslawsky studied the relation between the coeff. of expansion and the structure. The **expansion and compressibility** of the vap. was studied by L. Troost and P. Hautefeuille. For the **boiling point** of the liquid, G. S. Scruilas gave 50° ; O. Haagen, 58° at 756 mm.; I. de Pierre, J. B. A. Dumas, and C. Maignon and F. Bourion, 59° at 766 mm.; H. V. Regnault, 56.81° at 760 mm.; T. E. Thorpe, 58° – 58.5° at 765.33 mm., and 57.57° at 769 mm.; W. Becker and J. Meyer, 56.9° at 760 mm.; and A. Stock and co-workers, 56.8° at 760 mm. According to S. Young, the observed b.p., θ , at a barometric press., p , is corrected by adding on the term $0.000126(760 - p)(273 + \theta)$. G. Rauter gave -102° for the **melting point** of solid silicon tetrachloride; W. Becker and J. Meyer, -89° ; W. M. Latimer, -70° ; and A. Stock and co-workers, -68.7° . The discrepancy in the data is in part due to the earlier preparations having been contaminated with higher boiling and lower melting chlorides. W. M. Latimer gave for the mol. sp. ht., C_p , per mol. $\div 5$, at different temp.:

$^\circ\text{K}$.	77.4°	81.3°	86.6°	131.3°	181.0°	185.8°	208.8°	294.3°
C_p	3.60	3.70	3.83	4.80	5.95	6.08	6.74*	6.94*

The numbers marked with an asterisk refer to the liquid, the others to the solid. The **entropy** at 25° is 56.43. H. V. Regnault represented the **vapour pressure**, p mm., at θ° by $\log p = 4.5959425 - 3.3287708\alpha\theta^{+26}$, where $\log \alpha = 9.9965260^{-10}$. R. Wintgen gave $\log p = 7.6443 - 1572.0T^{-1}$. W. Becker and J. Meyer gave:

p	0°	5°	10°	15°	20°	25°	56.8°
	11.6	13.3	15.0	17.5	21.6	26.1	76 cm.

and H. V. Regnault gave:

p	-25°	-10°	0°	10°	30°	50°	60°	65°
	1.906	4.646	7.802	13.500	29.444	60.746	83.723	97.274 cm.

D. I. Mendeléeff gave 230° for the **critical temperature**; W. Ramsay and J. Shields calculated 213.8° ; and C. M. Guldberg, 221° . D. A. Goldhammer applied the theory of corresponding states to silicon tetrachloride; and calculated for the **critical density** 0.5275. W. M. Latimer gave 10.85 cal. per gram for the heat of fusion at -70.3° . J. Ogier found the **heat of vaporization** to be 6.3 cal. per mol., and A. Stock and co-workers, 7.19 cal. per mol. R. Wintgen gave 7185 cal., and for the mol. heat of vaporization, at 0°K ., 7946.2 cal., or 6925 cal. at $T^\circ\text{K}$; 21.0 for Trouton's constant. H. V. Regnault gave 0.1904 for the **specific heat** of the liquid between 10° and 15° ; J. Ogier obtained a similar result; and L. Kahlenberg and R. Koenig gave 0.1904 between 20° and 40° . H. V. Regnault found for the sp. ht. of the gas between 90° and 234° , $C_p = 0.1322$. J. W. Capstick obtained 1.129 for the ratio of the two sp. hts. of the vap. M. Berthelot, and L. Troost and P. Hautefeuille gave for the **heat of formation**, $\text{Si}_{\text{cryst.}} + 4\text{Cl} \rightarrow \text{SiCl}_{4\text{gas}} + 121.8 \text{ Cal.}$; and with $\text{SiCl}_{4\text{liquid}}$, 128.1 Cal. M. Berthelot measured the heat of decomposition

by water: $\text{SiCl}_4 + \text{Aq.} = \text{SiO}_2 \text{ aq.} + 4\text{HCl aq.} + 69 \text{ Cals.}$ J. Thomsen gave 69.3 Cals. L. Gattermann and K. Weinlig gave 1.404 for the **index of refraction** for red light. O. Haagen gave for the red ray, H_α , 1.4119; for the green ray, H_β , 1.4200; and for the violet ray, H_γ , 1.4244. G. Abati gave 1.41019 for the H_α -ray; 1.41829 for the H_β -ray; 1.41257 for the D -ray; and 1.42306 for the H_γ -ray, and he calculated 47.528 for the mol. **refraction** for H_α from the n -formula, and 28.55 from the n^2 -formula; for the sp. refraction, the numbers are respectively 0.277989 and 0.167978. The sp. **dispersion** for H_γ and H_α is 0.008722. J. H. Gladstone made some observations on this subject; and A. Stiefelhagen gave for the **index** of refraction of rays of wave-length $\lambda = 226, 394$, and $589 \mu\mu$, the index of refraction $\mu = 1.50823, 1.43334$, and 1.4182 respectively, and $\mu^2 = 1.31377 + 0.66590\lambda^2 (\lambda^2 - 125.562)^{-1}$. H. H. Marvin studied the optical dispersion. The **spectrum** was examined by L. Troost and P. Hautefeuille, W. Jevons, and G. Salet. According to C. Lüdeking, silicon tetrachloride is not decomposed by the electric discharge, and P. Hautefeuille found that the effect of heat, and of the voltaic arc, resembles that with silicon tetrafluoride (*q.v.*). P. Walden found the **electrical conductivity** of liquid silicon tetrachloride to be negligible. H. Schlundt gave 2.40 for the **dielectric constant** at 16° with wave-lengths $\lambda = 80 \text{ cm.}$ P. Pascal measured the **magnetic susceptibility** of silicon tetrachloride.

The chemical properties of silicon tetrachloride.—The composition of silicon tetrachloride was established by the analyses of J. Pelouze,³ J. B. A. Dumas, and J. Schiel. K. Fajans studied the electronic structure of the silicon halides. According to C. Friedel and A. Ladenburg, when a mixture of silicon tetrachloride vap. and **hydrogen** is heated to redness a little silicochloroform, SiHCl_3 , is produced. A. C. Vournasos found that the nascent hydrogen produced when silicon chloride vap. is passed over heated sodium formate, furnishes a little silane; C. Friedel and A. Ladenburg, when a mixture of silicon tetrachloride vap. and dry **oxygen** or **air** is heated, an oxychloride is formed: $4\text{SiCl}_4 + \text{O}_2 = 2\text{Si}_2\text{OCl}_6 + 2\text{Cl}_2$; and, according to M. Berthelot, some silica is also formed. L. Troost and P. Hautefeuille obtained the same oxychloride by passing the gas through a heated porcelain tube with or without a packing of fragments of felspar or alkali silicate: $2\text{SiCl}_4 + \text{K}_2\text{SiO}_3 = 2\text{KCl} + \text{SiO}_2 + \text{Si}_2\text{OCl}_6$. The presence of hydrogen chloride does not accelerate the reaction. L. Troost and P. Hautefeuille found that on sparking a mixture of oxygen and silicon tetrachloride vap., the same oxychloride is formed, and if the free chlorine simultaneously produced is absorbed by mercury as fast as it is formed the oxychloride can be collected. According to J. J. Berzelius, silicon tetrachloride first floats on the surface of **water**, and it then dissolves with decomposition, forming hydrated silica and hydrochloric acid. W. Becker and J. Meyer said the reaction is very slow with ice-cooled water. According to A. Stock and F. Zeiler, silicon tetrachloride and water form $\text{Si}(\text{OH})_2\text{Cl}_2$. N. V. Sidgwick explained the reaction with water on the basis of the co-ordination theory. C. Langlois found that the hydrated silica produced by exposing silicon tetrachloride to moist air resembles hydrophane. At a red heat, A. Daubrée found that water-vapour and silicon tetrachloride furnish crystals of silicon dioxide. The fumes which are developed when the tetrachloride is scattered in the atm. by means of an explosive bomb were utilized to a small extent as clouds in the 1914-1918 war; sometimes in conjunction with ammonia. The subject was discussed by G. A. Richter.

H. Moissan found that **fluorine** does not act on silicon tetrachloride at -23° , but at 40° , the formation of silicon tetrafluoride is accompanied by a feeble flame. N. W. Taylor and J. H. Hildebrand measured the solubility of **chlorine** in silicon tetrachloride and found at 0° , 0.131 grm. gas per gram of solvent is taken up. W. Biltz and E. Meinecke found the f.p. curves of mixtures of silicon tetrachloride and chlorine have a eutectic pt. -117° and 80 at. per cent. chlorine as indicated in Fig. 200. P. Hautefeuille found that when a mixture of silicon tetrachloride vap., hydrogen, and a little **iodine** is passed through a tube at a dull red heat, a heavy liquid is formed which, when fired from iodine by digestion with mercury, and fractionally

distilled, furnishes a series of chloroiodides. J. A. Besson found **hydrogen iodide** and silicon tetrachloride vap. at a dull red heat furnish a mixture of chloroiodides; but O. Ruff and C. Albert observed no reaction at 120° in a sealed tube. J. A. Besson also reported the formation of chlorobromides when a mixture of **hydrogen bromide** and silicon tetrachloride is passed through a tube at a dull redness. O. Ruff and C. Albert found that in the presence of copper, silicon tetrachloride does not react with gaseous or liquid bromine. Silicon tetrachloride is not decomposed in the cold by hydrogen bromide or iodide. G. Gustavson found that with **carbon tetrabromide** in a sealed tube at 150° – 200° , some silicon tetrabromide is formed.

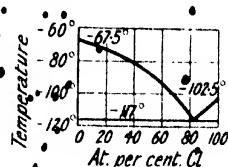

FIG. 200. — Freezing-point Curves of Cl-SiCl_4 Mixtures.

G. Rauter observed no reaction between silicon tetrachloride and **sulphur** at 200° – 300° . J. I. Pierre, and C. Friedel and A. Ladenberg found that **hydrogen sulphide** does not act on silicon tetrachloride at ordinary temp., but at a red heat, silicon tetrahydrosulphide is formed; and M. Blix and W. Wirbelauer likewise obtained the chlorosulphide, SiS_2Cl_2 . O. Ruff and C. Albert found that in the presence of zinc, silicon tetrachloride does not react with **hydrogen chloride**; nor when treated with hydrogen chloride in a sealed tube at 100° . G. S. Sérullas found that conc. **sulphuric acid** decomposes silicon tetrachloride, forming silica and hydrochloric acid; G. Gustavson found that the tetrachloride is decomposed by **sulphur trioxide**, forming pyrosulphuryl chloride—*vide infra*, silicon oxychlorides; F. Clausnizer also found that the tetrachloride is decomposed by **chlorosulphonic acid** in sunlight or at 170° . J. F. X. Harold, and G. Rauter observed no reaction between **sulphur chloride** and silicon tetrachloride.

F. Lengfeld said that gaseous **ammonia** reacts with silicon tetrachloride alone or dissolved in benzene, forming silicon tetramide; and M. Blix and W. Wirbelauer showed that by saturating silicon tetrachloride with dry ammonia, a white mass of **silicon hexamminotetrachloride**, $\text{SiCl}_4 \cdot 6\text{NH}_3$, is formed; the compound is decomposed by water. The ammine was made by J. Persoz in 1830, M. Blix and W. Wirbelauer showed that the hexammine is possibly a mixture of ammonium chloride and silicon imide, $\text{SiCl}_4 \cdot 6\text{NH}_3 = \text{Si}(\text{NH})_2 + 4\text{NH}_4\text{Cl}$, because liquid ammonia washes out the ammonium chloride—*vide* boron hexamminotrichloride, and zirconium octamminotetraiodide. F. Lengfeld also obtained a product approximating **silicon octamminotetrachloride**, $\text{SiCl}_4 \cdot 8\text{NH}_3$, by passing ammonia gas into a soln. of silicon tetrachloride in benzene in an atm. of dry nitrogen. The product is probably a mixture of silicon tetramide and ammonium chloride. E. Lay found that with **hydrazine**, a white, fuming compound, probably **silicon tetrahydrazine tetrachloride**, $\text{SiCl}_4 \cdot 4\text{N}_2\text{H}_4$, is formed by the action of a benzene soln. of silicon tetrachloride on an emulsion of hydrazine in benzene. He also showed that the tetrachloride reacts with **sodamide**, NaNH_2 , at 150° , forming silicon, and a sublimate of ammonium chloride, and silicon tetraaminotetrachloride. J. F. X. Harold said that the tetrachloride does not react with **nitrogen peroxide**, or a mixture of nitrogen peroxide and chlorine. R. Weber found that neither **nitric acid** nor **aqua regia** unites with silicon tetrachloride; with nitrous acid, it forms nitrosyl chloride. C. Friedel and A. Ladenburg, and G. Rauter found that at a red heat, **phosphorus pentoxide** forms oxychlorides of phosphorus and, probably, silicon. J. F. X. Harold observed no reaction between silicon tetrachloride and **phosphorus chlorides**. A. Besson observed that silicon tetrachloride does not absorb phosphine at ordinary temp., but at -20° it dissolves 20 times its vol. of phosphine, and 40 times its vol. at -50° . By strong compression at -23° there is formed what is thought to be **silicon diphosphinetetrachloride**, $\text{SiCl}_4 \cdot 2\text{PH}_3$. The product is liquid at -60° . Another product was obtained which is crystalline at 10° and 20 atm. press., or at -35° and atm. press. H. Moissan found that **arsenic trifluoride** reacts in the cold, forming silicon tetrafluoride and arsenic trichloride. G. Rauter examined the

action of silicon tetrachloride on the **arsenic oxides**, and the **antimony oxides**; no reaction occurred with **arsenic sulphide** and the **antimony sulphides**.

L. Troost and P. Hautefeuille obtained evidence of the possible formation of a subchloride when silicon tetrachloride vap. is passed over heated **silicon**, and L. Gattermann and K. Weinlig represent the reaction $3\text{SiCl}_4 + \text{Si} = 2\text{Si}_2\text{Cl}_6$; but G. Martin could not confirm this. O. Ruff found that silicon tetrachloride is not affected by **carbon** at high temp.; while J. N. Pring and W. Fielding observed the formation of silicon carbide only in the presence of hydrogen at 1700° —*vide* silicon. G. Rauter observed no reaction between silicon tetrachloride and **carbon disulphide**. J. F. X. Harold found that the tetrachloride does not react with **cyanogen chloride**. Silicon tetrachloride reacts with **fatty acids** forming their chlorides, and with **alcohol** forming ethyl silicate.

The tetrachlorides of carbon and silicon possess acidic characters in common with the other group elements, and combine with the bases to form stable well-defined compounds. Ammonia, the substituted ammonias, and other bodies of a distinctly **basic** character, so far as has been observed, react similarly with all. Titanium, one of the sub-group elements with the least pronounced metallic character, and tin in the other sub-group, having a distinct metallic character and a high at. wt., appear to be the most reactive members of group IV. when in the form of their tetrachlorides. Titanium tetrachloride, the metal with the lowest atomic weight of the first sub-group, is the most reactive since it forms compounds with bodies of a distinctly acidic nature—hydrogen cyanide, cyanogen chloride, nitrogen oxide; zirconium tetrachloride, on the other hand, and the next tetrachloride, germanium, show no such tendency, for their combinations seem limited to compounds of a basic character. In the first sub-group, therefore, the reactivity decreases with increasing at. wt. The following selection from J. F. X. Harold's list of the double compounds of the tetrachlorides of elements of group VI with various acidic and basic compounds, shown in Table XXXV, illustrates these statements. If the table c denotes that a compound is formed, n indicates that no compound is formed, and - means that no data are available.

Silicon tetrachloride is a convenient starting-point for the preparation of the so-called organic derivatives of silicon, because the chlorine atoms can be exchanged for organic radicals through the agency of zinc alkyls, or of sodium and alkyl bromides or iodides—*Fittig's reaction*; or by the *Grignard's reaction* in which magnesium reacts with one alkyl or aryl bromide in ethereal soln. producing magnesium alkyl or aryl bromide, MgBrX , which can then exchange its organic radicle for a chlorine atom of silicon tetrachloride: $\text{MgBrX} + \text{SiCl}_4 = \text{MgBrCl} + \text{SiCl}_3\text{X}$. Reactions between silicon tetrachloride and organic compounds have been studied

by F. S. Kipping and co-workers, A. Harden, J. E. Reynolds, A. Rosenheim and co-workers, F. Lengfeld, C. Friedel and co-workers, G. Rauter, O. Ruff and C. Albert, W. Dilthey, C. Willgerodt, H. N. Stokes, F. Taurik, F. Eduardoff, etc.

G. S. Sérullas found that silicon tetrachloride can be distilled from sodium or potassium and the tetrachloride boils below the m.p. of these metals. A. C. Vournasos observed no action at the temp. of boiling toluene. J. J. Berzelius found that when potassium is heated in the vap. of silicon tetrachloride, the metal burns forming potassium chloride and silicon; if molten potassium be dropped into liquid silicon tetrachloride an explosion results. H. C. Oersted found that potassium amalgam does not react with the tetrachloride at ordinary temp. C. Friedel and A. Ladenburg, and N. N. Beketoff showed that sodium, zinc, and silver at a red heat withdraw the chlorine from the tetrachloride without forming higher chlorides. O. Ruff and C. Albert found that sodium hydride, and calcium hydride do not react at 100°, and in the presence of aluminium chloride. G. Rauter found that zinc, aluminium, beryllium, and magnesium react at 200°-300° forming the metal chloride and silicon. K. Seubert and A. Schmidt observed that with magnesium at a dull red-heat, magnesium silicide and silicon are formed without incandescence; G. Rauter observed no reaction with iron at 200°-300°. N. Parravano and C. Mazzetti found that silicon tetrachloride reacts with iron at 900° forming an iron silicide. E. Vigouroux showed that with reduced iron at a dull red-heat, iron silicide and ferrous chloride are formed; cobalt similarly reacts at 1200°-1300°; nickel also forms silicides.

According to G. Rauter, most of the metal oxides react with silicon tetrachloride, forming the metal chloride or oxychloride and silica. In some cases, the reaction occurs at ordinary temp.; in others, the oxide must be heated. At higher temp., crystalline silica and different silicates may be formed as in the syntheses by A. Daubrée, and L. Troost and P. Hautefeuille. G. Rauter examined the reaction with silver oxide and the two copper oxides; G. Rauter, and A. Daubrée, the reaction with calcium, strontium, and barium oxides; and also with beryllium and magnesium oxides; G. Rauter, the reaction with zinc, cadmium, and mercuric oxides, and with boric oxide; G. Rauter, A. Daubrée, and L. Troost and P. Hautefeuille, the reaction with aluminium oxide; G. Rauter, the reaction with thallium oxide, the bismuth oxides, and tin and lead oxides. With heated lead oxide, C. Friedel and A. Ladenburg said the reaction occurs with incandescence, forming lead chloride and silicate; L. Troost and P. Hautefeuille, the reaction with zirconium oxide; G. Rauter, the reaction with titanium oxide; chromium oxides; molybdenum oxides; tungsten oxide, uranium oxide; the manganese oxides; the iron oxides; cobalt oxide; and nickel oxide. The metal salts with inorganic acids generally behave like mixtures of the acid anhydrides and the basic oxides; borax has scarcely any action on silicon tetrachloride; but G. Rauter observed the reaction with the alkali carbonates; potassium nitrite and nitrate; potassium chromate and dichromate; cupric sulphate; and with potassium permanganate, chlorate, bromide, and iodide; no action was observed with calcium fluoride, sodium sulphite, potassium polysulphide, or mercuric sulphide. In general, the heavy metal sulphides have scarcely any action. A. F. Holleman and H. J. Sluiper found that sodium fluoride reacts, forming sodium chloride and silicon tetrafluoride; and P. Miquel found that at ordinary temp. lead thiocyanate forms silicon tetrathiocyanate and lead chloride. C. Friedel and A. Ladenburg represented the reaction with red-hot sodium oxide, $\text{SiCl}_4 + 4\text{Na}_2\text{O} = \text{Na}_4\text{SiO}_4 + 4\text{NaCl}$; the alkali oxide is supposed to be contained in the sodium silicate.

From the analogy between methane and silane, it would be anticipated that the hydrogen atoms of silane could be replaced by chlorine atoms one by one. All three substitution products have been obtained so that the series of silicon chloro-

is complete. The first substitution product was discovered by H. Buff and F. Wöhler⁴ in 1857, and it was at first supposed to be a compound of silicon chloride and hydrogen chloride; but in 1867, C. Friedel and A. Ladenburg showed that the compound has a formal analogy with chloroform, CHCl_3 , and it was therefore called **silicochloroform**, SiHCl_3 . It is also called **trichlorosilane**. O. Ruff and C. Albert were not able to obtain this compound by the action of reducing agents on silicon tetrachloride; but A. J. Besson and L. Fournier did obtain a small quantity of silicochloroform by passing the vap. of silicon tetrachloride over red-hot calcium hydride. H. Buff and F. Wöhler made trichlorosilane by heating silicon in a current of dry hydrogen chloride. This process was employed by C. Friedel and A. Ladenburg, and E. Vigouroux. The product was separated by fractional distillation from the other silicon chlorides formed at the same time. The trichlorosilane distils between 35° and 37° , and the silicon tetrachloride towards 60° . L. Cambi found trichlorosilane to be the chief product of the action of dry hydrogen chloride on silicon sulphide, SiS . L. Gattermann obtained it among the products of the action of dry hydrogen chloride on the crude silicon or magnesium silicide obtained by reducing quartz sand with magnesium. F. Lengfeld said the yield is improved by using an excess of sand with the magnesium. H. N. Warren passed hydrogen chloride over ferrosilicon containing 15 per cent. of silicon; and H. Moissan and A. Holt, by passing hydrogen chloride over heated vanadium silicide, V_2Si . In all these cases, the trichlorosilane is to be separated by fractional distillation from the condensed liquid. C. Combes passed dry hydrogen chloride over copper silicide heated in a vap.-bath of sulphur, mercury, or diphenylamine. The yield of trichlorosilane is about 80 per cent. of the theoretical, and the remaining 20 per cent. is mainly the tetrachloride which can be separated by fractional distillation. O. Ruff and C. Albert considered this to be the best method of preparation. A. Stock and F. Zeidler worked at 300° , and found the purification by distillation in vacuo to be very tedious because the hydrogen chloride and silicon tetrachloride are retained very tenaciously; indeed, the former appears to be continuously produced probably owing to the slight but unavoidable water-content of the glass.

Trichlorosilane at ordinary temp. is a colourless, mobile liquid with a smell like that of silicon tetrachloride. The analyses of H. Buff and F. Wöhler, C. Friedel and A. Ladenburg, and O. Ruff and C. Albert established the composition; and C. Friedel and A. Ladenburg's **vapour density**, 4.64, agrees with the value 4.69 calculated for the formula SiHCl_3 . H. Buff and F. Wöhler gave 1.65 for the **specific gravity** of the liquid; while O. Ruff and C. Albert gave 1.3438 at 15° ; and A. Stock and F. Zeidler gave 1.35 at 0° . H. Buff and F. Wöhler gave 42° for the **boiling point**; C. Friedel and A. Ladenburg, 35° – 39° ; L. Gattermann, 35° – 37° ; A. J. Besson, 34° ; O. Ruff and C. Albert, 35° – 34° ; C. Pape, 33° ; A. Stock and F. Zeidler, 31.8° . The last-named gave for the **vapour pressure**, p mm., at different temp.:

85.0°	-70.1°	-50.0°	-30.5°	-10.5°	0°	10.5°	25.0°	32.0°
0.7	2.8	13.0	45.5	132	218	338	598	765

They also gave for the **melting point** -126.4° to -126.6° , and O. Ruff and C. Albert gave -134° . It will be observed that chloroform boils at 61.5° , and that in general, apart from polymerization, the silicon compounds are generally more volatile than the corresponding carbon compounds. H. Buff and F. Wöhler found trichlorosilane to be a non-conductor of electricity.

According to H. Buff and F. Wöhler, when the vap. of trichlorosilane is passed through a red-hot tube, hydrogen chloride, silicon tetrachloride, and a brown mirror of amorphous silicon are produced; O. Ruff and C. Albert deny the production of hydrogen chloride, and they represent the decomposition as a balanced reaction: $4\text{SiHCl}_3 \rightleftharpoons \text{Si} + 2\text{H}_2 + 3\text{SiCl}_4$; and if hydrogen be mixed with the vap., the temp. of decomposition is higher—about 900° . A. Stock and F. Zeidler said that trichlorosilane is remarkably stable towards heat, but at 900° it suffers almost quanti-

tative decomposition into silicon, hydrogen, hydrogen chloride, silicon tetrachloride, and a trace of liquid less volatile than the latter. A. J. Besson and L. Fournier found that when a mixture of dry hydrogen and the vap. of trichlorosilane is exposed to the dark electric discharge, a yellow oily liquid containing a mixture of more or less condensed silicon chlorides of the series $\text{Si}_n\text{Cl}_{2n+2}$ is formed. H. Buff and F. Wöhler reported that the vap. of trichlorosilane is as inflammable as that of ether, and it burns in air with a green-mantled flame like that of chloroform, producing white clouds of silica, and hydrogen chloride; a mixture of trichlorosilane and air can be exploded, forming silica, silicon chloride, and hydrogen chloride. C. Friedel and A. Ladenburg said that a warm body like a hot glass rod will ignite the mixture. H. Buff and F. Wöhler noted that a detonation occurred during the distillation when air was present in the retort. A. J. Besson and L. Fournier found that if trichlorosilane at -80° be sat. with dry oxygen and the soln. left for some days in a sealed tube exposed to sunlight, a mixture containing silicon oxychloride, Si_2OCl_6 , is produced; and a similar reaction occurs with a mixture of ozone and oxygen at 0° . Unlike chloroform or carbon tetrachloride, but like silicon tetrachloride, trichlorosilane fumes in moist air, and is decomposed by water with the evolution of heat, forming silicic and hydrochloric acids, and A. Friedel and A. Ladenburg observed that if the reaction with water occurs at 0° , the hydrogen is retained and a white insoluble powder of the so-called silicoformic anhydride, $\text{H}_2\text{SiO}_2 \cdot \text{OSiH}_3$, is produced: $2\text{HSiCl}_3 + 3\text{H}_2\text{O} \rightarrow 6\text{HCl} + (\text{HSiO})_2\text{O}$. A. Stock and F. Zeidler say that the polymerized dioxodisiloxane (silicoformic anhydride) has been isolated in the homogeneous condition, and is then remarkably stable towards water. In the gaseous condition, the chloro-compound reacts only slowly with a deficiency of water vap., without giving any indication of the formation of products intermediate between it and dioxodisiloxane. Attempts to isolate the latter in a less highly polymerized form by decomposing trichloromonosilane in the presence of benzene were unsuccessful. It gives indications of its ability to form salts in the absence of water. At ordinary temp., chlorine converts trichlorosilane into hydrogen chloride and silicon tetrachloride; bromine, at 100° , converts it into hydrogen bromide and silicon chlorobromide. A. J. Besson and L. Fournier showed that trichlorosilane reacts slowly with hydrogen chloride, forming unsaturated silicon chlorides.

O. Ruff and C. Albert observed no change when trichlorosilane and sulphur are heated in a sealed tube to 150° . H. Buff and F. Wöhler found that trichlorosilane is not changed by hydrogen sulphide. O. Ruff and C. Albert showed that when trichlorosilane is treated with sulphur dioxide, some sulphur, silica, silicon tetrachloride, and hydrogen chloride are formed; and with sulphur trioxide, sulphuryl chloride, silica, silicon oxychloride, chlorosulphonic acid, and hydrogen chloride are formed; while A. J. Besson and L. Fournier found that at 100° sulphur trioxide forms sulphur dioxide, pyrosulphuryl chloride, chlorosulphonic acid, and viscous silicon oxychloride. Aq. ammonia, like water, was found by C. Friedel and A. Ladenburg to form silicoformic anhydride, followed by a further decomposition: $\text{SiHCl}_3 + 3\text{NH}_4\text{OH} \rightarrow \text{H}_2 + \text{SiO}_2 + 3\text{NH}_4\text{Cl} + \text{H}_2\text{O}$. O. Ruff and C. Albert showed that trichlorosilane unites with gaseous ammonia, but the product has not a definite composition. A. Stock and F. Zeidler found that in the gaseous phase under diminished press. and at atm. temp., the reaction is symbolized: $2\text{SiHCl}_3 + 9\text{NH}_3 \rightarrow 6\text{NH}_4\text{Cl} + (\text{NH} : \text{SiH})_2\text{NH}$; the same products are obtained if the components are successively condensed in the same vessel and the mixture gradually warmed. When the product is gradually heated, the anhydride decomposes: $(\text{NHSiH})_2\text{NH} \rightarrow \text{NH}_3 + 2\text{SiNH}$. A. J. Besson and L. Fournier showed that an explosion occurs when trichlorosilane is mixed with nitrogen peroxide at -20° ; and if the materials are diluted with carbon tetrachloride, the reaction is symbolized: $\text{SiHCl}_3 + 2\text{NO}_2 \rightarrow \text{SiO}_2 + 2\text{NOCl} + \text{HCl}$. Red phosphorus produces some phosphine and a high boiling silicon compound. A. Besson found that with phosphine and trichlorosilane at 15° under a press. of 40 atm., or at -35° under a press. of 20 atm., an unstable

crystalline compound is formed. O. Ruff and C. Albert showed that alkaline or neutral soln. of **arsenious oxide**, or **antimonious oxide**, are reduced to the metal by the action of the liberated hydrogen. A soln. of **arsenic trifluoride** furnishes trifluorosilane and arsenic; with **arsenic trichloride** in a sealed tube at 150°, no alteration was observed. Arsenic trichloride is miscible in all proportions with trichlorosilane.

C. Friedel and A. Ladenburg found that with absolute **alcohol**, trichlorosilane forms not ethyl orthosilicate but *ethyl orthosilicoformate*, $\text{SiH}(\text{OC}_2\text{H}_5)_3$. According to C. Combes, when trichlorosilane is treated with an excess of **aniline**, $\text{C}_6\text{H}_5\text{NH}_2$, in benzene soln., white acicular crystals of *tri-anilinosilane*, $\text{H}-\text{Si}(\text{NHC}_6\text{H}_5)_3$, are formed. This compound begins to decompose at 114°, and regenerates trichlorosilane when exposed to dry hydrogen chloride. O. Ruff and C. Albert found trichlorosilane to be miscible in all proportions with **carbon disulphide**, **carbon tetrachloride**, **chloroform**, and **benzene**; **paraffin** is dissolved by the hot liquid, and given up again on cooling. Other reactions with organic compounds have been reported by C. Pape, C. Combes, L. Gattermann, A. Polis, etc.

O. Ruff and C. Albert showed that trichlorosilane suffers no perceptible change when heated in a sealed tube to 150° with **sodium**, **sodium amalgam**, **mercury**, **silver**, **copper**, or **tin**; on the other hand, A. Stock said that it reacts with sodium amalgam: $\text{SiHCl}_3 + 3\text{Na} = 3\text{NaCl} + (\text{SiH})_n$, since volatile compounds are not produced in appreciable amounts. When heated 12 hrs. with **chromic anhydride** in a sealed tube at 150°, silica, chromic oxide, and chromyl chloride are formed. A. J. Besson and L. Fournier said that the reaction takes place at ordinary temp. when an unstable brown compound, Cr_3OCl_7 , is formed. The reaction with a dil. soln. of **sodium hydroxide** is represented: $3\text{NaOH} + \text{SiHCl}_3 + \text{H}_2\text{O} = \text{Si}(\text{OH})_4 + 3\text{NaCl} + \text{H}_2$. Trichlorosilane does not react when heated with **silver fluoride** or **lead fluoride**; but with **stannic fluoride** or **titanic fluoride**, trifluorosilane is formed. Trichlorosilane is miscible in all proportions with **silicon**, **tin**, and **titanium tetrachlorides**. A. Stock and F. Zeidler found aluminium chloride has no action at 175°.

F. Lengfeld⁵ thought that **silicomethylene chloride**, or **dichlorosilicomethane**, or **dichlorosilane**, SiH_2Cl_2 , was formed as a by-product in the preparation of trichlorosilane. A. J. Besson and L. Fournier obtained this compound and also **silicomethyl chloride**, or **chlorosilicomethane**, or **monochlorosilane**, SiH_3Cl , by passing dry hydrogen chloride over heated amorphous silicon, and absorbing the products in silicon tetrachloride cooled by means of solid carbon dioxide. By fractional distillation of the soln., the compounds, SiH_3Cl , which boils at about -10°, and SiH_2Cl_2 , which boils at about 12°, were obtained. Both these chlorides are colourless, mobile liquids, which have a large coeff. of expansion, and are decomposed by water and alkalis with evolution of hydrogen. A sulphur compound boiling at about -25° was also obtained in small quantity; the formation of this is attributed to the presence of sulphur as an impurity in the amorphous silicon. In an attempt to make these compounds by passing silicon tetrachloride vap. over calcium heated to a temp. below redness, the products obtained were hydrogen, hydrogen chloride, **silicochloroform**, calcium chloride, and either calcium silicide or an amorphous silicon, depending on the temp. At a relatively low temp. and with excess calcium hydride, calcium silicide is formed, whereas at a higher temp. and with excess of silicon tetrachloride, amorphous silicon is obtained. According to A. Stock and F. Zeidler, with water, and ammonia, monochlorosilane yields respectively the substances $(\text{SiH}_3)_2\text{O}$ and $(\text{SiH}_3)_3\text{N}$, which are unimolecular and volatile. According to A. Stock and C. Somiesky, monochlorosilane and silver cyanide at 150° yield hydrogen cyanide and cyanogen as gaseous products. At 300°, monochlorosilane is decomposed by silver sulphide into non-volatile silicon compounds, hydrogen, and hydrogen sulphide. Monochlorosilane and hydrogen sulphide at 150° in the presence of aluminium chloride give hydrogen, dichloromonosilane, and a volatile compound containing sulphur—possibly SiH_3SH or $(\text{SiH}_3)_2\text{S}$. The main products of the action of sodium amalgam on dichloromono-

silane are monosilane and the unsat., yellow, polymerized hydride, $(\text{SiH})_x$. The course of the reaction is represented by the equations $\text{SiH}_2\text{Cl}_2 + 4\text{Na} \rightarrow \text{SiH}_2\text{Na}_2 + 2\text{NaCl}$; $\text{SiH}_2\text{Na}_2 + \text{mercury} \rightarrow \text{SiH}_2 + \text{sodium amalgam}$; $3\text{SiH}_2 \rightarrow \text{SiH}_4 + 2(\text{SiH})_2$. A. Stock and F. Zeidler found that, when the dichloro-compound is treated with water, and ammonia, it gives respectively the products SiH_2O and $\text{SiH}_2 : \text{NH}$, which can be preserved for a short time in the volatile form with low mol. wt., but rapidly become associated to non-volatile polymerides. Trichlorosilane yields respectively $(\text{SiOH})_2\text{O}$, and $(\text{NH} : \text{SiH})_2\text{NH}$; and tetrachlorosilane, respectively $\text{Si}(\text{OH})_2\text{O}$, and $\text{Si}(\text{NH}_2)_2\text{NH}$. R. Wintgen represented the vap. press., p , of monochlorosilane and dichlorosilane, respectively by $\log p = 7.6251 - 1148 \cdot 17 T^{-1}$, and $\log p = 7.8001 - 1378 \cdot 8 T^{-1}$; the latent heat of vaporization by 5248 and 6302 cal.; the mol. heat of vaporization at 0°K . by 6329.9 cal. and 5929.5 cal.; and at $T^\circ \text{K}$., by 4802 cal. and 6016 cal.; and Trouton's constant by 19.8 and 21.4.

The homologous series of the chlorine derivatives of the silanes, $\text{Si}_n\text{Cl}_{2n+2}$, has been followed as far as $n=6$:

	SiCl_4	Si_2Cl_6	Si_3Cl_8	$\text{Si}_4\text{Cl}_{10}$	$\text{Si}_5\text{Cl}_{12}$	$\text{Si}_6\text{Cl}_{14}$
B.p. . .	56.9°	147°	216°	150°	190° (15 mm.)	Sublimes 200°

L. Troost and P. Hautefeuille⁶ prepared hexachlorosilicoethane, or hexachlorodisilane, or perchlorosilicoethane, Si_2Cl_6 , by passing the vap. of silicon tetrachloride over white-hot silicon, contained in a porcelain tube, and by cooling the products rapidly. The hexachlorodisilane is separated by fractional distillation from the unchanged tetrachloride and other silicon chlorides. L. Gattermann and K. Weinleg obtained hexachlorosilane by fractionating the products obtained by the action of chlorine on the crude silicon obtained by reducing quartz sand with magnesium. 50 grms. of crude silicon tetrachloride so obtained furnished 10 grms. of hexachlorodisilane. C. Friedel obtained this compound by the action of chlorine on the corresponding iodide, Si_2I_6 ; and C. Friedel and A. Ladenburg, by gently heating a mixture of this iodide with mercuric chloride. A. J. Besson and L. Pongnier obtained hexachlorodisilane by the fractional distillation of the complex liquid obtained by the action of the electrical discharge on a mixture of dry hydrogen and silicon tetrachloride.

L. Troost and P. Hautefeuille showed that the hexachlorodisilane is not formed by the action of the vap. of silicon tetrachloride on silicon below 250° , and the vap. of hexachlorodisilane is not decomposed at this temp. This is regarded by P. Duhem as *une region des faux équilibres*. At 350° , the vap. is decomposed very slowly and the action is limited: $2\text{Si}_2\text{Cl}_6 \rightleftharpoons 3\text{SiCl}_4 + \text{Si}$. The deposit of silicon is scarcely appreciable after 24 hrs. The reverse action is quite inappreciable. As the temp. is raised, the decomposition of the hexachlorodisilane becomes more and more marked—at 440° , the decomposition is marked, and at 800° , complete. On the other hand, the decomposition is partial at 1000° , and at this temp. the tetrachloride unites with silicon to form hexachlorodisilane. The observations of L. Troost and P. Hautefeuille are illustrated graphically by Fig. 201, due to P. Duhem—vide volatility of silicon. In the preparation of hexachlorodisilane the need for rapid cooling past the region of complete decomposition will be apparent. The diagram also explains how during the passage of silicon tetrafluoride or tetrachloride over heated silicon, an annular deposit of crystalline silicon is formed about that part of the porcelain tube which is just below red heat in the case of the tetrafluoride and when the temp. is 500° – 800° in the case of the tetrachloride.

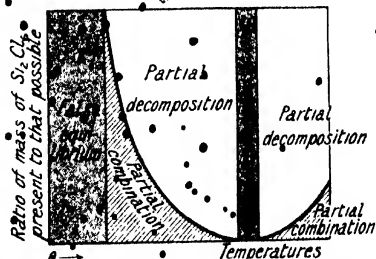

Fig. 201.—Equilibrium Conditions of Hexachlorodisilane (Diagrammatic).

Hexachlorodisilane is a colourless fuming liquid at ordinary temp. L. Troost and P. Hautefeuille gave 1.58 for the sp. gr. at 0°; G. Martin, 1.5624 at 15°/4°; and for the vap. density, 9.7 at 239°, when the theoretical value for Si_2Cl_6 is 9.29. The b.p. is 146°–148°. G. Martin gave for the b.p. at different press., p , mm.:

p	12	20	50	705	130	150	200	760
B.p.	40°	50°	55°	84°	92°	95°	102°	144°–145.5°

L. Troost and P. Hautefeuille found that hexachlorodisilane freezes at -14° to large tabular crystals resembling those of boric acid. L. Gattermann and K. Weinleg gave -1° for the m.p. of the crystals; and 1.45 for the index of refraction in red light. G. Martin gave 7.4748 at 18° for the D -line. P. Pascal studied the magnetic susceptibility of this compound. L. Troost and P. Hautefeuille found that the heated vap. of hexachlorodisilane inflames in air; and that the liquid in contact with water decomposes, forming silico-oxalic acid and hydrochloric acid: $\text{Si}_2\text{Cl}_6 + 4\text{H}_2\text{O} = \text{HOOSiSiOOH} + 6\text{HCl}$; and with soln. of ammonia or potassium hydroxide, silicic acid is formed since silico-oxalic acid is decomposed by alkalis: $\text{Si}_2\text{Cl}_6 + 6\text{H}_2\text{O} = 2\text{H}_2\text{SiO}_3 + 6\text{HCl} + \text{H}_2$. G. Martin showed that hexachlorodisilane reacts with chlorine $\text{Si}_2\text{Cl}_6 + \text{Cl}_2 = 2\text{SiCl}_4$. With gaseous ammonia it forms **hexachlorododecamminodisilane**, $\text{Si}_2\text{Cl}_6 \cdot 12\text{NH}_3$, which begins to lose ammonia at 160° , and is slowly decomposed by water. According to A. J. Besson, phosphine is reduced by hexachlorodisilane at -50° , forming a solid phosphorus hydride. J. Gattermann and K. Weinleg found that with sodium and chlorobenzene, tetraphenylsilicon, not hexaphenylsilicon, is formed. When silicon tetrachloride is poured into absolute alcohol, there appears to be a momentary evolution of heat followed by a powerful cooling action. The cooling appears to be a secondary effect due to the rapid evolution of a large amount of hydrogen chloride, so that the heat of the chemical action is masked by the cooling due to the passage of dissolved hydrogen chloride into the gaseous state. In the case of the hexachlorodisilane, the cooling is so great that hoar-frost collects on the side of the reaction vessel. With silicon tetrachloride, **ethyl orthosilicate**, $\text{Si}(\text{OC}_2\text{H}_5)_4$, b.p. 160° , is formed. G. Martin has isolated six substitution derivatives from the products of the reaction between hexachlorodisilane and alcohol. Some properties of these compounds are indicated in Table XXXVI.

TABLE XXXVI.—ETHOXY-DERIVATIVES OF HEXACHLORODISILANE.

Compound.	Formula.	B.p. (<34 mm.).	Sp. gr. 15°–20°.	Refractive index D -line 14.5°.
Hexachlorodisilane	Si_2Cl_6	60.5°	1.562	1.4748 (18°)
Pentachlorethoxydisilane	$\text{Si}_2\text{Cl}_5(\text{OC}_2\text{H}_5)$	84°	1.388	1.4568
Tetrachlorodiethoxydisilane	$\text{Si}_2\text{Cl}_4(\text{OC}_2\text{H}_5)_2$	104°	1.270	1.4432
Trichlorotriethoxydisilane	$\text{Si}_2\text{Cl}_3(\text{OC}_2\text{H}_5)_3$	122°	1.163	1.4433
Dichlorotetraethoxydisilane	$\text{Si}_2\text{Cl}_2(\text{OC}_2\text{H}_5)_4$	—	—	—
Chloropentethoxydisilane	$\text{Si}_2\text{Cl}(\text{OC}_2\text{H}_5)_5$	138°	1.092	1.4205
Hexethoxydisilane	$\text{Si}_2(\text{OC}_2\text{H}_5)_6$	141°	0.972	1.4134°

There is a progressive increase in the b.p., a progressive decrease in the sp. gr., and in the refractive indices as the chlorine atoms are replaced one by one by the ethoxy-group, OC_2H_5 . The member $\text{Si}_2\text{Cl}_2(\text{OC}_2\text{H}_5)_4$ was not obtained pure enough for the determination of the constants. Theoretically, there should be a pair of isomeric forms for the third, fourth, and fifth members of the above table, but only one form of each has, as yet, been obtained.

By the rectification between 210° and 215° of the products of the action of chlorine on the crude silicon obtained by the action of magnesium on quartz sand, L. Gattermann and K. Weinleg⁷ obtained **octochlorotrisilane**, or **octochloropropane**, Si_3Cl_8 . The unrectified product, consisting mainly of silicon tetrachloride and hexachloro-

disilane, contains 0.5–1.0 per cent. of octochlorotrisilane. According to L. Gattermann and E. Ellery, and C. Combes, its formation depends on the presence of magnesium silicide in the crude silicon. A. J. Besson and L. Fournier obtained octochlorodisilane by the fractional distillation of the complex liquid obtained by the action of the electrical discharge on a mixture of hydrogen and trichlorosilane. Octochlorosilane is a colourless liquid and, according to L. Gattermann and K. Weinleg, has a vap. density 13.0 when the theoretical value for Si_3Cl_8 is 12.8. G. Martin found for the sp. gr. 1.61 at $15^\circ/4^\circ$. According to A. J. Besson and L. Fournier, the b.p. is $215^\circ\text{--}218^\circ$; and G. Martin found for the b.p. at a press., p mm.:

p	17	30	60	80	90	110	760
B.p.	100°	113°	129°	139°	143°	149°	$210^\circ\text{--}213^\circ$

A. J. Besson and L. Fournier obtained, after solidification, the m.p. -67° . L. Gattermann and K. Weinleg found the index of refraction for red light to be 1.52; and G. Martin, 1.5135 at 14.5° for Na-light. This substance is quickly decomposed by water, and, if the temp. be about 0° , mesosilico-oxalic acid is formed: $\text{Si}_3\text{Cl}_8 + 6\text{H}_2\text{O} = 8\text{HCl} + \text{HOOSi}(\text{OH})_2\text{SiOOH}$.

A. J. Besson and L. Fournier found that the silicon chlorides obtained by the action of an electric discharge on silicochloroform are of the sat. series, so that the action which occurs in an atm. of hydrogen or of hydrogen chloride is accompanied by a liberation of hydrogen and hydrogen chloride. The fraction of the product intermediate between Si_2Cl_6 and Si_3Cl_8 shows, however, an undoubted deficit of chlorine, and may contain small quantities of unsaturated chlorides. The mixture of silicon tetrachloride and dichlorosilane obtained by acting on amorphous silicon with hydrogen chloride, when submitted to the electric discharge, seems to give the same mixture of sat. compounds instead of unsat. substances. Seemingly, the excess of hydrogen chloride acts on the unsat. silicon chlorides with the liberation of hydrogen. By the action of the electric discharge on hydrogen and silicon tetrachloride, a mixture of sat. silicon chlorides is produced, which are, however, present in proportions differing from those in the mixture just described. The fractional distillation of the mixture of silicon chlorides obtained by the action of the electrical discharge on a mixture of hydrogen and silicon tetrachloride, after separating the tetrachlorosilane, hexachlorosilane, and octochlorotrisilane, furnished **decachlorosilicobutane** or **decachlorotetrasilane**, $\text{Si}_4\text{Cl}_{10}$, as an oily liquid, boiling at $149^\circ\text{--}151^\circ$ and 15 mm. The liquid fumes in the air, is readily decomposed by water, forming a white product resembling silica, and often gives off sparks and ignites when gently rubbed. They also obtained **dodecachlorosilicopentane**, or **dodecachloropentasilane**, $\text{Si}_5\text{Cl}_{12}$, as a very viscous liquid boiling at about 190° and 15 mm.; and **tetradecachlorosilicohexane**, or **tetradecachlorohexasilane**, $\text{Si}_6\text{Cl}_{14}$, as a white solid, melting at 170° with decomposition, and subliming in vacuo at about 200° . The sublimate consists of crystals with a waxy consistency, and which are readily decomposed by water giving a white combustible substance. After the above-named compounds have been removed by prolonged heating at $200^\circ\text{--}210^\circ$ in a vacuum, there remains a solid, reddish-yellow, glassy mass, which is almost entirely soluble in light petroleum or carbon tetrachloride, and is apparently a mixture of a number of chlorides.

The silicon oxychlorides.—The reaction between sulphur trioxide and carbon tetrachloride furnishes phosgene, COCl_2 , and pyrosulphuryl chloride, $\text{S}_2\text{O}_5\text{Cl}_2$, if no moisture be present: $2\text{SO}_3 + \text{CCl}_4 = \text{COCl}_2 + \text{S}_2\text{O}_5\text{Cl}_2$; and in the presence of moisture some chlorosulphonic acid is formed. According to G. Gustavson,⁸ silicon tetrachloride furnishes pyrosulphuryl chloride when it reacts with sulphur trioxide. C. R. Sanger and E. R. Riegel, however, have shown that there is no sign of the formation of *silicophosgene*, or *silicetyl chloride*, SiOCl_2 , analogous to phosgene, or carbonyl chloride, COCl_2 . Sulphur trioxide is dissolved by silicon tetrachloride, and at ordinary temp. reacts very slowly, but at 50° the reaction

is quicker (5-6 hrs.), and when the product is distilled at atm. press. a fuming liquid is obtained between 135° and 150° , which reacts vigorously with water. The indefiniteness of the b.p. suggests that the distillate is a mixture; but the constituents have not been separated. Analyses and the b.p. of artificial mixtures indicate that the product contains pyrosulphuryl chloride, $\text{S}_2\text{O}_5\text{Cl}_2$, and silicon oxychloride, Si_2OCl_6 , in equimolar proportions. This is confirmed by redistillation from a great excess of phosphorus pentoxide or of sodium chloride, whereby the silicon is largely decomposed and an impure pyrosulphuryl chloride is formed. The main reaction between sulphur trioxide and silicon tetrachloride is therefore symbolized: $2\text{SO}_3 + 2\text{SiCl}_4 = \text{S}_2\text{O}_5\text{Cl}_2 + \text{Si}_2\text{OCl}_6$, and not $2\text{SO}_3 + \text{SiCl}_4 = \text{S}_2\text{O}_5\text{Cl}_2 + \text{SiOCl}_2$. The fraction which distils below 135° is a mixture of silicon tetrachloride and sulphur trioxide. If a mixture of the reacting constituents be allowed to stand for three summer months, a considerable amount of silica separates, and the distillate contains an excess of pyrosulphuryl chloride, accordingly, after the reaction $2\text{SO}_3 + 2\text{SiCl}_4 = \text{Si}_2\text{OCl}_6 + \text{S}_2\text{O}_5\text{Cl}_2$; when the sulphur trioxide is in excess, it is assumed that a consecutive reaction occurs: $\text{Si}_2\text{OCl}_6 + 6\text{SO}_3 = 2\text{SiO}_2 + 3\text{S}_2\text{O}_5\text{Cl}_2$.

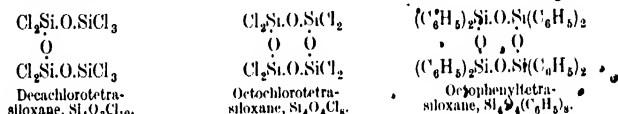

The first silicon oxychloride was made by C. Friedel and A. Ladenburg⁹ by passing the vap. of silicon tetrachloride through a porcelain tube packed with fragments of felspar, and heated to whiteness. The condensed liquid was fractionally distilled to free it from unchanged silicon chloride. The required fraction was collected between 136° and 139° . The composition corresponded with **silicon oxychloride**, or **hexachlorodisiloxane**, Si_2OCl_6 , or $(\text{SiCl}_3)_2\text{O}$. C. R. Sanger and E. R. Riegel found this oxychloride among the products of the action of liquid sulphur trioxide on silicon tetrachloride—*vide supra*. L. Troost and P. Hautefeuille made it by passing a mixture of chlorine with one-half or one-fifth its vol. of oxygen, over crystalline silicon, when a mixture of silicon oxychlorides and chlorides is obtained. The heat evolved is sufficient to continue the reaction when once it has commenced. Too high a temp. is to be avoided, since the vap. of the dichloride and oxychlorides form a thick cloud which is only condensed with difficulty. The action of the mixture on silicon is not so violent as that of chlorine alone; but it is not known whether silicon tetrachloride is first formed and chlorine afterwards displaced in it, or the oxygen and chloride both unite directly with the silicon. A. J. Besson and L. Fournier prepared hexachlorodisiloxane and some of the other oxychlorides by the action of oxygen or chromic acid on trichlorosilane. A. Stock and co-workers obtained it by the action of chlorine on disiloxane, $(\text{SiH}_3)_2\text{O}$, which is vigorous even at -125° . The primary product may be isolated, but most of it decomposes into silica and silicon tetrachloride: $4(\text{SiCl}_3)_2\text{O} = 2\text{SiO}_2 + 6\text{SiCl}_4$. H. N. Stokes tried unsuccessfully to make this compound by the action of phosphoryl chloride on the chlorohydrins of ethyl ortho- and di-silicates. Hexachlorodisiloxane is a colourless, limpid, fuming liquid; and the vap. density, 10.05, obtained by C. Friedel and A. Ladenburg, is very close to the value 9.86 calculated for Si_2OCl_6 . The constitution is therefore likely to be $\text{Cl}_3\text{Si.O.SiCl}_3$. The liquid boils at 137° to 138° , and A. Stock and co-workers obtained 137° at 760 mm. for the b.p., and -33° for the m.p. R. Wintgen gave for the vap. press., p , of hexachlorodisiloxane, $\log p = 8.2936 - 2197.4T^{-1}$; 10941 cal. for the latent heat of vaporization; 11,174 cal. for the mol. heat of vaporization at 0° K., and 8868 cal. at T° K.; and 2.16 for Trouton's constant. C. Friedel and A. Ladenburg found that the compound can be heated much above its b.p. without decomposition, but it is decomposed on exposure to air, and vigorously when in contact with water, forming silicic and hydrochloric acids; it is miscible in all proportions with carbon disulphide, carbon tetrachloride, chloroform, silicon tetrachloride, and ether; but with absolute alcohol it forms hexethoxydisiloxane: $(\text{SiCl}_3)_2\text{O} + 6\text{C}_2\text{H}_5\text{OH} = 6\text{HCl} + \text{Si}_2\text{O}(\text{OC}_2\text{H}_5)_6$; and with zinc ethyl at 180° , its reaction is supposed to be in accord with the equations, $(\text{SiCl}_3)_2\text{O} + 4\text{Zn}(\text{C}_2\text{H}_5)_2 = 2\text{Si}(\text{C}_2\text{H}_5)_4 + \text{ZnO} + 3\text{ZnCl}_2$, and $(\text{SiCl}_3)_2\text{O} + 3\text{Zn}(\text{C}_2\text{H}_5)_2 = 3\text{ZnCl}_2 + \text{Si}_2\text{O}(\text{C}_2\text{H}_5)_6$. According to C. R. Sanger and E. R. Riegel, hexachlorodisiloxane and pyrosulphuryl chloride appear to

form a compound on warming, which solidifies at -78° ; a simple mixture of the two substances solidifies about -38° .

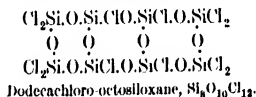

A number of the less volatile oxychlorides was found to accompany hexachlorodisilane; and L. Troost and P. Hautefeuille found that the best method of preparing them was by the direct action of oxygen on hexachlorosiloxane. A mixture of oxygen and vap. of hexachlorodisiloxane was passed several times backwards and forwards through a glass tube filled with fragments of porcelain, and heated by a gas-furnace. At the end of the operation, a liquid was obtained, containing, besides the excess of hexachlorodisiloxane employed, a whole series of oxychlorides of silicon. They were separated, their percentage compositions, and their condensation in the state of vapour at 440° were determined. Some properties of these compounds are as follows:

	B.p.	Vap. density at 440° .
SiO_2OCl_2	$136^{\circ}\text{--}139^{\circ}$	Found. 9.86 Theory. (10.95)
$\text{SiO}_2\text{O}_3\text{Cl}_{10}$	$152^{\circ}\text{--}154^{\circ}$	—
$\text{Si}_4\text{O}_6\text{Cl}_8$	$198^{\circ}\text{--}202^{\circ}$	15.5
$\text{Si}_4\text{O}_{10}\text{Cl}_{12}$	c. 300°	31.2
$(\text{Si}_4\text{O}_3\text{Cl}_2)_n$	$<400^{\circ}$	28.0
$(\text{Si}_4\text{O}_7\text{Cl}_2)_n$	(Solid) 440°	—

There is no actual evidence of the constitution of these compounds. The second, **decachlorotetrasiloxane**, $(\text{SiCl}_3)_2\text{O}_3(\text{SiCl}_2)_2$ and the third, **octachlorotetrasiloxane**, $(\text{SiCl}_2)_4\text{O}_4$, in the list may be related to the phenyl derivative prepared by F. S. Kipping, and represented:

The fourth member, **dodecachloro-octosiloxane**, $(\text{SiCl}_2)_4(\text{SiCl})_4\text{O}_{10}$, may consist of two rings of the preceding member of the series united by oxygen atoms:

The mol. wt. of the other two members of the series are unknown. The complexity of the oxychlorides recalls that of the complex silicic acids and of the silicates.

§ 58. The Silicon Bromides

G. S. Sérullas¹ made silicon tetrabromide, or tetrabromosilane, SiBr_4 , by passing the vap. of bromine over a red-hot intimate mixture of silica and carbon. J. E. Reynolds made the carbon-silica mixture from pellets of silica and syrup of sugar, dried, and ignited. J. E. Reynolds purified the crude product by passing dry hydrogen through the liquid to remove most of the free bromine; and the product was then shaken up with metallic mercury. The liquid was then subjected to fractional distillation, and the fraction boiling at 153° collected. G. P. Baxter and co-workers described the purification of silicon tetrabromide for their work on the at. wt. of silicon.

E. Lay said that only a poor yield was obtained by passing bromine over a mixture of freshly precipitated silica and carbon. L. Gattermann made silicon tetrabromide by passing bromine vap. over the crude silicon made by reducing quartz sand with magnesium. The liquid, which was collected in a receiver cooled with ice and salt, was purified by fractional distillation; shaking with mercury; and redistilling. M. Blix made the compound by the action of bromine vap. on purified silicon at a red heat, and he purified the product by digesting it with mercury on an oil-bath. E. Lay recommended making silicon tetrabromide by the action of a mixture of bromine vap. and hydrogen on ferro-silicon at 60° , and purifying the product by J. E. Reynolds's process. It is also made by passing a rapid current of hydrogen bromide over silicon at a red heat, and purifying the products by fractional distillation. L. Gattermann found that a better yield of the tetrabromide is obtained by passing hydrogen bromide over the crude silica freed from magnesia by washing with dil. acid. The product is separated from the accompanying tribromosilane by fractional distillation. G. Gustavson obtained

silicon tetrabromide as a product of the action of silicon tetrachloride on carbon tetrabromide. A. J. Besson and L. Fournier found silicon tetrabromide among the products of the action of an electrical discharge on tribromosilane.

Silicon tetrabromide is a heavy colourless liquid which evolves dense white fumes when exposed to air. The ethereal odour in G. S. Sérullas' preparation was attributed to the presence of carbon tetrabromide. J. I. Pierre gave 2.9128 for the sp. gr. at 0°; J. E. Reynolds, 2.82; G. Abati, 2.77223 at 23.5°. G. S. Sérullas gave 148°–150° for the b.p.; J. E. Reynolds, 153°; L. Cattermann, 153°–154°; G. Abati, 153.4° at 741.4 mm.; and M. Blix, 150.8° at 751.4 mm. G. S. Sérullas said that the liquid freezes at –12° to –15°; and M. Blix gave 5° for the m.p. of the solid. C. M. Guldberg gave 383° for the critical temp. J. I. Pierre found the vol., v , which unit vol. of liquid acquires at θ° is $v = 1 + 0.0352572440\theta + 0.007567420\theta^2 + 0.002920740\theta^3$; or the coeff. of expansion at 20° is 0.03983. J. J. Saslawsky studied the relation between the coeff. of expansion and the structure. M. Berthelot gave for the heat of formation with crystalline silicon and liquid bromine $\text{Si} + 4\text{Br} = \text{SiBr}_4(\text{liq.})$, 71 Cals.; and with $\text{SiBr}_4(\text{gas})$, 858 Cals. G. Abati gave for the indices of refraction, 1.55820 for the H_α -line; 1.57410 for the H_β -line; 1.56267 for the D -line; and 1.58370 for the H_γ -line; for the mol. refraction for the H_α -line with the n -formula, 70.07; and with the n^2 -formula, 40.48; and for the sp. dispersion, $(\mu_\gamma - \mu_\alpha)/D = 0.00920$.

The general properties of the tetrabromide resemble those of the tetrachloride; but, unlike silicon tetrachloride, A. J. Besson and L. Fournier found that when the tetrabromide is mixed with hydrogen, and subjected to the electrical discharge, there is very little change. C. Friedel and A. Ladenburg found that oxygen decomposes the vap. of silicon tetrabromide. According to G. S. Sérullas, water rapidly decomposes silicon tetrabromide with a considerable rise of temp.; the hydrolysis is accompanied by the formation of silicic and hydrobromic acids. M. Berthelot gave $\text{SiBr}_4(\text{liq.}) + 2\text{H}_2\text{O} + \text{Aq.} = \text{SiO}_2(\text{aq.}) + 4\text{HBr} + 85.8$ Cals. A. J. Besson showed that when distilled with iodine, with or without hydrogen, over heated silicon, bromoiodides are formed; and with dry hydrogen iodide, at a red heat, silicon bromoiodide is produced. M. Blix found that hydrogen sulphide is without action on the liquid tetrabromide; G. S. Sérullas, that under sulphuric acid, the tetrabromide is resolved into silica and bromine in the course of a few days; and A. J. Besson, that silicon tetrabromide absorbs ammonia, forming white amorphous *silicon heptamminotetrabromide*, $\text{SiBr}_4 \cdot 7\text{NH}_3$, which is decomposed by water. E. Lay could not make the heptammino-compound, but by mixing ammonia with the vap. of silicon tetrabromide, diluted with hydrogen to keep down the temp., he obtained *silicon hexamminotetrabromide*, $\text{SiBr}_4 \cdot 6\text{NH}_3$; and the same compound was obtained by the action of ammonia on a soln. of silicon tetrabromide in benzene.

The white pulverulent hexammine has d.sp. gr. 2.307 at 17°. It is slowly decomposed by exposure to moist air; and when heated, both bromine and ammonia are given off. All the bromine can be expelled by heating the hexammine to 900° in a stream of ammonia, or carbon dioxide. Lead peroxide is reduced to lead; and, when heated with potassium chlorate, there is a vigorous reaction and much bromine is evolved. Two mols. of ammonia are lost in contact with water—slowly in the cold, rapidly when heated: with boiling alkali-lye, ammonia is evolved; conc. nitric acid reacts vigorously, giving off bromine and nitrogen oxides; and when heated with conc. sulphuric acid, bromine is given off: $\text{SiBr}_4(\text{NH}_3)_6 + 5\text{H}_2\text{SO}_4 = \text{Si}(\text{OH})_4 + 3(\text{NH}_4)_2\text{SO}_4 + 2\text{Br}_2 + 2\text{SO}_2$.

A. J. Besson found that silicon tetrabromide is without action on phosphine under ordinary press., even at the l.p.; but after repeated compression, and maintaining the press. for several hours, a colourless liquid is formed which becomes white and opaque, and changes into an amorphous white solid. As shown by J. E. Reynolds, silicon tetrabromide forms additive compounds with various organic bases, aniline, and thio- and alkylated ureas. G. S. Sérullas noted that when gently heated with potassium, the hexammine explodes violently and breaks the glass containing vessel. C. Friedel and A. Ladenburg found that with lead oxide at 250°, lead bromide and silicate are formed. A. J. Besson obtained yellow

tabular crystals of what was considered to be a *silicon oxybromide* when air reacts gradually with a mixture of silicon tetrabromide and tribromosilane. The oxybromide is volatile in a current of nitrogen, and is decomposed by water into hydrobromic and silicic acids.

As in the case of silicon tetrachloride, a complete series of hydrogen substitution products, *silicon bromohydrides*, $\text{SiH}_n\text{Br}_{4-n}$, has been obtained with silicon tetrabromide.

	SiBr_4	SiHBr_3	SiH_2Br_2	SiH_3Br	SiH_4
B.p.	150°8'	111°	66°	1°9'	-11°

H. Buff and F. Wöhler² made *silicobromoform*, or *tribromosilane*, SiHBr_3 , from the products obtained by passing hydrogen bromide over heated silicon as in the case of silico-chloroform. A. J. Besson and L. Fournier used a similar process. They found that 98 per cent. of the liquid consisted of silicon tetrabromide and the remaining 2 per cent. consisted of the tri- and di-bromosilanes. The compound was purified by shaking it with mercury, and by fractional distillation. L. Gattermann used the crude silicon obtained by reducing quartz sand with magnesium, after washing out the magnesia with dil. acid; and C. Combes used copper silicide containing 20 per cent. of silicon. The preparation of this bromide by O. Ruff's method used for tri-iodosilane was unsatisfactory because tribromosilane and benzene boil so close together that they cannot be separated by fractional distillation. The colourless, fuming, liquid tribromosilane, according to A. J. Besson, ignites spontaneously in air. H. Buff and F. Wöhler found the sp. gr. of the liquid to be 2.5; and L. Gattermann, 2.7 at 17°. The latter said that the preparation of H. Buff and F. Wöhler was probably impure. A. J. Besson said that in a neutral atm., tribromosilane boils without decomposition at 109°-110°. A. J. Besson and L. Fournier gave 110°-122°, and L. Gattermann, 115°-117°. A. J. Besson said that the liquid does not freeze at -60°. Tribromosilane is decomposed by water, and if the mixture be kept cool, silicoformic anhydride is produced. It reacts with iodine forming silicon tribromiodide. It reacts energetically with ammonia with the development of heat and light, but the white product contains silicop, hydrogen, and ammonia. Phosphine does not combine with tribromosilane at -40° under ordinary press., but at 15° and 25 atm. press., it produces a white solid *phosphinetribromosilane*.

A. J. Besson and L. Fournier obtained *dibromosilane*, or *silicomethylene bromide*, or *dibromosilicomethane*, SiH_2Br_2 , as indicated above, from the products of the action of hydrogen bromide on red-hot silicon. Under ordinary conditions the reaction between bromine and silane is very violent, but A. Stock and C. Somiesky found that if an excess of gas is led into a large vessel on the walls of which solid bromine is deposited, and the temp. maintained at about -80° to -70°, the mono- and di-bromides can be obtained comparatively free from silicon tetrabromide and tribromosilane. The products can be separated and purified by fractional distillation. A. J. Besson and L. Fournier found dibromosilane to be a mobile, highly refracting, colourless, fuming liquid which inflames spontaneously when exposed to air. A. Stock and C. Somiesky found that it can be kept a long time in thoroughly dried vessels; and that the sp. gr. of the liquid is 2.17 at 0°. A. J. Besson and L. Fournier gave c. 75° for the b.p., and A. Stock and C. Somiesky, 66° at 760 mm., or 18° at 12 mm. The m.p. is -70.1°. R. Wintgen gave for the vap. press., p , of dibromosilane, $\log p = 6.642 - 1620/277 + 1$; for the latent heat of vaporization, 7405 cal. The liquid is very sensitive to moisture, and is decomposed by water into hydrobromic acid, and a solid, $(\text{SiH}_2\text{O})_n$. Alkali-lye decomposes it in accord with $\text{SiH}_2\text{Br}_2 + 4\text{NaOH} = 2\text{H}_2 + 2\text{NaBr} + \text{Na}_2\text{SiO}_3 + \text{H}_2\text{O}$.

A. J. Besson and L. Fournier obtained evidence of *silicomethyl bromide*, *monobromosilane*, or *bromosilicomethane*, SiHBr , in the low-boiling products of the action of hydrogen bromide on red-hot silicon; and, as indicated above, A. Stock and C. Somiesky isolated it from the products of the action of silane on solid bromine at -80° to -70°. At ordinary temp., monobromosilane is a colourless gas

with a pungent odour reminiscent of silane. The liquid has a sp. gr. 1.533 at 0° ; it boils at 1.9° and 760 mm.; its m.p. is -94° . R. Wintgen gave for the vap. press., p , of monobromosilane, $\log p = 7.5243 - 1276.5T^{-1}$; for the latent heat of vaporization, 5834 cal.; for the mol. heat of vaporization at 0° K., 5386.0 cal., and at T° K., 5852 cal.; and for Trouton's constant, 21.3. It may be preserved over mercury for some time, but it detonates on exposure to the air, giving silicic acid and brown silicon. It reacts with cold water according to the equation: $2\text{SiH}_3\text{Br} + \text{H}_2\text{O} = 2\text{HBr} + (\text{SiH}_3)_2\text{O}$; whilst it may be analyzed by measuring the vol. of hydrogen produced under treatment with 30 per cent. sodium hydroxide, according to the equation: $\text{SiH}_3\text{Br} + 3\text{NaOH} = 3\text{H}_2 + \text{NaBr} + \text{Na}_2\text{SiO}_3$.

A complete series of **silicon chlorobromides** has been obtained ranging between the extremes silicon tetrachloride and tetrabromide:

	SiBr_4	SiCl_3Br_3	SiCl_2Br_4	SiClBr_3	SiCl_4
B.p.	150.8°	127°	104°	80°	58°

G. S. Scullas³ obtained **chlorotribromosilane**, SiClBr_3 , as a by-product in the manufacture of the tetrabromide, and J. E. Reynolds found it to be present in the fraction boiling between 140° and 144° . A. J. Besson separated it from the by-product in the preparation of the dichlorodibromide by fractional freezing, not fractional distillation. A. J. Besson and L. Fournier found it among the products obtained by passing the electrical discharge through a mixture of silicon tetrachloride, bromine, and hydrogen. All three chlorobromides are formed. The dichlorodibromide appears to be the chief constituent of the mixture, and when this is submitted in the presence of hydrogen to the further action of the discharge, it undergoes decomposition in accordance with the equation: $2\text{SiCl}_2\text{Br}_2 = \text{SiCl}_3\text{Br} + \text{SiClBr}_3$. If a mixture of the three chlorobromides is treated in the same way, derivatives of the type Si_2X_6 appear to be formed, but their separation has not been satisfactorily accomplished. The chlorotribromide appears as a colourless liquid which fumes in air. J. E. Reynolds gave 2.432 for the sp. gr., and 10.43 for the vap. density when the value calculated for SiClBr_3 is 10.47. A. J. Besson found that it solidified when cooled below -50° ; and the m.p. of the solid is -39° ; J. E. Reynolds gave 140° - 141° for the b.p., and A. J. Besson, 126° - 128° . When treated with water it rapidly decomposes, forming silicic, hydrochloric, and hydrobromic acids. A. J. Besson obtained a white solid **silicon hemihenadecaminochlorotribromide**, $2\text{SiClBr}_3 \cdot 11\text{NH}_3$, which is decomposed by water. The composition may be really that of a hexamine.

C. Friedel and A. Ladenburg heated trichlorosilane and bromine in a sealed tube over 100° , and obtained a mixture of trichlorobromosilane and **dibromodichlorosilane**, SiBr_2Cl_2 , which were separated by fractional distillation at about 100° ; the trichlorobromosilane collects between 78° and 82° . The products are purified by shaking with mercury followed by redistillation. A. J. Besson likewise obtained it from the products which are formed when a mixture of bromotrichlorosilane and hydrogen bromide is passed through a red-hot porcelain tube; and, as indicated above, A. J. Besson and L. Fournier found it among the products obtained by passing the electric discharge through a mixture of silicon tetrachloride, bromine, and hydrogen. A. J. Besson found that the colourless fuming liquid does not freeze when cooled to -60° , and also that it boils at 103° - 105° ; C. Friedel and A. Ladenburg gave 100° . It forms **silicon pentamminodibromodichloride**, $\text{SiBr}_2\text{Cl}_2 \cdot 5\text{NH}_3$, when treated with dry ammonia. The white amorphous pentamine is decomposed by water. It may be a hexamine.

C. Friedel and A. Ladenburg prepared **trichlorobromosilane**, SiBrCl_3 , as indicated above, and also by dropping the calculated quantity of bromine into silicon trichlorohydrosulphide; there is a copious evolution of hydrogen bromide; and sulphur bromide is formed: $\text{SiCl}_3(\text{HS}) + 3\text{Br} = \text{SBr} + \text{HBr} + \text{SiCl}_3\text{Br}$. The product is purified by fractional distillation, and shaking with mercury. A. J. Besson obtained trichlorobromosilane by the rectification of the products obtained when

a mixture of hydrogen bromide and silicon tetrachloride vapour is passed through a red-hot porcelain tube; and, as indicated above, A. J. Besson and L. Fournier found it among the products obtained by passing an electric discharge through a mixture of silicon tetrachloride, bromine, and hydrogen. The colourless fuming liquid was found by A. J. Besson not to freeze at -60° . C. Friedel and A. Ladenburg gave 80° for the b.p., and they found that it is decomposed by water into silicic, hydrochloric, and hydrobromic acids. A. J. Besson obtained a white solid, **silicon hemihenadecaminotrichlorobromide**, $2\text{SiBrCl}_3 \cdot 11\text{NH}_3$, which is decomposed by water. It may really be a hexammine. He also found that with phosphine, at -30° and 25 atm., or -22° and 17 atm., a white addition product is obtained which is decomposed when the temp. is raised. The **homologous series** of the bromine derivatives of the silane series, $\text{Si}_n\text{Br}_{2n+2}$, has been followed as far as $n=4$:

	SiBr_4	Si_2Br_6	Si_3Br_8	$\text{Si}_4\text{Br}_{10}$
M.p.	5°	95°	133°	185°

C. Friedel⁴ discovered **hexabromosilicoethane**, or **perbromosilicoethane**, or **hexabromodisilane**, Si_2Br_6 , in 1869. C. Friedel and A. Ladenburg made it by the action of bromine on an eq. amount of hexaiododisilane dissolved in carbon disulphide; the liberated iodine was removed by decantation; the soln. was shaken with mercury; and the solvent evaporated from the soln., taking care to exclude moisture from the atm. The solid can be purified by re-soln. in carbon disulphide, and agitation with mercury. A. J. Besson and L. Fournier found it among the products of the action of an electrical discharge on the vap. of tribromosilane. H. Moissan and A. Holt obtained it by the action of bromine on vanadium silicide. At ordinary temp., hexachlorodisilane forms white, crystalline plates which are optically biaxial. C. Friedel and A. Ladenburg said that it boils at about 240° ; and A. J. Besson and L. Fournier gave 265° for the b.p., and 95° for the m.p. When treated with potash-lye, it develops the theoretical quantity of hydrogen. Its general reactions resemble those of hexachlorosilane.

According to R. Mahn, the interaction of bromine and silane furnishes a little silicon tetrabromide, and **pentabromodisilane**, Si_2HBr_5 , which was separated from the excess of bromine by distillation in a stream of carbon dioxide. The solid melts at 89° , and on cooling furnishes a mass of needle-like crystals which can be distilled at 230° in a stream of hydrogen or carbon dioxide. It sublimes slowly at 100° . It inflames when heated in air. The crystals fume in air, and when treated with water give hydrobromic acid and a white amorphous solid which gives off hydrogen when treated with aq. ammonia, and forms silicic acid. The alleged pentabromodisilane may be impure hexabromodisilane. The impure **silicon bromohydride**, $\text{Si}_2\text{H}_2\text{Br}_4$, of H. Duff and F. Wöhler is probably impure silicon tetrabromide and tribromosilane.

A. J. Besson and L. Fournier, after separating silicon tetrabromide, and hexabromodisilane from the products of the action of an electric discharge on tribromosilane, obtained colourless crystals of **octobromosilicopropane**, or **octobromotrisilane**, Si_3Br_8 , m.p. 95° , b.p. 265° ; crystals of **decabromosilicobutane**, or **decabromotetrasilane**, $\text{Si}_4\text{Br}_{10}$, melting with decomposition at 185° ; and a yellow residue.

§ 59. Silicon Iodides

J. J. Berzelius said that silicon ignited in iodine vap. does not absorb any iodine. If their study of the action of dry hydrogen iodide on silicon at a temp. above a red heat, H. Buff and F. Wöhler¹ obtained a product containing hydrogen, and they assigned to it the formula $\text{Si}_2\text{H}_7\text{I}$, which C. Friedel showed to be a mixture of silicon tetraiodide and tri-iodosilane, and he prepared **silicon tetraiodide, tetra-iodosilicomethane, or tetraiodosilane**, SiI_4 , in a fairly pure condition by passing the vap. of iodine entrained in carbon dioxide over red-hot silicon, and purifying the sublimate by dissolving it in carbon disulphide, shaking it with mercury, and distilling the liquid in a stream of carbon dioxide. L. Gattermann used the crude silicon obtained by reducing quartz sand with magnesium. A. J. Besson obtained silicon tetraiodide mixed with other products by passing silicon chloroiodide, or a mixture of silicon tetrachloride and iodine over heated silicon; and M. Guichard prepared it by passing iodine vap. over silicon heated under reduced press. to 500° . O. Ruff found the solid residue obtained when tri-iodosilane is heated to 300° consists chiefly of silicon tetraiodide, which can be isolated by sublimation.

According to C. Friedel, the vap. of silicon tetraiodide condenses to the solid state when cooled to atm. temp., and the compound can be readily crystallized from its soln. in carbon disulphide. Silicon tetraiodide then furnishes detached crystals belonging to the cubic system, and they are isomorphous with those of carbon tetraiodide. The crystals are colourless or tinged slightly yellow. The vap. density, 19.12, corresponds with 18.56 calculated for SiI_4 . Silicon tetraiodide melts at 120.5° , and boils at about 290° . According to M. Berthelot, the heat of formation is $\text{Si}_{\text{cryst.}} + 4\text{I}_{\text{solid}} = \text{SiI}_{4\text{solid}} + 6.7$ Cals., and with the 4I_{gas} , 33.9 Cals. When the compound is exposed to air, it acquires a colour owing to the separation of iodine; and water decomposes it into silicic and hydriodic acids. M. Berthelot gave $\text{SiI}_4 + 2\text{H}_2\text{O} + \text{Aq.} = \text{SiO}_2 + 4\text{HI}_{\text{soln.}} + 85.7$ Cals. When heated in air, the vap. burns with a red flame which gives off iodine vap. With bromine, silicon tetraiodide furnishes silicon bromoiodide; and when heated with finely divided silver, it forms hexa-iodosilane. 100 parts of carbon disulphide at 27° dissolve 220 parts of silicon tetraiodide. The tetraiodide reacts with alcohol with avidity, forming not ethyl silicate, but silicic and hydriodic acids and ethyl iodide: $\text{SiI}_4 + 2\text{C}_2\text{H}_5\text{O} = \text{SiO}_2 + 2\text{C}_2\text{H}_5\text{I} + 2\text{HI}$; and with ether it does form ethyl silicate: $\text{SiI}_4 + 4(\text{C}_2\text{H}_5)_2\text{O} = 4\text{C}_2\text{H}_5\text{I} + \text{Si}(\text{OC}_2\text{H}_5)_4$.

H. Buff and F. Wöhler obtained impure **silicoiodoform, or tri-iodosilane**, SiHI_3 , by passing hydrogen iodide over silicon at a red heat. C. Friedel showed that the product contained about 8 per cent. of tri-iodosilane; and that the yield is much greater if the hydrogen iodide be mixed with hydrogen in its passage over the heated silicon. The mixture of crystals of tetraiodosilane and liquid tri-iodosilane which is formed, is separated and the liquid purified by fractional

distillation. O. Ruff found that tri-iodosilane can be obtained by the action of hydrogen iodide on silicon imide, Si_2NH , suspended in cold carbon disulphide: $\text{Si}_2\text{NH} + 4\text{HI} = \text{SiHI}_3 + \text{NH}_4\text{I}$, or more readily by treating in benzene soln., triphenylaminosilane, $\text{SiH}(\text{NHC}_6\text{H}_5)_3$, with hydrogen iodide: $\text{SiH}(\text{NHC}_6\text{H}_5)_3 + 6\text{HI} = \text{SiHI}_3 + 6\text{C}_6\text{H}_5\text{NH}_2\cdot\text{HI}$. R. Mahn obtained a mixture of silicon tetraiodide and tri-iodosilane by the action of iodine on silane. C. Combes could not make it by the action of hydrogen iodide on copper silicide. Tri-iodosilane is a colourless liquid which C. Friedel found to have a sp. gr. about 3.362 at 0° and 3.314 at 20° ; O. Ruff gave 3.286 for the sp. gr. at 23° , and 8° for the f.p. Tri-iodosilane decomposes slowly when heated above 150° , liberating hydrogen, and what is probably a volatile silicon iodohydride. The b.p. is about 220° at 760 mm. press., and the temp. of the vap. 205° ; but on continued boiling the temp. slowly rises to 300° , and the residue remaining in the retort is mainly silicon tetraiodide. The tri-iodosilane can be distilled under reduced press. at 106° and 14 mm.; 111° and 22 mm.; 132° and 67 mm.; and at 155° and 122 mm. On exposure to air, the liquid reacts slowly with oxygen with the separation of iodine, and the formation of what is probably a *silicon oxyiodide*; it is combustible in air, forming water, silica, and iodine. The vap., admixed with air, is explosive. The liquid is decomposed by water, forming hydriodic acid and silicoformic anhydride. The liquid is miscible in all proportions with benzene and carbon disulphide.

A. J. Besson² found that dry hydrogen iodide has no action on silicon tetrachloride at the ordinary temp., but at a high temp., products of partial substitution are obtained; the determining cause of the reaction being the difference between the heats of formation of hydrogen chloride and hydrogen iodide, and the partial dissociation of the latter at the temp. of the experiment. Hydrogen iodide, mixed with vap. of silicon tetrachloride, is passed somewhat rapidly through a glass tube heated to redness; the product is agitated with mercury to remove free iodine, and when fractionated furnishes a complete series of *silicon chloroiodides*, $\text{SiCl}_n\text{I}_{4-n}$:

B.p.	SiCl_4	SiCl_3I	SiCl_2I_2	SiClI_3	SiI_4
	58°	$113^\circ\text{--}114^\circ$	172°	$234^\circ\text{--}237^\circ$	290°

A. J. Besson also found that the three chloroiodides are produced when the vap. of iodine monochloride is passed over crystallized silicon heated nearly to redness. The product is purified from free iodine by distillation from copper turnings, and fractionally distilled. A. J. Besson and L. Fournier prepared the chloroiodides by the analogous method employed for the chlorobromides (*q.v.*). In addition to the general methods of preparation, *silicon trichloroiodide*, or *trichloroiodosilane*, SiCl_3I , can be made by heating silicon tetrachloride with iodine in a sealed tube at $200^\circ\text{--}250^\circ$. Silicon trichloroiodide is a colourless liquid which boils at $113^\circ\text{--}114^\circ$, and does not solidify, even at -60° . It is not affected by light alone, but when exposed to air it becomes brown from separation of iodine, and this change is accelerated by light. It fumes in the air, is decomposed by water, and combines with ammonia to form a white, amorphous *silicon tetramindecaminotrichloroiodide*, $2\text{SiCl}_3\text{I} \cdot 11\text{NH}_3$, which is also decomposed by water; it does not form a compound with hydrogen phosphide, even under press. and at a low temp.

In addition to the general methods of preparation, where the yield is small, *silicon dichloroiodide*, or *dichloroiodosilane*, SiCl_2I_2 , can be made by saturating trichloroiodosilane with hydrogen iodide at -22° ; and heating the soln. for 24 hrs. in a sealed tube at 250° . Dichloroiodosilane boils at 172° , does not solidify even at -60° , and rapidly becomes brown, owing to separation of iodine. It fumes in the air, burns with liberation of iodine, and is decomposed by water; when dissolved in carbon tetrachloride, it combines with ammonia to form a white, amorphous *silicon pentaminodichloroiodide*, $\text{SiCl}_2\text{I}_2 \cdot 5\text{NH}_3$, which is decomposed by water.

There is only a small yield of *silicon chlorotriiodide*, or *chlorotriiodosilane*, SiClI_3 , by the general methods of preparation. Chlorotriiodosilane is a colourless

liquid which, on exposure to air, rapidly becomes red, and gives off a combustible vap. It boils at 234° – 237° , and when strongly cooled remains in a surrused condition, but when strongly agitated furnishes a white solid which melts at 2° . Chlorotriiodosilane combines with ammonia gas forming a white solid.

A. J. Besson³ obtained a mixture of the three silicon bromoiodides, $\text{SiBr}_n\text{I}_{4-n}$, by several different methods.

	SiBr_4	SiBr_3I	SiBr_2I_2	SiBrI_3	SiI_4
B.p.	150.8°	192°	230° – 231°	255°	290°

(i) Tribromosilane and iodine were heated in a sealed tube at 200° – 250° ; the main product was the iodotribromide mixed with a small quantity of the other two bromoiodides. (ii) Dry hydrogen iodide and silicon tetrabromide vapour at a little below red-heat furnish the tribromoiodide as the main product and a small quantity of the other bromoiodides. The yield is small. (iii) Iodine monobromide was passed over crystalline silicon nearly at a red heat and a mixture of the three bromoiodides, and some silicon tetrabromide and tetraiodide results. The products may be decolorized by fractionation over copper turnings. The separation of the last two mixed halides by fractional distillation is very difficult.

The first mixed halide, silicon tribromoiodide, or tribromoiodosilane, SiBr_3I , is comparatively easy. It forms a colourless liquid distilling at 192° , and it may be cooled to -20° without solidifying, but the solid melts at 14° . Silicon dibromoiodide, or dibromoiodosilane, SiBr_2I_2 , is a white solid which melts at about 38° and distils at 230° – 231° . Silicon bromotriiodide, or bromotriiodosilane, SiBrI_3 , is a white solid melting at 53° and distilling at 255° . It is difficult to separate it from silicon tetraiodide. The silicon bromoiodides colour rapidly in the air; they absorb dry ammonia gas with the production of white, solid compounds decomposed by water. Silicon tetrabromide in which much iodine has been dissolved may be used in place of the iodine bromide; with the tetrachloride, no reaction occurs.

The second member of the homologous series, $\text{Si}_n\text{I}_{2n+2}$, hexaiodosilicoethane, or hexaiododisilane, Si_2I_6 , was made by C. Friedel and A. Ladenburg.⁴ The compound was made by heating silicon tetraiodide with finely divided silver (reduced by zinc from moist silver chloride), in sealed tubes at 290° – 300° for several hours. The contents of the tube were freed from unaltered tetraiodide by repeated washing with small portions of dry carbon disulphide; a larger quantity of hot carbon disulphide was then added, and the mixture filtered as rapidly as possible out of contact with the moisture of the air. On cooling, the soln. deposited small, colourless, hexagonal prisms of the hexaiodosilane. The compound is of interest since in its formation there is a linking of the silicon atoms in pairs:

Hexaiododisilane furnishes colourless, hexagonal, doubly refracting, prismatic or tabular crystals which can be fused in vacuo, with partial decomposition at 250° . It cannot be distilled at atmp. press. or in vacuo, but on heating, a portion sublimes, and the remainder decomposes into silicon tetraiodide, and orange-coloured tetraiodosilene, Si_2I_4 . When hexaiododisilane is treated with water at 0° , it forms hydrated silico-oxalic acid. It is converted by hydriodic acid into hexabromodisilane; and by mercuric chloride into hexachlorodisilane. It dissolves in potash-lye with the evolution of hydrogen: $\text{Si}_2\text{I}_6 + 6\text{KOH} = 2\text{SiO}_2 + 2\text{H}_2\text{O} + 6\text{KI} + \text{H}_2$. At 19° , 100 parts of carbon disulphide dissolve 19 parts, and at 27° , 26 parts of hexaiodide.

As indicated above, when hexaiodosilane is heated, the orange-red residue with the ultimate composition SiI_2 is considered to be tetraiodosilene, or tetraiodosilicoethylene, or tetraiodosilicoethene, Si_2I_4 . Water decomposes it, forming a greyish-white mass, probably silico-formic acid, SiH_2O_2 , since, when dried in vacuo and treated with potash-lye, the hydrogen evolved corresponds with

$\text{SiO}_2\text{H}_2 + 2\text{KOH} = \text{K}_2\text{SiO}_3 + \text{H}_2\text{O} + \text{H}_2$, and when heated in air it oxidizes to silica with detonation. Tetraiodosilene is decomposed by potash-lye: $\text{Si}_2\text{I}_4 + 8\text{KOH} = 4\text{KI} + 2\text{K}_2\text{SiO}_3 + 2\text{H}_2\text{O} + 2\text{H}_2$; and it does not dissolve in carbon disulphide, chloroform, benzene, or silicon tetrachloride.

§ 80. Silicon Sulphides

According to J. J. Berzelius,¹ silicon disulphide, SiS_2 , is formed when silicon is ignited in the vap. of sulphur, or when the sulphur vap. is passed over silicon at a white heat; the combination is attended by incandescence. Part of the silicon may be protected from the sulphur by the sulphide which is formed. I. G. Rankin and S. M. Revington's analyses agreed with J. J. Berzelius' view of the nature of the white silicon sulphide. W. Hempel and H. von Haasy considered that the best way to make this sulphide is to heat to redness an intimate mixture of amorphous silicon and three times its weight of sulphur in a crucible. The product contains 92-95 per cent. of silicon disulphide which can be isolated by sublimation at 60 mm. press. E. Vigouroux, and A. F. Hollemann and H. J. Slipper prepared the disulphide by a similar process. G. L. J. de Chalmot obtained some disulphide by heating over 300° a mixture of one of the copper sulphides and sulphur; and H. Moissan, by the action of lithium silicide on molten sulphur. P. Sabatier, and N. D. Costenau made it by passing a current of hydrogen sulphide over crystalline silicon at a red heat. E. Vigouroux also used this process; but W. Hempel and H. von Haasy obtained poor yields. A. Gautier and L. Hallopeau obtained it by heating metal silicides at 1300° - 1400° in a stream of carbon disulphide; and E. Frémy made pellets from an intimate mixture of oil, lampblack, and silica, and heated them to redness in a crucible. The pellets were then heated to the highest available temp. in a porcelain tube through which was passed a slow current of carbon disulphide. The silicon disulphide collected in long needles in the cooler part of the tube if moisture is present the product is contaminated with silica. E. Frémy found that if carbon be not present along with the quartz-glass, porcelain, or felspar--there is only a very small yield of silicon disulphide. In any case, W. Hempel and H. von Haasy found that the yield is poor. E. Frémy was unable to obtain any appreciable quantity of the disulphide by passing sulphur vap. over an intimate mixture of silica and carbon at a red heat. A. Gautier obtained some silicon disulphide by heating china clay to redness in a stream of carbon disulphide; and by heating silica in a mixture of hydrogen sulphide and carbon disulphide. J. I. Pierre obtained the disulphide by the action of silicon tetrachloride on hydrogen sulphide. After distilling the first product of the reaction, there remains a mixture of silicon disulphide and sulphur; and the latter can be removed by distilling off the sulphur in a stream of nitrogen. W. Hempel and H. von Haasy obtained only a poor yield by this process; M. Blix and W. Wirbe-lauer also obtained the disulphide as a by-product in the dry distillation of silicon dichlorosulphide: $2\text{SiS}_2\text{Cl}_2 = \text{SiCl}_4 + \text{SiS}_2$. R. Amberg, M. Haff, W. Fielding, and

B. Neumann discussed the formation of silicon disulphide in the action of ferro-silicon on iron sulphide, and the part it plays in the desulphurization of iron.

When free from uncombined silicon, the disulphide prepared by J. J. Berzelius was white and earthy; that prepared by sublimation forms white or grey acicular crystals. The heat of formation obtained by P. Sabatier with octahedral sulphur was $\text{Si}_{\text{cryst}} + 2\text{S} = \text{SiS}_{2\text{solid}} + 10.4 \text{ Cals.}$ J. J. Berzelius found that water instantly decomposes silicon disulphide into hydrosulphuric and silicic acids; in the moist air, it gives off hydrogen sulphide and is gradually transformed into silicic acid. It can be preserved in sealed glass tubes. P. Sabatier found that decomposition of one eq. of silicon disulphide by water gives 38.5 cal. at 9.5° . E. Frémy said that *unactive effervescence* is produced when silicon disulphide is projected on water; and he emphasized the stability of the resulting colloidal soln. of silica. He added that the formation of hydrogen sulphide and soluble silica by the action of water on silicon disulphide is of great geological interest since it explains the production of silica incrustations and the presence of silica in mineral waters, and also the formation of natural sulphurous waters. Silicon disulphide burns to sulphur dioxide and silica when it is heated in air. E. Frémy found that it reacts vigorously with nitric acid, forming sulphuric and silicic acids; and it reacts at ordinary temp. with alcohol and with ether. A. Colson found it to be insoluble in benzene. M. Blix and W. Wirbelauer showed that it reacts with liquid ammonia, forming silicon diimide, $\text{Si}(\text{NH})_2$. A. Colson showed that mercuric salts in benzene soln. do not act on silicon disulphide; powdered mercuric chloride forms silicon tetrachloride; and mercuric cyanide gives silicon cyanide. A. C. Vournasos observed that nascent hydrogen, obtained by heating the sulphide with sodium formate yields a little silane.

Silicon disulphide, said J. J. Berzelius, unites with potassium sulphide, forming a sulphide—presumably *potassium sulphosilicate*; and, according to W. Hempel and H. von Haasy, when silicon sulphide unites with metal sulphides, *sulphosilicates*, or *thiosilicates*, are formed. The same salts were found by A. Gautier to be formed by the action of sulphur, hydrogen sulphide, or carbon disulphide on some silicates at a red heat. These products are usually insoluble in water, and decomposed by steam at 250° , forming hydrogen sulphide, the metal hydroxide, and silicic acid.

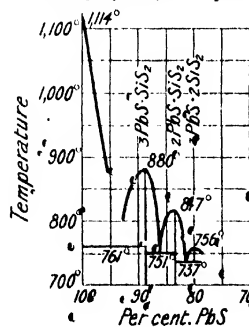

FIG. 202.—Freezing Points of the PbS-SiS_2 System.

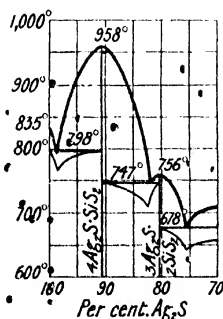

FIG. 203.—Freezing Points of the $\text{Ag}_2\text{S-SiS}_2$ System.

When heated, they may decompose into their components. W. Hempel and H. von Haasy formed *sodium sulphosilicate*, Na_2SiS_3 , by melting together sodium sulphide and silicon disulphide. The dark brown mass is decomposed by water, forming hydrogen sulphide; and all the residue is dissolved; the aq. soln. gives off no hydrogen sulphide when treated with acids. L. Cambi prepared a number of sulphosilicates by heating mixtures of finely divided silicon and metals in an atm. of hydrogen sulphide to 800° or 1000° . The thermal analysis of the PbS-SiS_2 system, Fig. 202, showed the presence of the compounds, namely,

$3\text{PbS} \cdot 2\text{SiS}_2$; $2\text{PbS} \cdot \text{SiS}_2$; and $3\text{PbS} \cdot \text{SiS}_2$. $\text{Pb}_3\text{Si}_2\text{S}_7$ is brick-red; the last-mentioned compound appears as brilliant crystals and fuses, accompanied by decomposition, at 737° ; **lead orthosulphosilicate**, Pb_2SiS_4 , is reddish-brown, forms large crystals which fuse, accompanied by decomposition, at 767° ; and **tri-lead pentasulphosilicate**, $\text{Pb}_3\text{Si}_5\text{S}_{16}$, is reddish-brown, does not occur in equilibrium with the soln., but is a result of a reaction between the solid constituents at 748° . In the $\text{Ag}_2\text{S} \cdot \text{SiS}_2$ system, Fig. 203, the compound $4\text{Ag}_2\text{S} \cdot \text{SiS}_2$ only has hitherto been determined, **octo-silver hexasulphosilicate**, Ag_8SiS_6 , forming greyish-black crystals which melt without decomposition at 960°C . **Silver orthosulphosilicate**, $\text{Ag}_2\text{Si}_2\text{S}_7$, melting at 756° , was prepared; and products richer in silicon disulphide, up to **silver meta-sulphosilicate**, $\text{Ag}_3\text{S} \cdot \text{SiS}_2$, were also obtained. The colour of these ranged from orange-red to yellow, and they often exhibit evidence of under-cooled or metastable forms. J. P. Leclèdeff's study of the system $\text{CaS} \cdot (\text{CaSiO}_3)_2$ has been previously discussed; and for the association of calcium aluminium silicates with sulphides, vide ultramarine, and *lapid lazuli*. L. Cambi made **calcium sulphosilicate**; and W. Hempel and H. von Haasy, **magnesium sulphosilicate**, MgSiS_3 , by melting together the components, magnesium sulphide and silicon disulphide. It is decomposed into its components by heat. L. Cambi also made magnesium, zinc, and mercury sulphosilicates. W. Hempel and H. von Haasy prepared an impure **aluminium sulphosilicate**, $\text{Al}_2(\text{SiS})_3$, by the action of sulphur vapour on an aluminium silicide, and by melting aluminium sulphide and silicon disulphide. The compound is unstable; attempts to make **ferrous sulphosilicate** on similar lines furnished a mixture $\text{FeSiS}_3 + 7\text{FeS}$.

The corresponding *orthosulphosilicic acid*, H_2SiS_4 , and *metasulphosilicic acid*, H_2SiS_3 , have not been made. F. Wöhler obtained a kind of *poly-sulphosilicic acid*, $\text{H}_2\text{Si}_4\text{O}_7$, which was called *sulphosilicon*, by the action of sulphurous acid and a little hydrochloric acid on calcium silicide. The reddish-brown plates after extracting the sulphur with carbon disulphide, and drying, furnished a light brown powder. The mass smells of hydrogen sulphide, and burns explosively when heated in air; with water, hydrogen sulphide is evolved; and with aq. ammonia, it gives off hydrogen, forming silica and sulphur.

In the preparation of silicon sulphide by heating amorphous silicon in a current of hydrogen sulphide, P. Sabatier² observed in the cold parts of a tube a large quantity of a yellowish-brown substance, consisting of a mixture of the ordinary sulphide, SiS_2 , and silicon. The production and the transference of the silicon was explained by supposing the formation of a volatile subsulphide at a low temp., which at a higher temp. is decomposed into the subsulphide and silicon, the change being analogous to that of hexachlorodisilane. A. Colson passed the vap. of dry carbon disulphide over silicon in a porcelain tube at a white heat for about an hour and obtained a yellow volatile compound with a composition corresponding with **silicon monosulphide**, SiS , and a yellowish substance, probably silicon oxy-sulphide, SiOS . I. G. Rankin and S. M. Revington also made the monosulphide. F. Wüst and A. Schüller obtained a substance with a similar composition by the action of ferrosilicon on iron sulphide in an at. of nitrogen; L. Cambi prepared the monosulphide as a sublimate when a mixture of sulphur and ferrosilicon is heated in the electric arc furnace; and W. Hempel and H. von Haasy obtained it as a by-product in the preparation of silicon disulphide. The yellow monosulphide obtained by F. Wüst and A. Schüller, was in needle-like crystals. According to L. Cambi, when silicon (in the form of ferrosilicon) and sulphur are heated together in an electric arc furnace, a vigorous reaction takes place, and a grey mass results, from which, by sublimation in the electric furnace, silicon monosulphide may be obtained. The compound sublimes at 940° – 980° at 20–30 mm., and it occurs in two forms, namely, a black solid which may assume a vitreous character, and a yellow powder. On resublimation of either form, both are produced, the yellow one being deposited in the colder parts of the tube employed. The sp. gr. is 1.833 at $15^\circ/4^\circ$. The yellow sulphide is less stable than

the black, and it rapidly absorbs moisture from the air and gives off hydrogen sulphide.

The yellow sulphide is decomposed by water with the evolution of hydrogen sulphide and the formation of a white insoluble substance, $\text{H}_2\text{Si}_2\text{O}_3$, which yields hydrogen when treated with alkalis, and reacts with alkali-lye with the evolution of hydrogen: $\text{SiS} + 2\text{KOH} = \text{SiO}_2 + \text{K}_2\text{S} + \text{H}_2$. The black sulphide is also decomposed by water with the formation of soluble silica and an oxygenated silicon hydride. Dry hydrogen chloride was found by L. Cambi to act on silicon monosulphide at 240° – 260° , forming hydrogen sulphide, etc.; by condensing the products of the reaction in a freezing mixture, a liquid consisting of trichlorosilane is produced.

According to A. Colson, if the contents of the tube used in preparing the silicon monosulphide are further heated with boiling potash-lye to remove the excess of silicon and its sulphur compounds, and then digested for some time with warm hydrofluoric acid, a greenish powder, of the composition of $\text{Si}_4\text{C}_4\text{S}_3$, *silicon sulphocarbide*, is obtained. When heated in a current of oxygen, the weight is not altered, but the compound is converted into an oxygenated product, $\text{Si}_4\text{C}_4\text{O}_2$. A. Colson thus infers that the analogy of sulphur and oxygen does not hold good at high temp., for CO_2 yields $\text{Si}_4\text{C}_4\text{O}_2$, and CS_2 yields $\text{Si}_4\text{C}_4\text{S}_3$.

As indicated above, A. Colson, in preparing silicon monosulphide, obtained **silicon oxysulphide**, or **silicel sulphide**, SiOS . A. Gautier obtained it by passing a mixture of hydrogen sulphide and carbon disulphide at a red heat over silica and aluminium silicate; some silicon disulphide was formed at the same time. A. Colson found the yellow substance is decomposed by water with the evolution of hydrogen sulphide; and it dissolves in cold dil. alkali-lye, without giving off hydrogen. The compound was also prepared by I. G. Rankin and S. M. Revington, who also reported *silicon dioxysulphide*, SiO_2S , but no confirmation or details are available.

J. I. Pierre³ discovered what he called *chlorosulphure de silicium* and gave an analysis corresponding with **silicon sulphodichloride**, or **silicon dichlorosulphide**, SiSCl_2 , but C. Friedel and A. Ladenburg showed that the alleged thiodichloride is really silicon trichlorohydrosulphide (*q.v.*). Silicon dichlorosulphide was first obtained by A. J. Besson, who found that the reaction which results in the production of silicon tetrachloride and sulphur from sulphur dichloride and silicon at a temp. below redness extends at a higher temp. to the formation of silicon thiochloride. A current of chlorine sat. with sulphur dichloride vap. is led over a quantity of crystalline silicon heated to bright redness in a porcelain tube, the silicon sulphide which rapidly chokes the tube being removed from time to time by allowing the chlorine to pass alone. The liquid product is fractionated from excess of sulphur chloride, and is purified from oxychloride by recrystallization from carbon tetrachloride, and subsequent sublimation in a current of dry air at 100° . M. Blix and W. Wirbelauer made it by passing silicon trichlorohydrosulphide through a glass tube at a dull red-heat—in an apparatus so arranged that the gases continually circulate in a closed system—and crystallized the product from its soln. in chloroform. E. Lay obtained the dichlorosulphide as a by-product in the action of chlorine on a mixture of ferrosilicon and sulphur. Silicon dichlorosulphide is a white solid which furnishes acicular crystals. A. J. Besson said its b.p. is 185° and its m.p. 74° ; M. Blix and W. Wirbelauer gave 75° for the m.p., and added that it distils at 92° under 22.5 mm. press., and that it is very easily decomposed by moisture or by distillation at ordinary temp. into silicon disulphide and tetrachloride. A. J. Besson found that it is unstable in moist air, and reacts violently with water, forming hydrogen sulphide and chloride, and silice. M. Blix and W. Wirbelauer said that it reacts readily with liquid anhydrous ammonia, forming silicon di-imide, $\text{Si}(\text{NH})_2$.

As indicated above, J. I. Pierre made **silicon trichlorohydrosulphide**, $\text{Si}(\text{HS})\text{Cl}_3$, by passing a mixture of the vap. of silicon tetrachloride and dry hydrogen sulphide through a red-hot porcelain tube: $\text{SiCl}_4 + \text{H}_2\text{S} = \text{SiCl}_3(\text{FS}) + \text{HCl}$. He added:

The best mode of preparation is to pass a current of hydrogen sulphide gas through silicon tetrachloride contained in a stoppered retort, the conducting tube being made to dip just under the surface of the liquid. The retort is then connected by means of a good cork with one end of a porcelain tube, the other end of which is attached to a U-shaped tube kept constantly cool. The porcelain tube is then made red hot, and as the mixture passes through, a fuming liquid rapidly condenses in the U-tube. The liquid thus obtained has a pungent, offensive odour resembling both silicon tetrachloride and hydrogen sulphide; it becomes clear on standing and is then distilled, the liquid which comes over at a temp. between 90° and 100° being kept apart. The process is stopped as soon as the pasty mass in the retort begins to evolve white fumes.

C. Friedel and A. Ladenburg employed a similar mode of preparation. Silicon trichlorohydrosulphide is a colourless fuming liquid which, according to J. I. Pierre, has a sp. gr. 1.45, and a b.p. of 100°. J. I. Pierre's, and C. Friedel and A. Ladenburg's analyses and vap. density, 5.24-5.74 between 155° and 161°, agree with the formula $\text{Si}(\text{HS})\text{Cl}_3$ for which the calculated vap. density is 5.83. J. I. Pierre found that in contact with water the trichlorohydrosulphide is decomposed, forming hydrogen sulphide, hydrochloric and silicic acids, and a little free sulphur; and if a mixture of hydrogen sulphide and the vap. of the trichlorohydrosulphide is passed through a strongly heated porcelain tube, a small quantity of a liquid is formed—possibly the dichlorosulphide—which decomposes into silicon disulphide, etc., when distilled. C. Friedel and A. Ladenburg showed that with bromine, the trichlorohydrosulphide is converted into chlorobromide; sodium does not remove the hydrogen; alcohol in excess forms hydrogen sulphide, hydrogen chloride, and ethyl silicate; and if 3 mols. of alcohol are present to one mol. of trichlorohydrosulphide a liquid—silicon triethoxyhydrosulphide, $\text{Si}(\text{OC}_2\text{H}_5)_3\text{HS}$ —boiling at 164°-167°, is formed.

According to M. Blix, silicon sulphodibromide, or silicon dibromosulphide, SiSBr_2 , is formed by the interaction of silicon tetrabromide and hydrogen sulphide at 150° in the presence of aluminium bromide as catalyst. The bromosulphide is separated from the unchanged tetrabromide by fractional distillation under reduced press. Silicon dibromosulphide forms colourless plates which can be recrystallized from carbon disulphide. It melts at 23°, forming a liquid which boils at 150° under 18.3 mm. press. The crystals fume in moist air, and react *explosionsartig* with water with the separation of silicic acid and the evolution of hydrogen bromide and sulphide. A soln. of the dibromosulphide in dry benzene reacts with dry ammonia, forming *silicothiourca*: $\text{SiSBr}_2 + 4\text{NH}_3 \rightarrow \text{SiS}(\text{NH}_2)_2 + 2\text{NH}_4\text{Br}$.

§ 61. Silicon Phosphates

F. Mylius and A. Meusser found that phosphoric acid at 400° has a strong corrosive action on quartz glass; while K. Hüttner showed that at ordinary temp. orthophosphoric acid has scarcely any action on glass, but at 100° – 150° the attack is marked—silicic phosphate, and metaphosphates are produced. Phosphorus pentoxide can be sublimed in glass vessels without affecting them appreciably. W. Skey, E. Laufer, and J. Hirschwald observed the behaviour of silica in fused sodium phosphate, and a well-known test for silica is based on the sparing solubility of silica in that menstruum. According to A. Müller,¹ phosphoric acid has a slight action on quartz at a low temp., and a vigorous action at a higher temp. when the quartz is transformed into hydrated silica. P. Hautefeuille and P. Margottet fused a dried mixture of gelatinous silica and metaphosphoric acid, extracted the mass with hot water, and so obtained transparent, colourless, isotropic, octahedral crystals. The composition corresponds with $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$, which K. Hüttner considers to be that of **silicic metaphosphate**, $\text{SiO}(\text{PO}_3)_2$. The substance so obtained has a sp. gr. 3.1 at 14° ; it scratches glass, and when heated melts to a glass which does not devitrify on cooling.

In their memoir: *Sur le polymorphisme du phosphate de silice*, P. Hautefeuille and P. Margottet showed that when a mixture of hydrated silica and orthophosphoric acid is gradually heated to 260° , about 5 per cent. of silica is dissolved, and a still larger proportion can be obtained in soln. by gradually heating a mixture of phosphoric acid and silicon tetrachloride. The soln. deposits crystals of silicic phosphate in forms varying with the temp. at which the deposition takes place. They found that (i) when the soln. of silica in orthophosphoric acid is allowed to cool below 260° , it deposits crystals having the appearance of flattened discs. Similar crystals are obtained when the soln. is mixed with conc. sulphuric acid and heated for some time at a temp. somewhat above the b.p. of the latter. These crystals are hexagonal prisms, frequently maced in the same manner as lamellar hematite. They act strongly on polarized light, and are, somewhat rapidly attacked by water, but do not alter in contact with alcohol. (ii) If the temp. of the soln. of silica is gradually raised from 260° to about 360° , it deposits an abundance of very thin hexagonal lamellæ, which act feebly on polarized light and resemble tridymite in appearance. They are, however, distinguished from the latter by the fact that they yield silver phosphate when fused with silver nitrate. These lamellæ are not altered by alcohol, but are slowly attacked by water with formation of orthophosphoric acid and soluble silica. (iii) If the soln. be heated rapidly, it remains limpid up to about 700° , but between 700° and 800° it deposits regular octahedra which are almost always modified by cubical faces. This form of silicon phosphate is that described above. (iv) When phosphoric acid containing only a small proportion of silica is rapidly heated to about 900° – 1000° , the crystals obtained are monoclinic prisms which act strongly on polarized light. At a high temp., these prisms are more stable than the other forms. If orthophosphoric acid sat. with silica be slowly heated to 1000° , a mixture of all four forms is obtained; but if the temp. is maintained the lamellæ and octahedra are quickly attacked, whilst the prisms continue to increase.

The crystals all have the same composition: The hexagonal crystals are formed below 300° , the lamellæ resembling tridymite at about 360° , the regular octahedra between 700° and 800° , and the monoclinic prisms between 800° and 1000° . This polymorphism is not due to different groupings of the same crystalline elements, for the hexagonal crystals are attacked by water, which has no action

SILICON

on the octahedra or prisms. According to H. N. Stokes, silicyl metaphosphate is probably formed when silicopyrophosphoryl chloride is heated above 200° until vap. of phosphoryl chloride is no longer evolved. P. Hautefeuille further found that if a conc. soln. of orthophosphoric acid containing about one-quarter of the quantity of silica required to saturate it, is heated at 125° for 7 or 8 days, it deposits concretions which gradually increase in size. They are separated from the mother liquor by pouring the hot liquid on to a previously heated porous plate, and are dried by exposure to dry air for about a week. The spherical globules thus obtained have the composition tetrahydrated silicyl metaphosphate, $\text{SiO}_2 \cdot \text{P}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$. When suspended in sulphuric acid, they act strongly on polarized light. Under the microscope, the concretions are seen to be formed of concentric coats of prismatic crystals with their principal axes radiating from the centre. The silicyl metaphosphate decomposes rapidly in moist air, and dissolves completely in water at 60° , but it is decomposed by water at the ordinary temp., with separation of gelatinous silica.

H. N. Stokes prepared a chloride corresponding with a second unknown silicopyrophosphoric acid, $\text{SiO}(\text{O} \cdot \text{P} \cdot \text{O} \cdot \text{OH})_2$, by heating a mixture of ethyl trichlorosilicate, $\text{C}_2\text{H}_5\text{O} \cdot \text{SiCl}_3$, or ethyl orthosilicate, $\text{Si}(\text{OC}_2\text{H}_5)_2$, and phosphoryl chloride in a sealed tube at 180° : $4(\text{SiCl}_3 \cdot \text{OC}_2\text{H}_5) + 2\text{POCl}_3 = 3\text{SiCl}_4 + 4\text{C}_2\text{H}_5\text{Cl} + \text{SiP}_2\text{O}_6\text{Cl}_2$. The product is silicopyrophosphoryl chloride, $\text{SiP}_2\text{O}_6\text{Cl}_2$, or $\text{SiO} \cdot (\text{O} \cdot \text{POCl})_2 \cdot \text{O}$. If the ethyl trichlorosilicate be in excess, an analogous reaction occurs, but the composition of the silicopyrophosphoryl chloride is different. Silicopyrophosphoryl chloride is a white, hygroscopic, amorphous powder which is freely soluble in alcohol and water. It loses hydrochloric acid when in contact with moist air. The aq. soln. is turbid owing to the separation of gelatinous silica, but a clear aq. soln. can be obtained by adding enough water to the alcoholic soln. Neither the acid nor its salts could be isolated. It decomposes slowly when warmed to 200° , and rapidly at a higher temp., forming phosphoryl chloride. When mixed with phosphorus pentachloride, and heated to 100° , silicon tetrachloride and phosphoryl chloride are formed. A cold aq. soln. from which the chlorine has been removed by silver nitrate in excess yields in order, when ammonia is added, silver pyrophosphate, silver orthophosphate, and silica.

 — fayalite, 906, 909
 — felspar, 662
 — ferrous orthosilicate, 909
 — fluosilicate, 953
 — glass, 442
 — leuc oxydisilicate, 880
 — lithium silicate, 444
 — manganese dihydroxyorthosilicate, 894
 — metasilicate, 440
 — nickel silicate, 933
 — orthosilicate, 438
 — — monohydrate, 442, 443
 — peroxydisilicate, 441
 — potassium silicate, 444
 — silicate, 438
 — silicic, 182
 — silicoarsenides, 188
 — silicododecatungstate, 871
 — silicododecatungstate, 879
 — spar, 442
 — staurolite, 909
 — sulphosilicate, 987
 — sulphosilicide, 182
 — thiocarbamate, 132
 — thiocarbonate, 127
 — trisilicate, 444
 — ultramarine, 590
 Zincum naturale calciforme, 442
 Zinkglaserz, 442
 Zinkspath, 442
 Zinnwaldite, 604
 Zircon, 846
 — — pyroxenes, 857
 Zirconium dihydroxytriorthosilicate, 846
 — disilicide, 186
 — fluosilicate, 955
 — octahydroxydiorthosilicate, 847
 — orthosilicate, 848
 — sodium calcium chlorotrimetrisilicate, 857
 — — chlorotriorthosilicate, 857
 — — columbasilicate, 858
 — (tri) octothium pentorthosilicate, 854
 Zirkonite, 855
 Zoblitzite, 423
 Zoisite, 719
 — α -, 720
 — aluminium-, 720
 — β -, 720
 — iron, 720
 Zenochlorite, 718
 Zinnite, 585
 Zurlite, 752
 Zynapite, 416
 Zynapite, 663
